Within the next three years additional triphenylmethane and azo- dyes were produced, deeper colour (red) being attained in the latter group by the use of naphthalene components in place of the benzene derivatives used in the earlier members, as eg in the Ponceaus (1878), and also by the introduction of an additional chromophore, as in Biebrich scailet (1878) consideration of the results now obtained, especially in the triphenylmethane and azogroups, led to the enunciation of Nietzki's Rule (1879), which states that the colour of a dyestuff can be deepened by adding groups so as to increase its molecular weight, and that the deepening of colour produced is more or less proportional to the increase of molecular weight (It should be noted that the term depth is used by colour-chemists in a very definite and limited way In ordinary language the term depth of colour has at least two meanings Blue and red are said to be deeper colours than yellow, and also one yellow is said to be deeper than another yellow if it is stronger or more intense. ie less admixed with white Colour-chemists restrict the use of the term, and employ it for the first purpose only. Blue is deeper than red or yellow, and red is deeper than yellow. The ordinary colours arranged according to depth are green, blue, violet, red, orange, yellow. i e. the complements to the ordinary colours of the spectrum taken in order from the red to the violet end This rule served for many years as a most valuable guide in extending the range of colours in many groups of dyes, especially in the azo- group, in which the deepest colours were now soon obtained (blue-black. 1882, Glaser) It may be said that this rule is still a valuable guide to the colour chemist

In 1885 Liebermann and v. Kostanecki published the results of their investigations of the colour and dyeing properties of the hydroxyderivatives of anthraquinone Although these authors did not commit themselves to any very definite statement, yet their publication drew the attention of colour-chemists to the ease with which colour could be deepened by the multiplication of auxochrome groups in the molecule, provided these groups were suitably This general principle may be said arranged to have been of equal value with Nietzki's Rule, and for many years the development of dye manufacture was almost entirely controlled by these two rules. Very interesting and ingenious methods were developed by Bohn and Schmidt in 1888 and 1890 for the multiplication of hydroxyl groups in the anthra-

quinone molecule with the result that a complete range of colours was soon available in this group of mordant dyes. The continued application of the same idea led somewhat later to the preparation of anthragumone dyes containing both amino- and hydroxyl- groups, such as alizarin saphirol (1898), which combines the advantages of deep colour and fastness with brightness and cleainess of tone. Liebermann and Kostanecki's Rule led at once to the careful study and production of dihydroxy-, amino-, hydroxy-, and diamino-naphthalene derivatives and their employment in the manufacture of azo- dyes This general principle led to the production between the years 1887 and 1897 of an enormous number of azo- dyes of all colours

In 1888 H E Armstrong put forward the best-known theory which has ever been formulated as to the cause of colour in organic com-This is known as the Quinonoid Theory. Its author pointed out that the chemical formulæ of the well-known dyestuffs either contained the quinonoid grouping or could be slightly modified or rearranged, in accordance with accepted ideas on tautomerism, so as to contain this grouping More recent work has shown that the original quinonoid theory cannot stand Modifications have been put forward by Baeyer (1907) and H v Liebig (1908), neither of which,

however, is entirely satisfactory

Of recent years it has come to be generally recognised that visible colour is only a special case of selective absorption. That some substances are coloured whilst others, nearly related, are colourless, must be regarded as more or less accidental, and due to a physiological cause rather than to any essential physical difference between them, viz to the fact that the human eye can only detect selective absorption within a limited range of the spectrum The problem of colour has thus resolved itself into two parts (1) the cause of selective absorption, (2) the cause of the absorption lying within the limits of the visible spectrum

As to the cause of selective absorption various theories have been put forward in iecent years. We may mention Baly and Desch's theory, according to which absorption bands are due to dynamic isomerism (1904-1905), Stewart and Baly's theory of isorropesis as the cause of selective absorption (1906), Watson and Meek's theory that absorption in the visible spectrum and its neighbourhood is due to the reversal during tautomeric change of a conjugate chain of alternate double and single bonds (1915), the theory that absorption bands in the visible part of the spectrum are due to the vibiation of elections, and Baly's theory (1914) that absorption bands in the visible and ultra-violet parts of the spectrum are due to overtones or summation or difference tones derived from fundamental vibrations causing infra-red absorption bands (infra-red absorption bands have been attributed by most investigators to the vibrations of definite chemical radicals, Abney and Festing\_(1881), Julius (1888), Coblentz (1904–1905), and Weniger (1910)) In 1897 Pauer showed that under certain circumstances ordinary broad absorption bands are replaced by a large number of fine bands, recalling the lines in the emission spectra of substances examined in flames or under the influence of the electric discharge. Hartley (1908) came to the conclusion that the ordinary broad absorption bands are formed by the fusion of these narrow bands. Various observers have shown the intimate connection between such fine absorption bands and the lines in the emission spectra of the same substances, e.g. Wullner (1863), Mitscherlich (1864), Salet (1872), Eder and Valenta (1899). And, finally, in certain cases (hydrogen and helium) the lines in the emission spectra have been deduced with great accuracy on the hypothesis that they are due to rotational vibration of electrons within the atoms.

The fact that so many different theories have been formulated makes it obvious that no final conclusion has been reached as to the cause of absorption bands in general

As to the causes which bring the absorption bands into the visible spectrum and influence their positions within the visible spectrum, many investigators showed that Nietzki's rule was only a first approximation to the facts, and many exceptions to this rule were collected by Schutze (1892) Hewitt (1907) suggested that the chief oscillation frequency was less, and consequently the colour was deeper, the longer the conjugate chain of alternate double and single bonds in the molecule. The present writer pointed out in 1914 that those dyes of which the molecular formula can only be written in a quinonoid form have all a deep colour, whilst if the formula can be written either in a quinonoid or a non-quinonoid form, even great molecular complexity may fail to produce any great depth of colour Watson and Meek (1915) showed that in several series the period of the absorption band is proportional to the length of the conjugate chain, which may be assumed to reveise during tautomeric change

No explanation has yet been offered of the great effect on depth of colour which is so frequently produced by a multiplication of auxochromes. The relative position of the auxochromes has a great effect on the colour Certain regularities in this respect have been pointed out by Kauffmann and Franck (1906), and Meek and Watson (1916)

It cannot be said that the theories which have been formulated since 1885 have proved of much service for the preparation of dyes In the older group of dyes a complete range of colours had already been attained by assiduous experiment, guided by Nietzki's and Liebermann and Kostanecki's rules It may perhaps be claimed that the quinonoid theory had some influence in the development of the azopyrazolone dyes. The present writer was able to apply one of the rules which he formulated to the production of deep-coloured dyes from the yellow flavones, and the work in this direction was perhaps of service for the recognition of the molecular structure of the colouring matters of flowers (anthocyanins) As to the new groups of valuable synthetic dyes which have been developed recently, the sulphide dyes, and the anthraquinone vat-dyes, the constitution of the former has been too little understood to allow of anything but empirical investigation, whilst in the latter group (the anthraquinone vat-dyes), our theories seem at

present quite unable to explain the wealth of colour phenomena exhibited by the dyes already synthesised

A short account is appended of some of the more important theories and rules above mentioned

Wut's Rule—This investigator pointed out (Ber 1876, 9, 522) that two things are required to give an organic substance colour and dyeing properties. The molecule must possess a certain grouping of atoms to give it the potentiality for colour, and it must also possess a salt-forming radical to bring out the colour and dyeing properties. The atomic groupings giving the potentiality of colour he termed chromophores, and molecules containing them were called chromogens. He specified the following chromophores and gave illustrations of chromogens containing them—

It will be noticed that some of the chromogens are colourless, eg nitrobenzene and phenolphthalein, whilst others have a feeble colour, eg azobenzene and anthraquinone; but none of the chromogens has any dyeing property. The colour is developed or strengthened by the introduction of sait-forming ladicals into the chromogens. These ladicals ne therefore termed auxochromes. Hydroxyl, aminoand substituted amino- groups, eg. NHCH<sub>3</sub>, N(CH<sub>3</sub>), &c, are the principal auxochromes. Not all salt-forming groups can act as auxochromes, eg. sulphonic and carboxyl groups are without this function. The following table shows how the chromogens already mentioned are converted into dyes by the introduction of auxochromes.—

$$\begin{array}{c} \operatorname{Chromogen} & \operatorname{Dye} \\ \operatorname{C}_6\operatorname{H}_5\operatorname{NO}_2 & \operatorname{C}_6\operatorname{H}_4(\operatorname{NO}_2)\operatorname{OH} \\ \operatorname{Nitrophenol} & \operatorname{C}_6\operatorname{H}_5(\operatorname{NO}_2)\operatorname{NH}_2 \\ \operatorname{C}_6\operatorname{H}_5-\operatorname{N}=\operatorname{N}-\operatorname{C}_6\operatorname{H}_5 & \operatorname{C}_6\operatorname{H}_6-\operatorname{N}=\operatorname{N}-\operatorname{C}_6\operatorname{H}_4\operatorname{OH} \\ \operatorname{Benzene-azo-phenol} & \operatorname{C}_6\operatorname{H}_5-\operatorname{N}=\operatorname{N}-\operatorname{C}_6\operatorname{H}_4\operatorname{OH} \\ \operatorname{Benzene-azo-phenol} & \operatorname{CO\cdot\operatorname{C}_6\operatorname{H}_4}\operatorname{NH}_2 \\ \operatorname{Anline vellow} & \operatorname{CO\cdot\operatorname{C}_6\operatorname{H}_3}\operatorname{OH} \\ \operatorname{C}_6\operatorname{H}_4 & \operatorname{O} & \operatorname{C}_6\operatorname{H}_4 & \operatorname{O} \\ \operatorname{CO\cdot\operatorname{C}_6\operatorname{H}_4} & \operatorname{CO\cdot\operatorname{C}_6\operatorname{H}_3}\operatorname{OH} \\ \operatorname{Fluoiescein} \end{array}$$

THE QUINONOID AND MODIFIED QUINONOID THEORIES.

In 1888 (Proc. Chem. Soc. 1889, 27-33) H. E. Armstrong pointed out that the chemical formulæ of the well-known dyestuffs either contained the quinonoid grouping or could be slightly modified or rearranged, in accordance with accepted ideas on tautomerism, so as to contain this grouping. The quinonoid grouping may be defined as a benzene nucleus to which

other atoms or groups are attached by double bonds in the para- or ortho- positions.

Armstrong was probably much impressed by the recently discovered fact that benzene azo-β-naphthol was identical with the phenyl hydrazone of  $\beta$ -naphthogumone, so that there was as much justification for the formula

as for the more usual one based on the formation of the substance from  $\beta$ -naphthol and a benzenediazonium salt, viz

$$HO$$

$$C_6H_5N=N$$

and if it were allowable to assume tautomerism to a quinonoid form in this case, it might be allowable in other cases, e.g. in the case of fluorescein

whilst in the case of p-rosaniline it was quite consistent with experimental fact to suppose that on the conversion of the base into salts there was elimination of a molecule of water and formation of a substance with a quinonoid structure

$$\begin{array}{cccc} \operatorname{HO-C} & \overset{\operatorname{C}_6H_4\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}}{\overset{\operatorname{HCl}}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{\operatorname{C}_6H_4-\operatorname{NH}_2}{\overset{C}_6H_4-\operatorname{NH}_2}{\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6H_4-\overset{C}_6$$

In many cases the ordinary formula already contained the quinonoid structure

The theory has been shown to be untenable On the one hand, substances have been prepared which have a quinonoid structure, but are colourless, and on the other hand, coloured substances are known to which a quinonoid structure cannot be assigned.

Colourless Substances possessing a Quinonoid Structure—Immoquinone (I), diimmoquinone (II), quinonedimethylimine (colourless in crystalline form, yellow in solution) (III), diphenoquinone (exists in two modifications, one of which is colourless) (IV), and fuchsonimine (V); also the dimethyl ether (VI), the diacyl

derivatives (VII), and the anhydride (VIII) of phenanthraquinone dioxime

Coloured Substances to which a Quinonoid Structure cannot be assigned -Nitroquinol dimethyl ether, the sulphate of p-trichlortriphenyl carbinol, the fulvenes, eg dimethylfulvene, and some fatty compounds, such as diacetyl, tertiary nitroso- compounds, e.g. tert-nitrosobutane, and dinitroparaffins.

Baeyer's Modification of the Quinonoid Theory—It has already been mentioned that fuchsonimine is colourless. The introduction of a para- amino group into one of the phenyl groups causes the development of colour

This and similar facts led A v Baeyer to suggest that the cause of colour is an oscillation of the quinonoid condition between two or more benzene nuclei (Jour Chem Soc Abs 1907, 1 504) If we call the three benzene nuclei in the above compound A, B, and C, it will be seen that the oscillation of a hydrogen atom will allow A and B alternately to become quinonoid:

$$\begin{array}{c|c}
NH = & A \\
NH_2 & B
\end{array}$$

$$\begin{array}{c|c}
NH_2 & A \\
\hline
NH = & B
\end{array}$$

$$\begin{array}{c|c}
C & C
\end{array}$$

Baeyer suggested that this oscillation was the cause of the colour.

Many strongly-coloured substances are known in which such an oscillation is not possible And necessarily all the arguments against the original quinonoid theory apply with still greater

H v Liebig's Theory that — A—A—A—is the Essential Organic Chromophore—The fact that the fulvenes are coloured, although they do not contain the quinonoid structure, led H. v Liebig to suggest that the essential cause of colour is the arrangement of linkages which is possessed both by quinonoid compounds and

the fulvenes, viz ——A—A——A—— (Annalen, 1908, 360, 128) This theory explains the colour of nitroquinol dimethyl other, which contains this arrangement of linkages —

The theory will not explain the colour of the tertiary fatty nitroso-compounds, and, of course, the existence of colourless quinonoid compounds is as much an argument against this modification as against the original quinonoid theory.

as against the original quinonoid theory
NIETZKI'S RULE The colour of a dyestuff
can be deepened by adding groups so as to increase
its molecular weight, and the deepening of colour

produced is, more or less, proportional to the increase of its molecular weight (Verhandl des Vereins zum Beforderung des Gewerbefleisses, 1879, 58, 231). This rule was probably formulated by Nietzki to summarise well-known facts in connection with the triphenylmethane group of dyes, but apparently was not based on any systematic investigation. The table on p. 349 shows that the rule applies to a considerable extent to other groups besides the triphenylmethane series.

The rule was subjected to a careful examination by Schutze (Zeitsch physikal Chem 1892, 9, 109 et seq), who pointed out many exceptions. He showed that in some cases, e.g on the addition of a nitro-group to indigo, the shade even becomes lighter instead of deeper, and he introduced the terms bathychrome and hypsochrome, the former being applied to those groups which produce a deepening of colour, and the latter to those having the contrary effect. Another example of a hypsochrome is the acetyl group All dyestuffs containing hydroxyl- or aminogroups become much lighter in colour when completely acetylated.

The following table is of interest, as showing that in some cases the molecular weight may be made very large without a deep colour being attained

Moleculai tormula	Mol wt	Shade of dyemg	
$('_{6}H_{5}-N=N-('_{6}H_{4}OH))$	198	yellow	
$C_{6}H_{5}-N=N-C_{6}H_{4}-N=N-C_{6}H_{2COOH}^{OH}$	346	brownish yellow	
${\rm C_6H_5-N\!=\!N\!-\!C_6H_4\!-\!N\!=\!N\!-\!C_6H_4\!-\!N\!=\!N\!-\!C_6H_{2\rm COOH}}$	450	brownish yellow	
$('_{6}H_{5}-N=N-('_{6}H_{3}('_{6}H_{9}))$	274	orange	
$C_6H_4$ — $N=N-C_6H_3$ $COOH$ $C_6H_4$ — $N=N-C_6H_3$ $OH$ $COOH$	482	yellow	
$({}^{\circ}_{6}H_{4}-N=N-({}^{\circ}_{6}H_{3COOH}^{3COOH}$ $({}^{\circ}_{6}H_{4}-N=N-({}^{\circ}_{6}H_{3COOH}^{3COOH}$ $({}^{\circ}_{6}H_{4}-N=N-({}^{\circ}_{6}H_{3COOH}^{3COOH}$	752	yellow	

HEWITT'S RULE This investigator's researches on the colour of azo-compounds led him to the conclusion that the chief oscillation frequency is less, and consequently the colour is deeper, the longer the conjugate chain,  $\iota$  e the chain of alternate double and single bonds, in the molecule (Chem. Soc. Trans. 1907, 91, 1251)

He noticed that in the case of many azodyes the introduction of a mitro-group into the benzene nucleus not containing auxochromes produced very pronounced deepening of colour in alkaline solution, eg p-nitrobenzeneazophenol and p-nitrobenzeneazonaphthol have much deeper colours (crimson and violet) than benzeneazonaphenol and benzeneazonaphthol (orange and crimson respectively) He brought forward evidence in favour of the assumption that in alkaline solution these nitro-derivatives

have an iso- nitroso structure, and in this form the nitro- derivatives have a much longer conjugate chain than the parent substances, eg —

$$N = \begin{cases} N - N = \\ N - N = \end{cases} = 0$$

compared with:

$$\langle$$
 NH-N= $\langle$  =0

Sircar (Chem Soc Trans 1916, 109, 757, et seq) showed that in very similar azo-compounds the length of the conjugate chain is not proportional to the depth of colour, e.q. 4-nitronaphthalene-1-azophenol only gives a red colour in alkaline solution, whilst p-nitrobenzene-azo- $\alpha$ -naphthol dissolves in the same solvent with a blue colour, whilst the two substances

have conjugate chains of the same length He came to the conclusion that in azo- dyes the depth of colour is proportional to the length of the conjugate chain reckoned from the auxo-

chrome to the azo- linkage

WATSON'S RULE —The present writer pointed out (Proc Chem. Soc 1913, 29, 348. Chem Soc. Trans 1914, 105, 759) that dyes which are quinonoid in all possible tautomeric forms have a deep colour, no matter how simple their structure or how small their molecular weight.

'In the following table there are placed opposite each other in the two columns dyes of very similar constitution which yet show remarkable differences in depth of colour -

Hexahydroxybenzophenone (Dyes yellow on alum and chrome )

$$C_6H_2(OH)_3$$
 CO  $C_6H_2(OH)_3$ 

Leather yellow (Dyes yellow on leather )

 $C_6H_4$  NH 2

 $C_6H_4$  NH 2

4 4'-Diaminoazobenzene (Yellow) NH2 C6H4 N N C6H4 NH2

Quercetin (Yellow on atum yellowish brown on chrome)

Myncetin (Dyes similar shades to queicetin)

Anthracene blue W R (Dyes violet on alum, blue on chrome )

O: 
$$C_6H(OH)_2$$
  $C_6H(OH)_3$ 

Magenta (Dyes bluish red ) C<sub>6</sub>H<sub>4</sub> NH<sub>2</sub> CH2N.C6H4 CC6H4NH2 Indamme (Blue)

NH · C<sub>6</sub>H<sub>4</sub> N C<sub>6</sub>H<sub>4</sub> NH<sub>2</sub>

Gallacetein (Dyes violet on chrome )  $C_6H_2(OH)_2$   $C_6H_2(OH)_2$  CH

'The dyes in the right-hand column can only be represented by formulæ containing a quinonoid arrangement. Whatever tautomeric change they may be supposed to undergo their formulæ still contain the quinonoid arrange-

Those on the left hand differ in that they ment can be represented by formulæ not containing this arrangement They can, of course,t be supposed to tautomerise into forms containing this quinonoid airangement, but in all cases it is possible to represent them also in a non-quinonoid form.' 'A survey of all the better known dye-stuffs fully bears out this theory. The triphenylmethane dyes, the pyronines, benzeins, and fluorones, the indophenols, indamines, oxazines, thiazines, azines (safianines, &c), all satisfy this requirement and exhibit deep colour, in many cases with little molecular complexity. Hæmatein and brazilein conform to this rule. They have almost the same molecular weight as the flavones, and there is considerable resemblance in their structure, but they conform to this rule, whilst the flavones do not, and consequently their colour is much The alizarin series, and also naphthazarin, illustrate the rule On the other hand, the monoketonic dyes, ey the benzophenone and xanthone derivatives, the flavones and flavonols, ellagic acid, and the azo-dyes can be represented by non-quinonoid formulæ, and many members of these groups, despite very considerable molecular complexity, have no great depth of colour

WATSON'S AND MEEK'S MODIFICATION OF HEWITT'S RULE—In passing from one tautomeric form to another there is a reversal of the conjugate chain, so that double and single bands change places all along the conjugate In that group of substances which can only tautomerise from one quinonoid form to another the conjugate chain reversed is generally longer than in the other group of substances which can tautomerise from a quinonoid to a non-quinonoid form An appreciation of this fact led to the formulation of a further modification of Hewitt's rule, viz. that the colour is deeper the longer the conjugate chain reversed during tautomenic change (Watson and Meek, Chem Soc Trans 1915, 107, 1567) This rule was tested by measuring the wave-lengths of the maxima of the absorption bands of seven pairs of substances which were selected as being very similar in structure, but having conjugate chains of different lengths reversed during tautomerism. It was found that in each of these seven pairs the period of the vibration was proportional to the length of the conjugate chain reversed (see table, p 352)

The reversal of the chain is shown in the following structural formulæ for 4 · 4'-tetramethyldiaminobenzhydrol (Michlei's hydrol) and 4 4'-tetramethyldiaminobenzophenone (Michler's ketone)

$$-(\operatorname{CH}_3)_2 \operatorname{N} = \operatorname{CH} - \operatorname{N}(\operatorname{CH}_3)_2 = \operatorname{CH} - \operatorname{CH} - \operatorname{N}(\operatorname{CH}_3)_2 = \operatorname{CH} - \operatorname{CH} -$$

# EFFECT OF MULTIPLICATION OF AUXOCHROMES ON DEPTH OF COLOUR

Additional auxochromes frequently deepen the colour to a very great extent. This may be regarded as an example of Nietzki's rule, but the effect produced is generally much greater than we should expect from the very moderate weight of the additional auxochromes, eq from the first table given in the paragraph on Nietzki's rule, it will be observed that two hydroxyl groups added to fluorescein (producing gallein) deepen the colour much more than four bromine atoms (producing cosin), although their weight is much less. The table on page 351 illustrates the great effect of additional auxochromes

The relative positions of the auxochromes has a very great effect on the colour, eq there are two isomeric hexahydroxyanthraquinones, anthracene blue WR and rufigallol, one of which is blue and the other brown

From a study of the polyhydroxyanthraqumones, Meek and Watson (Chem Soc Trans. 1916, 109, 557, et seq) suggested the following rules as to the influence on the colour of the relative positions of the auxochromes —

(a) Two hydroxyl groups in one benzene nucleus in the o- or p-position with respect to one another are necessary to produce a deep colour

(b) The colour is still further deepened if both benzene nuclei contain pairs of hydroxyl groups in the o- or p-position to one another

(c) Three hydroxyl groups in the 1 2 4-position in one benzene nucleus produce a deeper colour than a pair of hydroxyl groups in the o- or p-position.

(d) Three hydroxyl groups in the 1:2·3-position in one benzene nucleus produce a brown colour.

And these rules are apparently applicable to all groups of dyes, eq

(a) The hydroxy- derivatives of azobenzene dissolve in potash with the following colours:—

p-Hydroxyazobenzene
o-Hydroxyazobenzene
Benzeneazoresoreinol
Benzeneazoetechol . Carmine
Benzeneazoquinol . Blue
Benzeneazopyrogallol . Brick-red

(b) Fluorescein, quinolphthalein, and catecholphthalein dissolve in potash with a yellow colour, hydroxyquinolphthalein gives a cheiryred, gallein a blue, and phloroglucinolphthalein an orange under the same conditions

(c) The same rules are seen to apply to the pyranol dyes

COLUMBIA BLACK, -BLUE, -GREEN v.

Azo- colouring matters

COLUMBIA YELLOW v Primuline and its derivatives.

COLUMBIC ACID, COLUMBAMINE, and COLUMBIN v CALUMPA

COLUMBITE. A columbate (mobate) of usually containing some manganese ' manganocolumbite') and tantalum, the general formula being (Fe,Mn)(Cb,Ta)<sub>2</sub>O<sub>6</sub> With an increase in the amount of tantalum, there is a transition to the isomorphous species, tantalite The orthorhombic crystals are dark brown or black and opaque, and range in sp gr. from 5 3 (columbite) to 7 3 (tantalite) It was in this mineral that C Hatchett discovered, in 1802, the element columbium, so named because the specimen he examined came from Columbite is usually found as single crystals embedded in pegmatite or granite; for example, at Haddam and Middletown in Connecticut, Chesterfield in Massachusetts, brilliant crystals in granite at Standish in Maine, large masses up to 2000 lbs in granite veins in the Black Hills of South Dakota, and at At lyigtut several other American localities in Greenland it has been found in the cryolite deposit Large crystals are found in the felspar quarries near Moss in Norway. Other localities are Rabenstein in Bavaria, Bushman Land in South Africa, Madagascar, &c.

COLUMBIUM (Niobium). Sym. Cb. At. wt 93.1 (Smith and van Haagen). Although this metal is still commonly termed niobium by the mineralogist and the metallurgist, the name columbium, which was given to it in 1802 by Hatchett, who first isolated it in the form of a new 'earth' (Cb2O5) from a mineral found in Connecticut, has been officially adopted by the chemist in English-speaking countries, and generally throughout the world, except perhaps in Germany.

Columbium is a member of a group of comparatively rare metals, including tantalum, tungsten, molybdenum, titanium, and uranium, commonly occurring together in minerals found in the oldest Plutonic rocks and especially in and around intrusions which traverse pegmatites and other extremely coarse-grained granito rocks. Monazite, and other minerals containing metals of the cerum group, zircons, cryolite, and fluorspar, and minerals containing lithium, cassium, and rubidium, are often associated with these minerals, and are probably intimately connected with their

Although an extremely rare metal, columbium exists as the pentoxide in a considerable number of minerals, in some of which—such as pyrochlore and columbite-it may be regarded as the essential constituent, while, in others, although practically always present, its proportion varies from a mere trace up to an amount which justifies its being considered as the principal oxide.

Columbium occurs in minerals only as the pentoxide Cb<sub>2</sub>O<sub>5</sub>, in combination with a base, the columbium in the few minerals (such as wohlerite) which contain silica, being present as a silico-columbate, and never as a silicate of

columbium

A list of thirty or forty minerals in which columbium is commonly found in association with tantalum might be given, but the principal will be given in the article TANTALUM, with which metal columbium invariably occurs in From the technical point of view, the principal columbium minerals are those which consist essentially of columbates of iron, man-ganese, and lime, zirconia and metals of the cerium group being also usually present in, or at any rate intimately associated with, such minerals as contain lime.

The mineral richest in columbium is pyrochlore, a columbate of lime containing titanium, cerium, and thorium, together with other alkaline earths and alkali bases and some fluorine The most important mineral, however, is the columbate of iron and manganese known as columbite or niobite, in which the Cb2O5 may even exceed 78 pc, a condition nearly reached by certain specimens occurring in the cryolite of Arsukfiord (Greenland).

The columbium is always partly replaced by tantalum, the proportion of which may vary from a trace through all gradations, until the mineral merges into tantalite which is isomorphous with columbite, and which occurs in much larger quantity and furnishes the bulk of the tantalum of commerce and, as a by-product, of the columbium. These two minerals are found in alluvial deposits with cassiterite and wolfram, and in isolated masses left by the denudation of

intrusions in pegmatites, &c, at Greenbushes and elsewhere in Western Australia, in Colorado (Cañon City), Dakota (Black Hills), North Carolina and other districts of the United States. and in Sweden, Norway, Greenland, Madagascar, Rhodesia, and many other districts. They may be considered to possess the general formula (FeMn)O(CbTa)<sub>2</sub>O<sub>5</sub>, the relative proportions of ferrous and manganous oxides varying within extremely wide limits

New deposits are constantly being discovered, and columbium, like many others of the rare metals for which a demand now exists, will doubtless be found to occur in much larger

quantities than is generally believed

Amounts, far in excess of present requirements, are obtainable as by-products from the preparation of the rare earths employed for incandescent mantles, from tin and wolfram ores, and from the heavy waste material obtained

in the dressing of cryolite

Metallic columbium may be prepared by passing a mixture of the vapour of the pentachloride and hydrogen through a red-hot tube (Roscoe), by electiolysis of the oxyfluoride; in a less pure condition, by heating the pentoxide with carbon in the electric furnace (Moissan), by the alumino-thermic process, and by the method of von Bolton, introduced with a view to the manufacture of metal filament lamps, before tantalum came into use. In this process, the pentoxide is mixed with paraffin and formed into threads which are heated in vacuδ to a temperature of over 1900° by passage of an electric current

By the alumino-thermic reaction, von Bolton has obtained columbium containing about 3 p c of aluminium which can be driven off with other impurities by prolonged heating in vacuo in the electric furnace The purest columbium hitherto prepared in bulk is said to have been thus obtained Like tantalum, it can also be obtained by reduction of the fluoride K2('bF7 with potassium, as a black powder from which the residual hydrogen may be expelled by shaping it into small cylinders and melting in vacuo in an electric furnace

Although the most important use of tantalum is for manufacture of electric lamps, in which case it requires to be separated from columbium, the amount actually consumed for the purpose is extremely small. The standard tantalum lamp, introduced in 1904, contained only one twenty-thousandth of a pound of tantalum, and those now manufactured contain much

The method employed for the separation of columbium from tantalum in the preparation of the latter element for electric lamp filaments probably depends essentially upon a fractional crystallisation of the mixed double fluorides of potassium with tantalum, columbium, and

Metallic columbium melts at 1950°, and has a sp.gr of 127, and an electrical resistance of 0.1870 ohm for a wire 1 metre long by 1 mm. diameter It is less malleable or ductile than tantalum, but the rolled metal has a hardness greater than that of wrought iron, and may be welded at a red heat.

Although the powdered metal oxidises rapidly when heated in air, the rolled or cast

COLUMBIUM.

metal is but little affected, as a protective coating of oxide rapidly forms. It is practi cally unaffected by an acid except hydrofluoric acid, or by solution of the alkalis, but is rapidly attacked by fused alkalis or alkaline nitrates

It combines with carbon when heated, and at dull redness rapidly absorbs hydrogen or nitrogen and becomes brittle, the hydride and nitride respectively being apparently formed.

It reacts violently when heated with sulphur or selenium, and forms the volatile penta chloride when heated to redness in chlorine

It does not form an amalgam with mercury, but alloys with many other metals and in all

354

proportions with iron
The compounds of columbium have not yet been applied commercially, but the pentoxide, generally known as columbic acid, and the fluorides, especially the double fluoride with potassium 2KF CbF, are of interest in connection with the preparation of the pure com-

pounds or metal from nunerals.

For methods of analysing columbites and tantalites, and of estimating columbium in presence of tantalum, see G Chesneau (Compt rend 1909, 149, 1132, J Soc Chem. Ind 1910, 29, 93), J Moir (J Chem. Met and Min Soc S Africa, 1916, 16, 189, J Soc Chem Ind 1916, 35, 637), Giles (Chem News, 1909, 99, 1), Simpson (Chem News, 1909, 99, 243), Metzger and Taylor (Zeitsch anoig Chem. 1909, 62, 383), Weiss and Landecker (Zeitsch anorg Chem. 1909, 64, 65), cf Foote and Langley (Amer J Sci. 1910, [iv] 30, 401), cf. Hauser and Lowite (Zeitsch angew. Chem. 1912, 25, 100), Meimberg (Zeitsch angew Chem 1913, 26, 83), Meimberg and Wintzer (Zeitsch angew Chem 1913, 26, 157), Levig (Analyst, 1915, 40, 204)

For a method of estimating columbium and tantalum based on the difference between the densities of the oxides of columbium (4.552) and tantalum (8.716), see Foote and Langley (Amer J Sci 1910, [iv ] 30, 393), see also Ruff and Schiller (Zeitsch anorg. Chem 1911, 72, GT. H 329).

## Compounds of Columbium.

Columbium dioxide CbO or Cb2O2, formed by heating potassium columbium oxyfluoride with sodium, is a white powder, which burns when heated in the air, forming the pentoxide In chlorine it ignites, forming the oxychloride CbOCl<sub>3</sub>. Is soluble in hydrochloric acid with evolution of hydrogen.

Columbium tetroxide CbO, or Cb<sub>2</sub>O<sub>4</sub>, a black powder, formed by heating the pentoxide in hydrogen, or with magnesium. Burns when

heated in the air to redness

Columbium pentoxide  ${\rm Cb}_2{\rm O}_5$ , a white infusible powder of sp gr 4.53-4.568 (4.8 Balke and

Smith).

Columbic acid HCbO<sub>3</sub>, a white powder formed by decomposing the oxychloride or pentachloride with water. Slightly soluble in hot hydrochloric acid. Yields the pentoxide when strongly heated. Potassium hexacolumbate K<sub>8</sub>Cb<sub>6</sub>O<sub>19</sub>,6H<sub>2</sub>O, formed by fusing the pentoxide with potassium carbonate. Large monoclinic crystals, efflorescing on exposure to dry air. Other potassium columbates are K<sub>6</sub>Cb<sub>4</sub>O<sub>13</sub>,13H<sub>2</sub>O; 2K<sub>2</sub>Cb<sub>4</sub>O<sub>11</sub>,11H<sub>2</sub>O; K<sub>4</sub>Cb<sub>2</sub>O<sub>7</sub>,11H<sub>2</sub>O Sodium columbate 7Na<sub>2</sub>O,6Cb<sub>2</sub>O<sub>5</sub>,32H<sub>2</sub>O (Bedford, J. Amer. Chem. Soc. 1904, 26, 1235); Sodium metacolumbate Na<sub>2</sub>O,Cb<sub>2</sub>O<sub>5</sub>,7H<sub>2</sub>O (Balke and Smith, J. Amer Chem Soc. 1908, 30, 1637) For the composition of other columbates, see Balke and Smith (lc)

Percolumbic acid HCbO4, an amorphous vellow powder, obtained by treating columbic acid with hydrogen peroxide Is decomposed on warming with sulphuric acid Potassium percolumbate or pyrocolumbate K<sub>4</sub>Cb<sub>2</sub>O<sub>11</sub>,3H<sub>2</sub>O, formed by mixing hydrogen peroxide with a solution of potassium columbate and adding Decomposed by water Yields hydroalcohol gen perovide and ozone with concentrated For other percolumbates, see sulphuric acid Balke and Smith (l c)

For the hydrosol's of columbic acid see Hauser and Lewike (Zeitsch angew Chem

1912, 25, 100)

For the electrolytic reduction of columbic acid and its salts, see Ott (Zeitsch-Elektrochem

1912, 18, 349)

When columbic acid is dissolved in concentrated sulphuric acid, the solution diluted, and then reduced with zine, an indigo-blue solution is obtained which reduces a solution of copper sulphate to metallic copper, the solution is thus more strongly reducing than one containing tervalent titanium.

Columbium pentafluoride  ${\rm CbF_5}$ , colourless, strongly refractive monoclinic prisms,  ${\rm D^{18}\,3\,293}$ ; 75.5° (corr), bp 217°-220°/760 mm (corr ) Obtained by the action of fluorine on Very hygroscopic; readily soluble columbium in water Solution precipitates columbic acid on addition of ammonia or sodium hydroxide (Ruff and Schiller, Ber 1908, 42, 492)

Columbium oxyfluoride CbOF, forms double salts with other metallic fluorides, of which the alkaline salts have been investigated by

Marignac.

Columbium trichloride CbCl3, a non-volatile, non-deliquescent crystalline substance resembling iodine, forming long dichroic needles Oxidised on exposure to air, and yielding columbium oxychloride CbOCl<sub>3</sub>, and carbon monoxide when heated in carbon dioxide (Roscoe)

Columbium pentachloride CbCl<sub>s</sub>, vellow needles, obtained by heating columbium pentoxide mixed with charcoal in a stream of chlorine Also formed by heating the pentoxide with sulphur monochloride S2Cl2, or, together with the oxychloride, by heating the pentoxide with carbon tetrachloride; mp 194°; bp. 240 5°; sp gr 2·73-2·77. Gives a normal vapour density. Soluble in carbon tetrachloride, chloroform, and alcohol. Its solution in hydrochloric acid gelatinises, and on addition of water, forms columbic acid. On reduction with sodium amalgam gives chlorocolumbrum chloride (Cb<sub>6</sub>Cl<sub>12</sub>)Cl<sub>2</sub>,7H<sub>2</sub>O, black, shining crystals, forming an olive-green powder, insoluble in cold water, but soluble in hot water to an olive-green solution Only two of the chlorine atoms are ionic. When treated with the equivalent amount of sodium hydroxide, chlorocolum-brum hydroxide (Cb<sub>6</sub>Cl<sub>12</sub>)(OH)<sub>2</sub>,8H<sub>2</sub>O is formed as a black microcrystalline precipitate, and from this the bromide  $(Cb_6Cl_{12})Br_2,7H_2O$  is obtained. The hydroxide is soluble in excess of sodium hydroxide, and from the solution excess of concentrated hydrochloric acid precipitates a brown powder  $C_6H_{14},9H_2O$  (Harned, J. Amer Chem. Soc. 1913, 35, 1078)

Reduction of a solution of columbium pentachloride at a platinum cathode gives a blue solution, which is of a colloidal character; with gold choude it gives a magnificent purple liquid, from which, on boiling, a purple precipitate deposits. This precipitate is similar to purple of Cassius; it colours glass a violet-red (Styhler, Ber 1914, 47, 841).

Columbium oxybromide CbOBr<sub>3</sub> and pentabromide CbBr<sub>5</sub> also exist, and an iodide has been formed (Bair, J. Amer Chem. Soc. 1908,

30, 1668)

**Columbium sulphides** CbS<sub>2</sub> and Cb<sub>2</sub>S<sub>5</sub>, corresponding to the oxides, have been prepared (Biltz and Gonder, Ber 1907, 40, 49, 63).

Columbium oxysulphide CbOS<sub>3</sub>, a black crystalline powder formed by heating the pentoxide in the vapour of carbon disulphide mixed with carbon dioxide

Columbium nitride  $\mathrm{Cb_2N_5}$ . A yellow powder formed by heating columbium in nitrogen (Moissan, Compt 1 end 1901, 133, 20, Muthman, Weiss and Reidelbauch, Annalen, 1907, 225, 529

The spectrum of columbium contains thirty-one more or less complete groups of five lines showing wave-number differences equal to 720 25, 1027 02, 355 19, and 303 29 respectively (cf. Siogbahn and Freman, Ann. Physik 1916, [iv.] 49, 611)

For are spectrum of columbium, see Hildebrand (J. Amer. Chem. Soc. 1908, 30,

1672)

For the magnetic resolution of the spectrum lines of columbium, see Jack (Proc. Roy. Irish Acad. 1912, A, 30, 42)

COLZA OIL v RAPE OIL

CONDENSERS. A condenser is an apparatus in which the vapour of a liquid may be cooled down to a temperature below that at which it is converted into the liquid state under the prevailing pressure The condensation of the vapour is usually effected by bringing it into contact with a cold surface, to which it imparts its heat, suitable arrangement being made for conveying away this heat from the cooling surface. Although air cooling is sometimes depended upon for this latter purpose, the arrangement usually adopted consists in causing a stream of cold liquid (water in the majority of cases) to circulate over the exterior of the con-densing chamber The following points should be considered in the designing of an efficient condenser :-

(a) The cooling surface must be made of material upon which the vapour has no chemical action, and should be capable of withstanding repeated variations of temperature without fracture

(b) The area of cooling surface should be as great as possible, without making the apparatus unduly large and heavy.

(c) The material should preferably have a

high specific heat, so that its rise in temperature may be kept within reasonable limits, and it should have a high thermal conductivity, in order that the heat it absorbs may be rapidly carried away

(d) The design should be such as to admit of

the condensor being readily cleansed.

It is not possible to obtain materials entirely satisfactory in each of the above respects, and so in practice the materials employed are those which combine cheapness with reasonable satisfaction in the foregoing particulars. For laboratory apparatus, the material commonly used is glass, metals (block tin, copper, &c) are less often employed, except for constructing fairly large pieces of apparatus, of iceent years, silica has found a limited use.

Condensers are used in two different kinds of operations. (1) for condensing vapours in distillation processes, in which case a still is attached to the upper end and a suitable receiver to the lower end; and (2) as 'reflux' apparatus in cases where it is necessary to boil a liquid for some time without sensible loss through evaporation, the vessel containing the boiling liquid is then attached to the lower end of the condenser and the condensed vapours flow back into the vessel. A number of condensers described below are specially designed for this

ourpose

The simplest type of condenser is the familiar form devised by Weigel in 1771, but usually known as Liebig's condenser It consists simply of a straight cylindrical glass tube, in which the vapour is condensed. The upper end is widened out slightly to facilitate connection with the still, and its lower end is cut off obliquely, a cylindrical glass jacket is slipped over the greater portion of the length of the tube, and through it, by appropriate entrance and exit tubes, cold water is circulated in an upward direction, so that the vapours passing down the inner condenser tube encounter a surface the temperature of which continuously falls in the direction of the receiver This type of condenser admits of considerable variation and modification in the precise details of construc-

tion, thus, with a view to exposing a large cooling surface, the portion of the condenser within the jacket is sometimes made of approximately rectangular section, thus

, being broadened considerably in one direction; in other condensers the central portion carries a series of bulbs blown on it Cooling surface is obtained in some condensers by replacing the central portion by a closely wound glass spiral, as in Fig. 1, the water-jacket being sealed on to the condenser proper. The modified Weigel condenser, shown in Fig. 2 (Chem. Zeit. 1902, 26, 633), is arranged for use with the two

limbs a and c of the inner U-tube

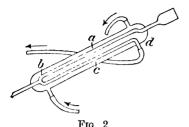

Fig. 1.

on the same level to prevent accumulation of liquid at b. The inner tube is fused into the outer tube at d.

Glass condensers with water-jackets sealed on are restricted in their use to the condensation of the vapours of liquids of fairly low boilingpoint (below 100°), since otherwise the glass joints are liable to crack For liquids of moderately high boiling-point (140°-200°), it

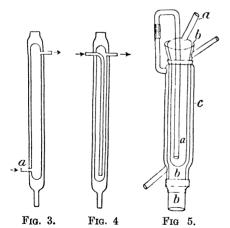

usually suffices to employ merely the inner tube

of a Weigel (Liebig) condenser (an condenser) In the reflux condensers illustrated in Figs 3 and 4 (J. Soc Chem. Ind. 1897, 16, 979) the relative positions of the vapour and cooling stream of water are reversed, the water entering as shown by the arrows (at a in Fig. 3) large area of exposed surface is obtained in these condensers, which, it will be observed, are of the 'double surface' type, since, in addition to the inner water-cooled surface, condensation also occurs on the outer surface, which exposes an even larger area to the cooling action of the an

Several vertical condensers have been devised by Friedrichs in which one of the two surfaces between which the vapours condense is constructed spirally (Zeitsch angew Chem 1910, 23, 2425)

A number of extremely useful, compact condensers of the 'double-surface' type have been described. The vapours are condensed in the annular space between two surfaces, both of

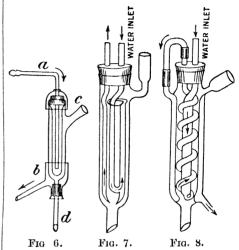

which are water-cooled, the design being such that one stream of water flows in succession over each The efficiency of this cooling process is so great that these condensers can be made quite short; they are readily fixed in a vertical position and occupy little bench space.

In the Burgess condenser (J Soc Chem Ind. 1905, 24, 1190), the tubes a and c (Fig. 5) are the cooling jackets, and b is the condensing tube

two concentric tubes joined together at the top; condensation is effected in the interior chamber thus formed. Water is conveyed into the inner tube by the tube a; overflowing, it passes round the exterior of the outer tube and flows away by the side tube b The vapour is led in through the inlet tube c

Another double-surface condenser of simple construction is illustrated in the article Analysis (Vol 1)

The condensers illustrated in Figs. 7 and 8

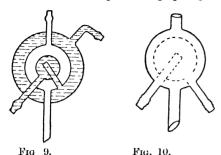

have the advantage of exposing four cooling surfaces to the vapour, and may be readily cleansed when necessary by removing the inner portions with the stopper (Chem. Zentr. 1908, ii 277)

An inquiry into the relative efficiency of laboratory reflux condensers made by Dover and Marden (J Ind Eng Chem 1916, 8, 834) showed that where a long condenser can be conveniently used, the Weigel is preferable, whilst the Friedrichs, or some modification of it, seems best where a short condenser must be used.

The condensers so far described are usually constructed of glass, but occasionally metals are employed. The use of aluminium for the inner tube of a Weigel condenser has been advocated by Norton (J Amer Chem Soc 1897, 19, 153) Many agricultural chemists, who have to deal with numerous ammonia distillations, prefer block-tin condensers; they are constructed like inverted U-tubes, one arm (the condenser arm) being much longer than the other and carrying a water-jacket if required, while the short arm is attached to the distilling A convenient method of constructing a number of such condensers in series to be cooled by one stream of water is described in J. Amer. Chem Soc 1906, 28, 999

A useful metallic condensor is the 'ball' type, used on the reflux principle in numerous experiments involving extractions with volatile solvents. Soxhlet's pattern is shown in Fig. 10. while the construction of a double-surface condenser of this pattern is sufficiently indicated in proper. Cribb's condenser (Fig 6) consists of Fig. 9. Storch's metallic reflux condenser is depicted and described in J. Soc. Chem. Ind. 1897, 16, 979.

The spiral (worm) type of condenser is frequently constructed of metal (copper) and enclosed in a metal tank which can be filled with cold water: these condensers find considerable use in small plants for preparing dis-

tilled water For this latter purpose, a novel form of condenser is described in Eng. Pat. 6916, 1905, which combines efficiency with extreme simplicity of construction The condenser, which is placed vertically above the evaporating chamber, consists of two metallic truncated cones, the lower being open at the top, while the upper is closed by a dome-shaped The outer surface of the upper cone is cooled by a continuous stream of cold water, and condensation is effected upon its inner surface. The condensed vapour collects in the annular space between the two cones, and the water is continuously run off into large earthenware jars Special apparatus, devised for preparing pure distilled water (so-called 'conductivity water') on a laboratory scale are described by Bousfield (Chem. Soc. Trans 1905, 87, 740); Golding (J. Soc. Chem. Ind 1906, 25, 678), and by Haitley, Campbell, and Poole (Chem Soc Trans 1908, 93, 428).

Condensers of various designs are described m J pr. Chem. [2] 34, 427; [2] 49, 44, Compt rend. 118, 478; Ber 1892, 24, 3950; 1895, 28, 2388, J Soc. CONDURANGO. The dried bark of Marsdenia condurango (Nichols) (Gonolobus Condurango triana, Reichenbach; family Asclepradaceæ). It is obtained from a half-climbing The bark comes or prostrate shrub of Ecuador into commerce in quills or quilled pieces, about 10 cm. long, and rarely exceeding 2 cm in diameter; externally brown grey, roughened, with scale like warts; internally, greyish or pale brownish-white, striate; fracture short, granular or slightly fibrous in inner layer. Taste, somewhat bitter; odour of fresh bark, aromatic.

Kubler (Arch. Pharm. 1908, 246, 620) states that the principal constituents of the bark are dextrose, other usual components of plants, the glucoside condurangin and a polyhydric alcohol

condurated. Condurangin C40H60O16 contains two methoxyl groups, is soluble in water, alcohol, and chloroform, insoluble in other. Dilute sulphuric acid hydrolyses it to dextrose and an amorphous powder, containing several substances; alcoholic potash yields some cinnamic acid. Conduitol  $C_6H_{10}O_4$  crystallises from hot alcohol in colourless prisms, and yields a tribenzoyl derivative, m p 142°-143°. According to Carrara (Gazz chim. ital 21, 1 204, 22, 1 236), commercial condurangin can be separated into two parts, one insoluble and the other soluble in water The former is a white powder,  $C_{20}H_{32}O_6$ , mp  $60^\circ$ - $61^\circ$ , and the latter a yellow substance,  $C_{18}H_{24}O_7$ , mp  $134^\circ$ . Hager (Handbook, 1900) has further investigated these substances and named them a- and b-condurangin; a-condurangin gives a green colour with Froehde's reagent (cone sulphuiic acid and molybdic acid), b-condurangin does not rara (l.c) also isolated a yellow powder,  $C_{30}H_{50}O_2$ , which he named conduransterm, mp 52 Fluckiger has isolated a small quantity of an alkaloid having a strychume-like action. Fulbas alkaloid having a strychnine-like action (Pharm. J 70, 417) treats the chloroform extract of the crude glucoside with a mixture of equal volumes of sulphuric acid, hydrochloric acid, and alcohol (Lafon's reaction) On warming, a green colour is produced, changing to bluish-green on the addition of a trace of ferric chloride Certain other glucosides give this reaction, but they are not likely to be present in the bark

Condurango has been employed for many years in South America as an alterative in the treatment of syphilis. It is used as a stomachic, and lessens gastuc catarrh and relieves the vomiting and nausea which are usually associated with caremoma of the stomach, it is also used to lessen the pain consequent upon gastric ailments, Condurango produces in large amounts incoordination of the muscles and convulsions, which may be followed by para-Dose, I fluid drachm of the fluid extract lvsis of condurango, or 4 fluid drachms of the wine of

condurango

There are many other varieties of condurango and marodenias The Guayaquil condurango has several peculiarities in the wood of the bank, and has not so many medullary rays Mexican condurangos contain a strong collenchyma next to the bark, while nearer the pith is a layer of bast fibres containing large crystals of calcium oxalate (Chem Zeit 11, 1601; 12,

CONDY'S FLUID v MANGANESE. CONESSINE or WRIGHTINE  $C_{24}H_{40}N_{2}$ exists in the bark and seeds (0 6 p c ) of Wrightia antidysenterica and in Holarihena africana (A DC), H congolensis (Stapf), and H anti dysenterica (Wall) Crystals, mp 122° (Polstorff, Ber 1886, 19, 78, 1682; Wainecke, ibid 1886, 19, 60, Arch Pharm 1888, [iii] 26, 248, 281; Pyman, Chem Soc Trans 1919, 163; Giemsa and Halberkann, Arch Pharm. 1918, 256, 201, Ulriei, Arch. Pharm. 1918, 256, 57). Soluble in acetone, from which it separates in large colourless plates, efflorescing in air; m p. 125° (coιr) [α]-1 90°

CONHYDRINE (Conydrine), Coniceine. See under Coniine, below.

CONIFERIN v GLUCOSIDES.

### CONIINE AND THE ALKALOIDS OF HEM-LOCK.

Conline  $C_sH_{17}N$  is one of several poisonous, volatile alkaloids found in hemlock, Continumaculatum (Linn) (0.2–0.9 p.c. in the not quite tipe seeds). Hemlock (Grande ciquë, Fr; Schierling, Ger) is a tall biennial of the temperate regions of Europe, Asia, and America, and was the essential ingredient in the potion administered to condemned criminals by the Greeks Besides contine, hemlock contains N-methyl-decontine, N-methyl-1 contine,  $\gamma$ -contictine, conhy-

drine, and pseudoconhydrine

Preparation — Comme is most readily separated from the crushed, unripe hemlock seeds by digesting them with water made alkaline with sodium carbonate, to decompose the conine malate, and distilling the mixture in a current of superheated steam. The distillate contains the comme, together with much ammonia derived from the ammonium salts present in the seeds The liquid is neutralised with hydrochloric acid and evaporated to dryness The dry residue is extracted with absolute alcohol, when most of the ammonium chloride remains undissolved, whilst the alkaloidal hydrochlorides go into solution If ether is added to the alcoholic solution a further quantity of ammonium chloride is separated. The residue left by the evaporation of the alcoholic solution is dissolved in cold water, ether added, and the comme liberated by the addition of potash. The ethereal layer is decanted, washed, dried with potassium carbonate and distilled at a low temperature, when the comme remains as an only liquid. It may be purified from the accompanying conhydrine by fractional distillation, the comme passes over first So prepared the comine contains y-coniceine from which it may be freed by conversion into the hydrochlorides and extracting these when dry with acctone, in which the γ-coniceine salt is soluble and the comme salt insoluble the separation of the subsidiary alkaloids by benzoylation, see von Braun (Ber 1905, 38, 3108)

Properties — ('olourless, alkaline liquid, having a remarkable, penetrating odour and a burning taste, b p  $166^{\circ}-167^{\circ}$ , m p  $-2^{\circ}$ , rel. den 0.8626 at  $0^{\circ}$ , dextrorotatory [a]<sub>p</sub>=  $+13.79^{\circ}$ 

Comme is slightly soluble in cold water, but less so in hot water, so that a clear, cold solution becomes turbid when warmed It dissolves about one-quarter of its own volume of water at the ordinary temperature. When boiled with water the alkaloid distils with the steam Conine mixes with alcohol in all proportions, and is also readily soluble in other, but only sparingly so in chloroform or carbon disulphide Exposed in the air it darkens and slowly resim-When administered internally confine acts as a powerful poison. It is a monacidic base The ordinary salts are crystalline and soluble in water or alcohol. The hydrochloride B HCl forms rhombic crystals and melts at 220° The aurichloride B HAuCl<sub>4</sub>, m p. 77°, forms minute yellow needles.

Reactions. -- Conline is a strong base, which

precipitates many metallic hydroxides from solutions of their salts.

It is a secondary amine. When oxidised with nitric acid it yields normal butyric acid among other products. When permanganate is used a-pyridinecarboxylic acid (picolinic acid) is obtained. On distillation with zinc-dust confine is decomposed into hydrogen and a-n-propylpyridine.

Ladenburg has inferred from these and other reactions that comine is a-propylpiperidine and has confirmed this by effecting the synthesis of the alkaloid by hydrogenating (with sodium

ın alcoholic solution) α-allylpyridine

 $C_5H_4N(C_3H_5)+8H=C_5H_{10}N(C_3H_7)$  The liquid thus produced possesses all the chemical and physical properties of the natural alkaloid except one, it is optically mactive (Ber. 1886, 19, 2579, 1906, 29, 2486). Ladenburg has also succeeded in resolving the mactive comine into dextrorotatory and lævorotatory forms and has shown the dextro compound to be identical with the natural alkaloid. This

was the first synthesis of a natural alkaloid. The toxicological recognition is somewhat difficult, in particular there are no reactions distinguishing it sharply from incotine. Auric and platinic chlorides do not precipitate a 1 p c aqueous connine solution, but do precipitate nectine at much greater dilution. A trace of conline evaporated in a desiccator with a drop of hydrochloric acid readily yields a crystalline hydrochloride, nicotine does not. Differences in odour, density, and solubility in water may also be used.

N-Methyl-d-conine  $C_8H_{16}(CH_3)N$  is stated to occur in hemlock (v-Planta and Kekulé, Annalen, 1854, 89, 150), and remains with  $\gamma$ -conceine when this is separated from comine by fractional crystallisation of the acid tartrates—It has been synthesised by methylating comine with potassium methyl sulphate (Wolffenstein, Ber. 1894, 27, 2611, cf. Passon, ibid—1891, 24, 1678). It is a colourless, only liquid, b p—173°—174°, closely resembling comine

N-Methyl-l-conline was obtained by Ahrens (*ibid* 1902, 35, 1330) from residues accumulated

in the preparation of conine.

Coniceines. This name has been applied to a series of isomeric bases, C<sub>8</sub>H<sub>15</sub>N, obtained in various ways from the hemlock alkaloids. Only one of them γ-coniceine (2-propyl-Δ'-tetrahydropyridine) occurs in hemlock and was isolated from crude comine obtained therefrom by Wolffenstein (Ber 1895, 28, 302); occasionally as much as 70 pc of the crude alkaloid was γ-coniceine. This base was first prepared by Hofmann by the action of alkalis on bromoconine. It strongly resembles connine in odour and appearance, boils at 171°−172° under 746 mm. pressure, yields crystalline salts, and furnishes connine on reduction. It has the constitution

$$\begin{array}{cccc} \operatorname{CH}_2 & \operatorname{CH}_2 \\ \operatorname{CH}_2 & \operatorname{CH}_2 & \operatorname{CH}_2 \\ \operatorname{CH}_2 & \operatorname{CH}_2 & \operatorname{CH}_2 & \operatorname{CH}_2 \\ \operatorname{NH} & \operatorname{NH} \\ \operatorname{\gamma-Coniceine} & \operatorname{Conine} \end{array}$$

Cf Hofmann, Ber. 1885, 18, 16, 27, 112; Lellmann, Annalen, 1890, 259, 127; Loffler and

colleagues, Ber. 1909, 42, 94, 107, 116, 124, 948, 3420; Gabriel, *ibid*. 1909, 42, 4059.

Conhydrine C<sub>2</sub>H<sub>17</sub>ON, also found in hemlock, may be separated from contine with which it occurs either by cooling the concentrated ethereal solution of the two alkaloids, when the conhydrine crystallises out; or it may be obtained by distilling the crude contine, when it remains behind in the retort, if the temperature has not exceeded 180°.

Conhydrine is a crystalline, basic substance, mp. 121°, bp. 226°,  $[\alpha]_{\rm D}+10^\circ$ . On heating with phosphorus pentoxide, or with concentrated hydrochloric acid, it furnishes a mixture of  $\alpha$ - and  $\beta$ -conicenes (see above). According to Willstatter it is 2: $\beta$ -hydroxy-propylpiperidine (Ber. 1901, 34, 3166; cf, however, Loffler and Tschunke, *ibid.* 1909, 42, 920)

42, 929).

Pseudoconhydrine  $C_8H_{17}ON$ , which is also found in hemlock, closely resembles conhydrine. It is a crystalline, strongly basic substance, in p.  $105^\circ-106^\circ$ ; b.p.  $236^\circ$ . It is a secondary base and forms crystalline salts (Ladenburg and Adam, Ber 1891, 24, 1671). Engler and Baur regard it as  $2 \cdot a$ -hydroxypropylpiperidine (*ibid* 1894, 27, 1777), and Löffler has suggested that it is 4-hydroxy-2-propylpiperidine (*ibid* 1909, 42, 116) G B

COPPER. Sym. Cu At. wt 63.57. Melting-point in air, 1062°; in reducing atmosphere, 1084°. Specific gravity: Roberts Austen (Int Study of Met. 1910, 15) gives 8.217 as the sp.gr. of the molten metal. Copper, deposited by electrolysis from an acid solution of copper sulphate and not subjected to any mechanical treatment, was found to have sp.gr. of 8.9544 at 15.5° in air (Watson, J. Soc Chem Ind. 2, 153)

Commercial copper, prepared in the usual way, is never pure, and the examination of the fractured surface of a cast ingot of copper shows a minutely vesicular structure. On this account the density of such metal is less than

the same sample of metal after it has been subjected to a compressing mechanical treatment, and varies from 8.2 to 8.6

Colour.—Copper has a characteristic red colour which, in a fractured surface of worked metal, may be described as salmon-red.

Lustre —A smooth cut or polished surface shows a bright metallic lustre which, however, soon tarnishes.

Crystalline system —Copper crystallises in the cubical system

Ores of copper. The following minerals are those from which copper is extracted on a commercial scale: native copper, cuprite, melaconite, malachite, azurite, chrysocolla, atacamite, chalcocite, bornite, chalcopyrite, fahl ore

The importance of the several species in the above list as ores of copper varies very much with the locality. Thus, while native copper is the chief ore in the Lake Superior district of North America, and atacamite in one or two localities in Chile, they would in other localities, and generally, be looked upon as rather rate, especially so in the case of the last species mentioned So also in the case of malachite, this species, as an ore of copper, is seldom met with except in small quantities in the upper and oxidised portions of some copper lodes, yet in the case of the once celebrated Burra Burra mine in Australia, and at Nischne-Tagilsk in Russia, it formed the bulk of the ore produced, and is also the chief ore in the Tanganyika district, Africa

Generally, in a copper-mining district, all the oxidised species mentioned above occur in varying proportions, but as depth is attained, and almost invariably at or about the level at which water is reached, the copper-bearing minerals change and the oxidised species give place to the richer sulphide species, and these finally to chalcopyrite intimately mixed with varying proportions of pyrite The intermingling of the two species last mentioned is frequently so intimate that it is not easy to distinguish the component minerals or to separate them. Chalcopyrite thus diluted down, as it were, with one or more of the mineralspyrite, pyrotite, &c —forms the ore from which the greater proportion of the world's copper supply is derived and the bulk of the material treated at the smelting works generally. Such ore frequently contains appreciable quantities of gold and silver The silver is frequently carried by intermixed fahl ore, but also, in many instances, by the pyritic mixture in which distinct silver-bearing minerals are not observable.

As by far the larger proportion of ore presented for metallurgical treatment is of the nature indicated above, viz. chalcopyrite mixed with varying quantities of the pyrite family of minerals, it will best serve the purpose of this article if the methods adopted for the extraction of copper from this material are first considered. The ores treated generally contain only small percentages of copper, frequently not more than 1 p c

The elimination of the several elements in the ore and the final production of the copper in the metallic state, are effected by two distinct series of chemical operations. One of these—the most important, because of its very general application—treats the ore by smelting, and

causes the necessary reactions to take place while the material is in a molten condition. The other-of limited application-treats the material in the wet condition, and causes the necessary reactions to take place in solutions

These two distinctly different methods of procedure may be distinguished as (a) dry

methods, and (b) wet methods

Dry methods. The object which the smelter keeps in view in the first stages of the processes is to concentrate the copper contained in the ore in as small a quantity of material as may be economical. For this purpose, the product known as 'matte' or 'regulus' is universally selected. This consists of cuprous sulphide Cu2S and non sulphide FeS in varying proportions, together with sulphides of certain The whole of the other metallic elements copper contained in the ore thus passes into the matte, while the silica combines with iron oxide and earthy bases, if present, and forms the The slag separates easily from the matte, owing to its lower specific gravity, and is thrown away Having thus concentrated the copper into regulus, or matte, the next stage of the process concerns itself with the decomposition of this matte in such manner as to eliminate the iron and sulphui and, as far as possible, other metallic elements which may be present and to yield the copper in the metallic state

The final process consists in refining the copper produced as above, or, in other words, removing, as far as practicable, the small quantities of such elements as may still be present in the product of the preceding operation which would injuriously affect the copper for

manufacturing purposes

The treatment of the ore involves, therefore, three distinct operations

I Smelting the one with the production of matte and slag.

II. Treatment of the matte for the production of crude copper

III Refining

The methods and the plant used for carrying out each of the three operations vary considerably, and the choice of any one depends upon local conditions, the nature of the ore as regards physical character, and the nature and quantity of the foreign elements present will not be possible within the limits of this article to study these considerations and the bearing they may have on the methods to be adopted, all that the space will allow of is a description of the methods as actually carried out under the most generally prevailing conditions

I Smelting the ore with the production of matte and slag -The object of this process being the concentration of the copper in the matte, the chief considerations kept in view are the production of a matte as rich in copper, and a slag as poor in copper, as is practically and economically possible

The grade of the matte to be produced having been decided upon, the smelter regulates this by suitably proportioning the sulphur in the ore to be treated so that there shall be sufficient to form Cu2S with all the copper, and a further proportion to form FeS with the iron present in such quantity as will cause the matte to contain the desired percentage of copper. From these

considerations it will be seen that the factor which regulates the grade of the matte is the quantity of sulphur present in the ore mixture smelted. With the class of ore under consideration, it invariably happens that the quantity of sulphur present is considerably in excess of requirements, and the production of the most suitable grade of matte necessitates the removal of this excess, which may be effected before the actual smelting of the ore is commenced. Under certain favourable conditions, however, it may be removed during the smelting process (see Pyritic smelting). This preliminary operation is designated 'calcining' or 'roasting.'

The process consists in subjecting the ore to

a dull-red heat under oxidising conditions, so that the sulphur is caused to combine with oxygen derived from an admitted into contact with the ore with the production of sulphur dioxide, while the non is also oxidised at the

The method of carrying out this calcining process depends upon whether the ore is to be

(a) In the rough—say in pieces from 3 inch cube upwards, or

(b) As fines or 'concentrates,' i.e. in which the particles are finely divided.

Under (a). The one may be calcined by forming heaps of it in the open air and staiting the combustion by means of a small proportion of wood, the combustion being maintained by the sulphur present in the ore.

The ore may also be calcined in stalls more or less open These consist of series of chambers in rows built back to back. The chambers are each bounded by three walls, viz back and two side walls, but are open in front and have no 100fs. Small flues, opening out into the chambers, are built in the walls separating them, and these flues connect with a larger flue in the central division wall between the two rows, and these again connect with a chimney stack

The ore is charged into these open chambers on to a layer of wood, when filled up, the wood is fired and combustion extends to the ore itself in the same way as in the case of the heaps The gases produced in the operation are to a large extent led away by the flues in the walls above referred to The annoyance caused by the escape of these gases at or near the ground level of the works—as is the case in open heap roasting-is in this way to a large extent avoided

The ore may be calcined in kilns - These are similar to the stalls, but are generally built of much larger size, are closed in on all four sides, and are roofed over They are provided with suitable openings in the roof through which the ore is introduced, and a doorway in the front wall (bricked up when the kiln is in operation) through which the calcined ore is removed. An outlet flue, connected to the roof or back wall, allows the gases to be conveyed to a chimney.

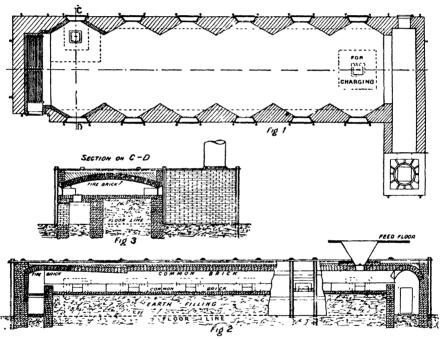

The ore may be calcined in 'burners.'-These are constructed and worked on very much the same lines as the 'burners' used for burning 'pyrites' at sulphuric acid works. In this plant, a number of closed cells or 'burners' are built in rows, back to back. Each cell is roofed in and connects at the back with a

central flue common to all the cells, by which the gases are led to the acid chambers. In the roof of each cell is an opening through which the ore can be charged from a hopper placed above. In this class of plant, the ore does not rest on the floor as it does in each of the cases previously considered, but upon a series of square bars suitably spaced. Below these bars is an enclosed space with suitable door through which the calcined ore is removed and by means of which the air supply is regulated

In operating this plant, the cell having been brought up to a good ied heat by the combustion of wood or other suitable fuel, ore in small quantities is gradually added as combustion proceeds, until the burner is full. At suitable intervals, a small quantity of the calcined ore is removed from the bottom of the

burner and a corresponding fresh supply of ore is added through the opening in the roof. In this way, the operation of the burner is rendered continuous, and no fresh extraneous fuel is required after the first starting of the fire

In all the methods of treatment described under (a), it is essential that proper care be taken to prevent the temperature reaching anything like melting-point. If the one melts of sinters together, calemation is delayed owing to the reduced surface on which oxidation can take place. Further, in the case of such sintered or melted material, difficulties are created in working the process. In the case of heap roasting and also in the stalls and kilns, the formation of large masses of sintered or melted one introduces undesirable inregularities in the air current through the mass of one under treatment, and

Figs. 1, 2, and 3.

causes trouble when the ore is removed. In the burners, the formation of sintered masses of ore must be avoided, as such masses would have to be broken up in the burner with suitable tools before it could be made to pass out between the grate bars.

Under (b) The ore may be calcined in hand calciners or mechanical calciners—The former are not much used at the present time, as the necessary labour is effectually replaced by mechanical appliances. The hand calciner, which was universally used some years ago, consisted of a long flat bedded reverberatory furnace, with the usual fire box at one end and the outlet flue for the exit of the gases at the opposite end (Figs. 1, 2, and 3). The ore was dropped from a hopper through an opening in the roof on to the bed at the flue end of the furnace, where it was spread out by means of

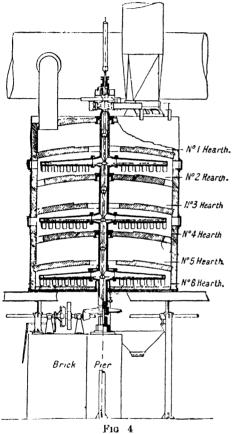

suitable tools worked by men at both sides of the furnace, operating through doors in the side walls

The conditions in the furnace were intensely oxidising, and it was necessary to stir the ore frequently to prevent it sintening. In the process of stirring, the ore was turned over and moved towards the fire end, thus making room for a fresh charge from the feed hopper. This process of stirring and moving the ore forward towards the fire end was continued until the ore reached close up to the fire box, at which point it was discharged through openings in the bed of the furnace into vaults, or chambers, constructed below, from which—when sufficiently cool—it was removed. The labour required on these furnaces was very heavy and the output small, and, except in unimportant installations, they have given way to furnaces in which the

ore is stirred, moved forward, and discharged by mechanical means operated by power. It will be impossible within the limits of this article to describe the many furnaces of this type which have been introduced, and it will suffice to describe one or two which will serve as examples of the class of plant employed

The McDougall furnace (Fig. 4) —This is very largely used, and consists of a series of flat

circular superimposed firebrick hearths, enclosed in a brick-lined cylinder of steel plate An iron shaft passes centrally up the cylinder through openings in the several hearths, and is

(From Gowland's Metallurgy Charles Griffin & Co , Lt1)

caused to revolve by suitable gearing attached either to its upper or lower end. This shaft may be made hollow and cooled by air or water circulation.

One or more iron arms are attached to this shaft above each bed The arms extend from the shaft to the periphery of the circular beds, and have attached to them a series of iron plates or ploughs set at a slight angle to the arm. The ore is fed from a hopper on to the top bed near the centre, and the angle of the ploughs is such that, as the arms revolve, they not only turn the ore over, but gradually move it from the centre to the edge of the bed. At one point in the edge of the bed is an opening through which the ore

falls on to the second bed. On this bed the ploughs are so set on the arms that the ore travels in the reverse direction and is drawn to the centre of the bed. Here it discharges on to the third bed, and so on until it escapes at the bottom of the furnace. The openings through which the ore falls from one bed to the other also serve as flues through which the gases pass upwards through the furnace, finally escaping through a flue above the top bed.

Attached to the lowest bed is a fire box by which the furnace is heated up in order to start it, but, after being once started, little or no fuel is required, as the oxidation of the ore provides sufficient heat throughout the apparatus

The straight-hearth mechanical furnace—This type of furnace passes under various distinctive names, according to the several methods adopted for operating the ploughs, and slight modifications in the construction furnace consists of a flat bed about 100 feet At one end is the long covered with an arch inlet for the ore, and at the opposite end is the outlet. At the ore inlet end is the flue for carrying off the gases, and at the opposite end, but to one side, is a fire box with the inlet to the furnace constructed in the roof of the latter similar fire boxes—one or two in number—are placed at intervals along the length of the A channel is constructed in the side walls of the furnace and in these a rail is laid. A suitable carriage with wheels iesting on the iails stretches from one side of the furnace to the other, and the bearings pass through slots in the two side walls and are carried by the wheels above referred to To this carriage, suitable ploughs are attached in such manner that, in the course of its travel from one end of the furnace to the other, the ploughs turn the ore over and also move it forward. The carriage is moved by a pair of chains or ropes travelling in the channels formed in the side walls, and at the two ends of the furnace these chains or ropes are carried round wheels sufficiently large in diameter to lead them back under the furnace, thus making them continuous. One pair of these wheels is driven by suitable gearing, thus causing the pair of ropes or chains-and with them the carriage -to travel the whole length of the bed of the furnace, returning through the tunnel under the bed, where rails are laid for supporting the carriage Two or more such carriages are attached to the ropes, or chains, at equal distances apart. The ore is fed mechanically on to the bed at intervals just as a carriage is about to enter, and the ore is spread, turned over, and moved forward gradually from one end of the furnace to the other. Each time a carriage emerges from the furnace, it draws with it a quantity of calcined ore The carriage and its attached ploughs are cooled during the passage through the tunnel The ends of the furnace are closed by light iron doors which hang down vertically and are automatically opened by the passage of the carriage and close themselves as soon as the carriage has passed.

There is yet another method of removing the excess sulphur which is sometimes used, known as 'pot roasting,' or 'blast roasting.' This method of calcining is advantageously applied to concentrates and fines, and, while it eliminates the sulphur, the heat attained is at the same

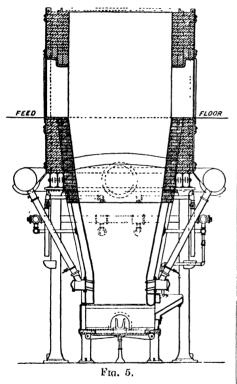

time sufficiently intense towards the end of the process to cause the ore to partially melt or sinter together, forming a mass which requires to be broken up before it can be treated in the smelting furnace. The process is carried out in a similar manner to that used in the treatment of lead ores, but is not very extensively used in the metallurgy of copper.

After the sulphur in the ore mixture has been reduced to the requisite amount, the ore is ready to be smelted. For this operation one of two distinctly different types of furnace are used,

these are:

(1) Blast furnace. (2) Reverberatory furnace

The choice between these two methods of carrying on the smelting operation depends on a

variety of circumstances, all of which must have proper consideration, but the following are the chief points, viz: If the ore is to be smelted in the state of fines or concentrates, it is unsuitable for blast-furnace treatment, while it is eminently suitable for the reverberatory furnace. On the other hand, rough ore is unsuitable for reverberatory-furnace smelting

Blast-furnace smelting—The furnace used may be built of brick, but is more generally, nowadays, constructed with water-cooled walls of steel plate (Fig 5), each section of which is termed a jacket. In the smaller furnaces the horizontal section is circular, but in the ordinary sized and larger furnaces the section is always rectangular. As the working of this type of furnace is—as its name implies—dependent upon an air blast projected into the interior,

the width of the furnace is limited by the strength of the blast which is required to penetiate the charge from the sides to the centre of the furnace, while the length of the furnace is only limited by the capacity required. The increase in length is obtained by clamping together two or more of the jackets on each side, thus extending the longer axis of the furnace.

The jackets stand on a thick cast-iron plate carried on non supports. In some cases these jackets are only used in the lower part of the furnace, all the upper part being constructed of brick, but the brickwork may, in certain cases, be advantageously replaced with a second tier of jackets, reaching up to the feed floor the feed floor the furnace is continued in the form of a covered-in brick chamber with lifting doors at each side and an outlet in the roof of the chamber, connecting, by means of a suitable iron flue, to the general flue system of the works Through the doors the charge, consisting of a proper mixture of ore—either raw and calemed, or partially calemed ore—is introduced. To this one mixture there is also added such flux, either limestone or silicious material, and the necessary amount of coke as is required to form a suitable smelting mixture As previously indicated, the object of this is to produce a matte of the desired grade and a slag which shall be as free from copper as possible and which shall be of such fusibility as to flow readily from the furnace On the lower or working floor, the furnace is provided, either at the ends or sides, with one or more spouts through which the molten products of the smelting operation Except in very large furnaces, only one such spout is used at a time, and if more than one is fitted, it is with the object of having one in reserve in case of a stoppage to the one in use.

The side jackets of the furnace are provided with circular openings (tuyères) passing from the outer to the inner surface. When the jackets are set up, these tuyères form a horizontal line of openings on each side of the furnace. The blast is brought down from the air main by light iron piping to the tuyères, and through these it passes to the interior of the furnace.

The blast, at a pressure of 10-42 oz. per square inch, is generated by a suitable blowing machine, which must be of the positive, and not the fan, type. A plentiful supply of water is circulated through all the jackets, and the overflow pipes from these, carrying away the hot water, discharge into sinks or launders.

The products of the smelting operation performed in this furnace flow out through the spout above described into the settler In the case of small furnaces this is a square cast-iron vessel open at the top and mounted on wheels to allow of easy replacement It is furnished with a cast-iron spout at its upper edge through which the slag overflows, and is provided with a tap hole near the bottom from which the matte is tapped from time to time. In the case of larger furnaces for this form of settler, there is substituted a circular tank, formed of steel plates lined with refractory material, placed permanently in position under the spout of the furnace. This form of settler may be 10 or more feet in diameter, and, like the smaller

pattern mentioned above, is provided with a slag spout near the top and a tap hole near the bottom.

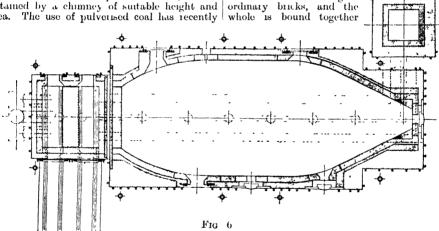

In the settler, a thorough separation of the slag and matte takes place. the matte, having the higher specific gravity, falling to the bottom of the vessel and the lighter slag rising to the top, where it overflows through the spout into suitable pots provided for its removal to the slag dunip. From time to time the matte is tapped off through the tap hole at the bottom of the settler The working of this type of furnace proceeds continuously, fresh ore charges being dumped in at the top at short intervals, while a constant flow of slag and matte passes out through the spout

Reverberatory-furnace smelting -The furnace used is essentially different both in construction and method of working from the one previously described. In the blast furnace, the fuel—coke -is burnt in contact with the materials to be smelted, and the intense heat required for the operation is obtained by uiging the combustion of the fuel by means of an air blast. In reverberatory furnace the material to smelted occupies one compartment of the furnace, while the fuel-coal or wood--is buint The draught required for the comin another bustion of the fuel is quite moderate, and is obtained by a chimney of suitable height and area. The use of pulverised coal has recently

been introduced in reverberatory furnace practice, with gratifying results, from a fuel economy point of view The working bed of the furnace in plan is a parallelogram (Fig. 6) with rounded corners At one end, and separated from it by a low partition, is the fire box, in which the fuel is consumed. At the opposite end is the outlet flue connecting with the chimney A brick aich extends from the back wall of the fire box to the flue This arches the furnace across from side wall to side wall, and is constructed with a fall from the fire-box end to the flue end of the furnace. The partition, or bridge, as it is termed, to which reference is made above as separating the working bed from the fire box, reaches to such a height above the bed that an opening is left between its top surface and the roof of the furnace. Through this opening above the bridge, the flame from the burning fuel passes over the bed on its way to the outlet flue. The side walls of the furnace are pierced with a number of openings used in working the furnace for spreading the ore charge, drawing off the slag, &c, and one opening is cut down to the lowest point of the bed for tapping the matte

The furnace walls and roof are constructed of highly refractory bricks

with an outside casing of

with steel girders placed vertically and tied together from one side to the other by non tie rods. The working bottom is variously constructed. It may be formed of highly refractory bricks, or of silicious sand or crushed quartz

The charging of this furnace takes place through one or more openings in the roof from hoppers supported above. Assuming that the furnace is heated up to the required temperature, a charge of ore mixture is dropped from the hoppers above through the openings in the roof. This is then spread over the bed by means of suitable tools operated by men working through the side and front doors. When this operation is completed, the doors are closed and the fire attended to so as to raise the temperature of the furnace as rapidly as possible to full heat. The charge is occasionally stirred, if necessary, to remove any agglomerated masses from the bottom of the furnace, and

finally, a molten bath is obtained composed of two distinct layers—the matte forming the bottom layer, and the slag floating upon it. When this stage is reached, another charge may be dropped and treated in the same way; and this may be repeated from time to time until the furnace is full of molten slag and matte A side door and end door are opened and the slag allowed to run off, and towards the end, this is drawn off by means of tools handled by the furnace-men until nearly all the slag has been removed. The tap hole is then carefully opened, and this being at the bottom of the furnace, the matte flows through it and is led by a launder into a ladle or into moulds placed When nearly all the on the floor to receive it matte has been run off, the tap hole is again closed and made secure, fresh charges are dropped in, and the operations repeated

The slage may be received in ladles mounted

on wheels, and in these may be removed to the dump, run into a stream of water and thus granulated and removed; or it may be run into sand moulds formed on the floor of the furnace house, and, when cool, broken up and removed to the dump.

The object attained in this operation in the reverberatory furnace is the same as with the blast furnace, viz. the production of the proper grade matte and a slag of easy fusibility

reasonably free from copper.

Pyritic smelting.—This method of working secures in one operation what, in the preceding descriptions, is attained in two processes carried on in separate appliances It has been shown that in order to produce a proper grade of matte from cupriferous iron pyrite, a certain proportion of sulphur must be oxidised to sulphur dioxide, and that, accompanying this action, a portion of the iron sulphide must also be oxidised. It has also been shown that, in ordinary working, this picliminary treatment and the actual smelting of the ore are carried out as two distinct operations. It has also been indicated that in the smelting operation proper, the high temperature necessary is obtained by the combustion of carbonaceous fuel. In pyritic smelting, the two processes referred to above are carried out as one operation in one furnace, and the high temperature necessary is derived from the rapid oxidation of the sulphur and iron (chiefly the latter) contained in the ore While this method of working is of the highest importance from an economical point of view, it is of somewhat limited application, owing to the fact that comparatively few mines produce ore which—as regards its physical condition and chemical constitution—is suitable for this method of treatment

The process is carried out in blast furnaces, and for its successful operation demands a larger volume of air per unit of time than the ordinary smelting process and an ore mixture in which the pyritic material is present in fairly large pieces. The silica must be, for the most part, free silica (quartz), and not combined with earthy bases as silicates. Under these circumstances the ore may be satisfactorily smelted, producing the required matte and slag with the consumption of but 1 to 3 p.c. of coke instead of 10 to 12 p.c. used in the ordinary method of smelting. A small amount of coke is found to be desirable in order to keep the charge open

II Treatment of the matte for the production of crude copper—It has already been pointed out that matte consists of cuprous sulphide Cu,S, with varying proportions of iron sulphide FeS, and the carrying out of the stage which is now to be considered involves the climination of the sulphur and iron, while the copper is left in the metallic state. The process is carried out by different methods, the chief of which will now be considered. In all of these the operation is performed in two stages, although, in some cases, these follow one immediately after the other and in the same apparatus, while in others the stages are performed as two separate operations and in two or more separate furnaces. The first stage in each case consists in the removal of the FeS with the production of Cu<sub>2</sub>S, and the second stage treats the Cu<sub>2</sub>S with the production of metallic copper. The carrying out of the

first stage depends upon the fact that, when matte is exposed to oxidising conditions, the iron sulphide is the first of its constituents to be decomposed, the sulphir being oxidised to sulphir dioxide. The resulting iron oxide is then caused to combine with silica, forming a slag which can be removed from the residual cuprous sulphide.

The second stage in the process depends upon one or more of the reactions represented

by the following equations .-

the first being the most important as representing the change which takes place in the largest proportion of the material. The reactions indicated are effected by bringing the several compounds together in a molten condition. The oxidised compounds may be added to the molten Cu<sub>2</sub>S from outside sources or may be, and generally are, produced by the oxidation of a portion of the cuprous sulphide itself.

The reactions outlined above are, at the present day, almost always brought about by what is termed the 'converter process,' also named 'Bessemeising,' the former name derived from the designation of the vessel in which the operation is performed, viz. converter, and the latter from the name of the distinguished inventor, Sir Henry Bessemer, who had many years previously applied a similar method and plant to the production of steel from pig iron

The converter consists essentially of a vessel formed of steel or iron plate, with a thick lining of either highly silicious rock to which a small quantity of clay has been added, sufficient only to give the necessary coherence, or of basic material The vessel is provided with a suitable aperture serving the purpose of a charging opening through which the matte to be operated upon is poured in a molten condition, also as an outlet through which the products of the operation are poured, as well as being an escape for the gases produced in the process. The vessel is supported on horizontal trunnions or on fuction rollers, and is capable of being iotated by electric or by hydraulic power (Fig. 7). The form of the vessel is more or less cylindrical with the axis of the cylinder placed vertically or horizontally. In the case of the former, a shallow circular enclosed space, termed the air box, is attached on the outside at the bottom of the vessel In the latter form, this air box takes the shape of a long rectangular box attached horizontally to the outside of the converter. From these boxes holes are led through the plates forming the casing of the converter, and are continued through the lining to the Air, at a pressure of from 8 to 12 lbs per square inch, is supplied to the air boxes as required, and the supply is controlled by suitable valves. Charging of the converter with matte is effected by means of a launder direct from the furnace, or settler, or by tapping these first into a steel ladle handled by an overhead crane which conveys it to the converter and pours it

the FeS with the production of Cu<sub>2</sub>S, and the second stage treats the Cu<sub>2</sub>S with the production of metallic copper. The carrying out of the fire, is placed upon the stand and connected up

to the air main. A charge of molten matte is then poured in, the converter having been tilted into a suitable position for receiving it The air being turned on, the converter is then tilted over so that the tuyères are brought beneath the surface of the matte, and the air,

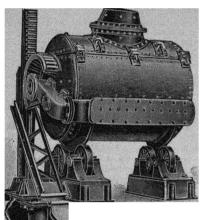

Fig. 7.

forced through being molten sulphides, causes a rapid oxidation of the constituents of the iron sulphide The sulphur is oxidised in this way to sulphur dioxide and the iron to oxide, which is immediately converted to silicate by combination with the silica of the lining

he oxidation proceeds, the temperature of the harge increases and the operation is continued ntil practically the whole of the iron sulphide as been decomposed, and the contents of the onverter consist of cupious sulphide and slag. he converter is now turned over and the slag in off into pots or moulds, and when this is one, it is again turned into the blowing position, hen the second stage of the oxidation is comienced. The passage of the air through the iolten cuprous sulphide brings about the xidation of a part of that material to cuprous xide, which immediately reacts upon unaltered iprous sulphide with the production of an juivalent quantity of metallic copper, in scordance with the reactions already given his action continues until all the cuprous sulhide has been decomposed and the contents of ie converter consist of metallic copper; any nall quantity of slag which may be on the irface is removed by turning down the vessel id skimming off. The metallic copper is ien poured by tilting the converter. As the ags produced in the operation contain a certain nount of copper they are resmelted in the rnace in which the matte was produced in the st place As soon as the copper has been oured, the converter is ready to receive another large, and the operations are repeated. When veral charges, generally 5 to 10, have been put rough (the number depending upon the nature the material of which the lining is formed and the care exercised in ramming it into place), the lining becomes too thin for further use; the converter is therefore removed to the relining department by means of the crane, the old lining is taken out and a fresh one put in, when,

Owing to the frequency of this relining necessary in the acid converters, basic lined converters have been introduced, magnesite bricks being used for this purpose The silica which is necessary to flux off the oxide of iron formed by the oxidation of the iron sulphide in the matte, is charged into the converter in the form of diled silicious ore. Very large basic lined converters are now being used and the method of working varies somewhat from that used in the case of acid lined converters. The copper from a previous charge having been poured, 30 to 40 tons of matte may be poured into the converter followed by about 3 tons of silicious ore which may itself be cupriferous. The blast is then put on and the converter slowly turned until the tuyères are below the level of the matte For the first few minutes a blast pressure of only 5 lbs is used, and after the matte and silica have thoroughly intermingled, the blast pressure is increased to about 12 lbs. per square inch. When the silica has been fluxed by the iron oxide, the converter is turned down and the slag poured off A further charge of 6 to 7 tons of matte and sufficient silicious ore are now added and the blow is resumed removal of slag and additions of matte and ore are continued until sufficient white metal or cuprous sulphide has accumulated in the converter to be blown to metal in the usual way

Another method for the production of metallic copper from the matte is conducted entirely in reverberatory furnaces, and is some-times employed where the output does not justify the more expensive converter plant previously described. In this method working, the first stage, viz. the removal of the iron sulphide of the matte by oxidation of its constituent elements, is effected by smelting the material with a proper proportion of calcined matte together with silica sufficient to form a silicate of iron slag with the iron oxide; or the matte may be smelted with oxidised copper ore, silica being also present. In either case, the result is that the iron sulphide is decomposed, the sulphur passing from the furnace as sulphur dioxide, and the iron forming, with the added silica, a slag, which is removed. The contents of the furnace at this stage consist chiefly of cuprous sulphide, Cu.S. Currents of heated air are directed over the surface of the molten bath. with the resulting formation of cuprous oxide and the concurrent reaction between this and the unchanged cuprous sulphide results in the production of metallic copper, in accordance with the equations previously set out. When this reaction has extended to the whole contents of the furnace, the heat is raised and the metallic copper is tapped out into moulds

III Refining—The method of treatment to be adopted in this operation depends upon whether (a) the copper is practically free from gold and silver and from deleterious elements; (b) the copper contains appreciable quantities of gold and silver, or contains undue quantities of

deleterious elements.

If the metallic copper produced by the operations previously described under I and II comes under the description (a) above, it can be refined by furnace treatment only; if it comes under (b) it must be refined electrolytically in order to recover the gold and silver or to obtain it free from the impurities.

Under (a), the furnace employed is of the reverberatory type, and the removal of the impurities is effected by slowly melting the pigs of copper under highly oxidising conditions, and maintaining the bath of molten copper under this condition until the impurities are oxidised and removed, either by volatilisation or by passing as oxides into the copper silicate slag formed. The oxidation of the impurities is facilitated by the fact that metallic copper has the property of dissolving a small proportion of cuprous oxide, which compound is brought into contact with the elements to be oxidised under the very favourable condition of fluidity.

The oxidising condition of the bath of molten copper is maintained until the impurities are removed, as far as practicable, and the copper contains a maximum quantity of dissolved cuprous oxide. In this condition the metal is said to be 'dry'. After removal of the slag, the next stage consists in reducing the greater portion of the dissolved cuprous oxide, which is effected by depressing poles of green wood below the surface of the bath of metal, when considerable agitation takes place and the cuprous oxide is subjected to the reducing action of the gases given off by the pole

The process is continued until only a small quantity of cuprous oxide remains, and the copper attains the physical condition known as tough pitch, when it is ladled out into moulds

of any required shape.

Under (b), the copper is refined electrolytically. This process depends for its operation upon the fact that if an electric current is caused to pass through a solution of copper sulphate, the copper in the solution is deposited at the cathode, while the acid is set free at the anode If the anode is composed of metallic copper, then the acid set free on its surface immediately dissolves an equivalent portion of copper which passes into solution, and is, in turn, deposited at the cathode, and the process thus becomes continuous so long as the current passes and there is copper at the anode to be dissolved. Assuming that the solution of copper sulphate is properly made up and maintained, and the voltage and current are suitably adjusted, then only copper will be deposited at the cathode, while the gold and silver and all the impurities contained in the copper anodes will either remain as insoluble slime, collected at the bottom of the vessel in which the operation is conducted, or will pass into the electrolyte. Gold, silver, and lead pass entirely into the insoluble slime; other elements, such as iron and nickel, pass wholly into the solution, and others again are to be found partly in the slime and partly in the electrolyte. cathode surface is, to start with, a very thin sheet of electro-deposited copper, and when-as the result of the operation-sufficient copper has accumulated upon its surfaces, it is removed from the bath and is ready for melting and casting into any required shape. In practice, a number of anode plates are hung in a lead-

lined wooden tank, and are suitably connected to the positive lead. Alternating with these anode plates are hung the cathode sheets, connected in parallel with the negative lead large number of tanks are connected in series, and the current is passed through the whole set of tanks. The electrolyte is caused to circulate through the whole series, and, after it has been in use for some time, a certain proportion must be removed regularly for purification. A quantity of anode copper remains undissolved, and when the tank is to be cleaned, this is taken out for remelting into anodes, the solution is run off, and the slime is removed. This latter is washed and dried, any large particles of copper removed by sieving, and the fine slime is then treated for the recovery of any silver or gold which it may contain

Copper flue dust. A considerable amount of copper may be carried forward in the waste gases from the furnaces and precautions are now taken to recover it. In modern well arranged plants, capacious flues and dust chambers are provided between the furnaces and the chimney for the deposition of the fine particles of ore carried forward, and for the condensation of copper fume, which is frequently arsenical. The Cottiell piocess of electrostatic precipitation of dust is sometimes used. The dust obtained is collected from time to time and retreated in reverberatory furnaces or is briquetted and smelted in blast furnaces.

Wet methods. Until recently these had a very limited application in the extraction of copper, but within the last few years have made remarkable strides, and extensive plants are now in operation in which new methods or modifications of the older methods are being used. The wet extraction of copper consists of leaching the ore either in its natural condition on after roasting and in a suitable state of subdivision, with a suitable solvent, in vats fitted with false bottoms and precipitating the copper from the solution thus obtained by suitable means.

Wet methods are specially suitable for the treatment of low grade oxidised ore and for oxidised tailings, but have also been successfully applied to the treatment of material containing the copper as sulphide. The most widely used method consists in leaching the ore with dilute sulphuric acid and recovering the copper from the solution by electrolysis or by precipitation on metallic iron. This method can be applied directly to oxidised ores, but in the case of sulphide ores a preliminary roast, in order to render the copper soluble in the acid, is frequently necessary.

At Rio Tinto the massive cupriferous pyrites is treated without roasting, large heaps of the mineral being allowed to oxidise slowly under the action of air and moisture, and the copper sulphate thus formed is washed out and precipitated on metallic iron. In some cases in which sulphuric acid leaching is followed by electrolytic deposition of the copper, the regeneration of sulphuric acid in the precipitation plant yields a solvent suitable for further leaching operations.

Another method used consists in roasting the cupriferous sulphide material with salt. Soluble copper salts are thus formed which may be recovered by solution and precipitation of the

copper on iron. A modification of this process is also used whereby silver is recovered with the

Other processes are sometimes used in which sulphurous acid, ferric sulphate, ferrous chloride and ammonia are used as solvents  $C \cup B$ 

#### COMPOUNDS OF COPPER.

Five oxides of copper are said to be Oxides. known: the quadrantovide Cu4O, the trientoxide Cu<sub>3</sub>O, the sub- or hemi-oxide Cu<sub>2</sub>O, the monoxide Other oxides CuO, and the peroxide CuO<sub>2</sub> have been described, but their existence is not proved

Copper quadrantoxide is stated to be formed by adding a solution of copper sulphate to a cooled dilute solution of stannous chloride in caustic potash (Rose, Pogg Ann. 1861, 120, 1) It is an olive-green powder, which rapidly absorbs oxygen from the air. According to Moser (Zeitsch anorg Chem 1909, 64, 200), this product is really a mixture of cuprous oxide and copper.

Copper trientoxide is obtained as a hard yellowish mass by heating cupile oxide at 1500°-2000°. It is unaffected by any acid except hydrofluoric (Bailey and Hopkins, Chem

Soc Trans 1890, 269)

Copper suboxide, or hemioxide, red oxide of copper, cuprous oxide  $\mathrm{Cu}_2\mathrm{O}$ , occurs native as cuprite or red copper ore, and as chalcotrichite

It may be prepared (1) by heating finely divided copper in an below a red heat, (2) by gently heating a mixture of 5 parts cuprous chloride and 3 parts sodium carbonate in a covered crucible, and separating the oxide by lixiviation; (3) by reduction of an alkaline solution of a copper salt by sugar or certain other organic bodies, as in Barreswil's (Fehling's) solution, (4) by heating in a covered crucible a mixture of 5 parts copper monoxide and 4 parts copper filings, (5) by the electrolysis of copper sulphate solutions under certain conditions (Miller, J. Phys. Chem. 1909, 256, Gillett, *ibid.* 1909, 332); (6) by heating cupric oxide in sulphur dioxide and treating the product with water, when cupric sulphate is dissolved and the  $3CuO + SO_2 = Cu_2O$ cuprous oxide remains +CuSO<sub>4</sub> (Hammick, Chem Soc. Trans 1917, 111, 384)

This oxide is decomposed by most acids into a cupric salt and copper; hydrochloric acid, however, converts it into cuprous chloride

Cuprous oxide fuses at a bright-red heat dissolves in metallic copper and renders it brittle or 'dry' when present in quantity much as 4 6 p.c. has been found by Abel in very dry copper, and, according to Watson (J. Soc. Chem Ind 1883, 154), from 1 to 2½ p c is present in ordinarily good copper

It is largely used in the manufacture of ruby glass, and for the production of a red glaze on pottery (Louth and Dutailly, Mon Ceram et Verr 19, 237), and, together with the black oxide, forms one of the so-called copper paints

used for painting ships' bottoms

A yellow form of the oxide is produced by the action of alkali on cuprous chloride, or better by the reduction of a cupric salt by means of hydroxylamine in presence of alkali. It can also be prepared electrolytically, using an alkali sulphate as the electrolyte and an anode of pure

copper. It may also be obtained by the reduction of Barreswil's (Felling's) solution in presence of a deficit of tartrate. The yellow precipitate thus formed is not a definite hydrate, but is a colloidal form of the oxide with an indefinite amount of water (Groger, Chem Zeit. Rep 1902, 197). It quickly changes to an orange or brick-red colour and can then be dried unchanged. The dried product contains from 2-3 pc of adsorbed water. At a low red heat it loses this water and changes into the red crystalline form. The yellow cuprous oxide is to be regarded as a primary metastable form, the red crystalline form being the stable one. It is a powerful reducing agent, especially in ammoniacal solution. This solution, which is colourless, immediately becomes blue from the formation of the monoxide on exposure to the atmosphere, and thus forms a delicate test for oxygen. The hydrated oxide dissolves in a concentrated solution of magnesium chloride

This oxide is produced in Hoepfner's process for extracting copper from ores, &c , with cupric chloride solution. Cuprous chloride is formed and treated with alkali to obtain cuprous oxide (J Soc Chem Ind. 1893, 932, Eng Pat 18900,

1892).

Copper monoxide, cupric oxide, black oxide of copper, 'copper oxide' ('uO, occurs as metaconite' or black copper, especially at Lake

It may be prepared by heating the nitrate or carbonate to dull redness or the sulphate to intense redness. The decomposition of the sulphate is the basis of Adcock's process for the preparation of the oxide direct from the natural carbonate or sulphate (Eng. Pat. 11678, 1900) The copper oxide used for organic analysis, &c., may be prepared by moistening copper scale (the mixture of suboxide and black oxide obtained while working copper sheet, &c) with nitric acid, and igniting

An electrolytic method of preparing the oxide has been described by Miller (J physikal. Chem. 1909, 256), and by Luckow (Zeitsch.

Elektrochem 1897, 482).

Copper oxide is a black powder which agglomerates when heated, and fuses at the melting-point of copper, forming cuprous oxide, or Cu<sub>3</sub>O, according to the temperature. It can be made to crystallise in regular tetrahedra is slightly hygroscopic, especially when in powder When heated with organic substances or certain gases, it is reduced to metal. The metal produced by reduction in hydrogen always contains that gas, but if the oxide be reduced in formic acid vapour, the metal is quite free from hydrogen and is suitable for organic analysis (Weyl, Ber. 15, 1138).

It dissolves in acids with formation of cupric salts. In oils, &c, it is soluble to some extent, it is for this reason that copper cooking

vessels require such constant cleansing.

Copper oxide is used in ultimate organic analysis; to make green and blue glass and glazes, and to some extent as a pigment. It has also been used as one electrode of a galvanic cell (v Lelande and Chaperon, Bull Soc chim. [2] 49, 173).

Cupric hydroxide CuO H2O may be prepared by precipitating a solution of a copper salt by addition of alkali and washing rapidly.

When heated with water, it becomes black and amorphous.

A colloidal form of the oxide has been obtained by Paal and Leuze (Ber 1906, 1545), which gives blue-violet solutions, and when dry retains its solubility indefinitely.

The hydroxide is used as a blue pigment by paper stainers, but becomes green on exposure. It corresponds closely with certain of the highly basic carbonates sold as verditers According to Dumas, it is best prepared as follows: 6 parts of copper sulphate are dissolved in water and mixed with a solution of 3 parts of The clear liquid is decanted calcium chloride from the precipitated calcium sulphate and is mixed with 1½ parts of lime made into a cream with water. The greenish precipitate is collected, washed, and mixed with one-fourth its weight of slaked lime and as much pearl ash, and to render the colour more permanent, onefourth its weight of ammonium chloride and one-half its weight of copper sulphate are usually added.

The hydrated oxide dissolves in ammonia, the saturated solution in strong ammonia being known as 'Schweitzer's reagent,' or curpanimonium. This solution has the property of gradually dissolving cellulose with formation of a viscid solution which is used for the preparation of the 'Willesden papers,' and for the production of 'artificial silk' on the large scale. This process consists in injecting the coppercellulose solution into strong solutions of alkah or acid. In either case, coagulation takes place with formation of a fibre of cellulose corresponding in thickness to the diameter of the jet

An aqueous solution of sodium hydroxide of sp gr 1 345-1 370, or of potassium hydroxide of sp gr 1 453-1 498, will dissolve 0 78 grm of cupric hydroxide in 100 c c giving a bright blue solution which yields no precipitate when boiled If a more dilute alkali solution be used the solution is not stable when further diluted and subsequently boiled (Justen-Mueller, Compt rend 1918, 167, 779)

Cuprammonium solutions are prepared on the large scale by the joint action of oxygen and ammonia on metallic copper at temperatures near 0° (Schaefer, U.S. Pat. 884298, 1908, Bronnert, Frémery, and Urban, Eng. Pat. 1763, 1900. Leccour, Fr. Pat. 374277, 1906).

Bellot has patented a continuous process of manufacture, using a series of closed vessels (Fr Pat 335207, 1903).

The solution should be purified by dialysis, as the presence of crystalline salt favours its decomposition (Leccui, Fr. Pat. 362986, 1906). Addition of 1–2 p.c. of polyhydric alcohols, carbohydrates, gum, &c., to cuprammonium solutions increases their stability and prevents the deposition of cupile hydroxide (Friedrich, Eng. Pat. 4104, 1909), and the presence of such substances facilitates manufacture of the solution, making it possible to employ copper concentrations up to 5 p.c. without cooling (Fr. Pat. 399911, 1909).

Chattaway has shown (Proc Roy Soc. 1908, 80, A, 88) that by the reduction of a cuprammonium solution with aromatic hydrazines, copper mirrors can be deposited on glass

Dawson states that a solution of cupric hydroxide in ammonia contains copper as the Vol. II.—T.

base Cu(NH<sub>3</sub>)<sub>4</sub> (OH)<sub>2</sub> (Zeitsch physikal Chem 69, 110) (For a general discussion of the constitution of cuprammonium salts, see Horn and Taylor (Amer. Chem. J. 1904, 253), and Horn (tbil 1907, 475))

Copper dioxide, copper peroxide CuO,, is obtained by the action of hydrogen peroxide on cupire hydroxide in neutral solution at 0° (Kruss, Ber 1884, 17, 2593, Moser, Zeitsch anorg Chem. 1907, 54, 121) The crystalline precipitate is washed with water, alcohol, and ether at 0°, and dried in vacuo 1t has a yellow-ish-brown colour, and decomposes at 180°, forming cupire oxide

ish-brown coron, conforming cupric oxide

Salts Two series of copper salts are known, cuprous and cupric. The former are mostly insoluble in water, and are of but little commercial importance. They act as powerful reducing agents and readily pass into the cupric condition. Cupric salts are mostly soluble, and are of wide application.

Cuprous chloride Cu<sub>2</sub>Cl<sub>2</sub> may be prepared, amongst other methods, by boiling cupric chloride with hydrochloric acid and copper turnings. On addition of water it is precipitated in white crystals

Zuloaga has suggested (Rev Chim Ind. 1900, 107) that the cuprous chloride solution used in the extraction of silver from its ores should be prepared by mixing solutions of cupric sulphite and of cupric sulphate and sodium chloride

Cuprous chloude melts below a red heat into a yellow transparent mass—The dry crystals become yellowish on exposure to light, if moist, they acquire a dirty-violet tinge—Plates of copper coated with this chloude by the action of chlorine will take photographic impressions, but cannot be made to withstand exposure to light (v Carlemann, J pr Chem 63, 475; and Priwoznik, Dingl-poly J 221, 38)

Cuprous chloride combines with ammonia to form three compounds

Cu<sub>2</sub>Cl<sub>2</sub> NH<sub>3</sub>, Cu<sub>2</sub>Cl<sub>2</sub> 3NH<sub>3</sub>, Cu<sub>2</sub>Cl<sub>2</sub> 6NH<sub>3</sub> Cuprous bromide and rodide form compounds analogous to the last two (Lloyd, J. Phys. Chem.

The hydrochloric acid solution, when exposed to air, absorbs oxygen and acquires a brown colour, subsequently depositing a pale bluishgreen insoluble copper oxychloride

An identical substance used as a pigment, and known as Brunswick green, is piepaied by boiling a solution of copper sulphate with a small quantity of bleaching powder solution; or by moistening copper turnings with free exposure to air. It occurs in nature as alacamite

The use of the oxychloride in preference to the sulphate for destroying mould on vines, &c., is recommended 200-250 grams per litre of water are employed (Deletrez, J. Soc. Chem. Ind. 1909, 438).

When a solution of cuprous chloride in potassium chloride, acidified with hydrochloric acid, is treated with acetylene, a yellow precipitate of Cu<sub>2</sub>Cl<sub>2</sub> C<sub>2</sub>H<sub>2</sub> is formed Other compounds containing copper oxide or potassium chloride can be obtained by varying the conditions (Chavastelon, Compt. rend. 132, 1489).

Acetylene reacts with solutions of cuprous

2в

chloride in ammonia to form a blood-red precipitate of cuprous accipiede, which, on dehydration, has the formula Cu<sub>2</sub>C<sub>2</sub>, and is highly explosive (Scheiber, Ber. 1908, 3816). Its decomposition by acids has been used as a means of preparing pure acetylene A colloidal solution of copper acetylide has been prepared by Kuspert (Zeitsch anorg. Chem 34, 453) (v. ACETYLENE)

Cuprous bromide Cu2Br, is obtained by the union of its elements or by boiling a solution of cupric bromide with copper, and forms a

brown crystalline mass

Cuprous iodide is the only known iodide of copper, and is obtained as a white precipitate by adding potassium iodide to a solution of copper sulphate containing ferrous sulphate or sulphurous acid It has a sp gr 5 653 at 15° (Spring, Rec trav chim 1901, 79), melts without decomposition at 628°, and is practically insoluble in water.

Cuprous sulphite Cu<sub>2</sub>SO<sub>3</sub>,H<sub>2</sub>O is obtained in microscopic nacreous plates by passing sulphur dioxide into a hot solution of cuprous accetate in acetic acid It forms double salts with the alkalı sulphites Cupro-cupric sulphite Cu<sub>2</sub>SO<sub>3</sub> Cu<sub>2</sub>SO<sub>3</sub>,2H<sub>2</sub>O is a red microcrystalline powder.

Cuprous sulphate Cu<sub>2</sub>SO<sub>4</sub> can be prepared by the action of dry dimethyl sulphate on dry powdered cuprous oxide (Recoura, Compt rend 148, 1909, 1105) A compound of cuprous sulphate and carbon monoxide Cu<sub>2</sub>SO<sub>4</sub> 2CO, H<sub>2</sub>O has been obtained by Joannis (ibid 1903, 615), by reducing cuprammonium sulphate hydroxylamine. Péchard has made ammoniocuprous sulphate Cu<sub>2</sub>SO<sub>4</sub> 4NH<sub>3</sub> (ibid 1903, 504) Cuprous sulphide Cu<sub>2</sub>S occurs as chalcone or

copper glance It may be prepared by heating copper to redness in sulphur vapour, or by heating a mixture of copper and sulphur—It melts at  $1130^{\circ}$   $D_{4^{\circ}}^{25^{\circ}}$  5 785—It is dimorphous, and has an inversion temperature at 91°

Cupric chloride CuCl2 may be prepared as a fused, liver-coloured, anhydrous mass by heating copper in excess of chlorine In solution it may be prepared by dissolving the oxide in hydrochlone acid - It crystallises in grass-green prisms or needles containing 2 molecules of They become pale-blue when dried in The anhydrous salt is obtained on gradual addition of a large excess of cone sulphuric acid to a solution of the chloride (Viard, Compt. 1end 1902, 135, 168)

Cupric chloride is very deliquescent, and is soluble in alcohol When a small quantity of potash is added to the aqueous solution, a paleblue basic oxychloride 2CuO CuCl<sub>2,4</sub>H<sub>2</sub>O is precipitated It turns to a black anhydrous powder when heated, but again becomes green with absorption of 3 molecules of water when moistened. It is an intermediate product in the manufacture of verditer (v. Copper carbonates)

Cupric chloride is used in calico printing, in the manufacture of methyl violet, and for the oxidation of Cutch colours

Green has shown that the chloride is a very effective disinfectant (Zeitsch. für Hygiene),

1893, 495).

When cupric chloride solution is mixed with excess of potassium thiocyanate solution, cupric throcyanate Cu(CNS)2 is produced. This is slowly acted on by water and is ultimately reduced to cuprous thiocyanate CuCNS with formation of carbon dioxide, ammonia, carbamide, hydrogen cyanide, throcyanic and sulphune acids (Philip and Bramley, Chem Soc. Trans 1916, 109, 597

Cupric bromide CuBr, is obtained by dissolving cupric oxide in hydrobromic acid and evaporating in vacuô It is dark-coloured, very deliquescent, and, when heated, decomposes into cuprous bromide and bromine It is used as an intensifier in photography, and for that purpose is made by dissolving in water a mixture of anhydrous copper sulphate and potassium bromide (Akt Ges f. Andinfabr D R. P. 201168, 1907)

Cupric sulphate, Blue vitrol CuSO<sub>4</sub>,5H<sub>2</sub>O, occurs naturally at Copaquire, Chile, the rock containing over 12 pc of the hydrated salt (Walker, Eng and Min J 1903, 710) This salt may be prepared by dissolving copper or

its oxide in sulphuric acid

It is prepared on the large scale from metallic copper in the following way. Old copper plates from the sheathing of ships, &c, are heated to strong redness in a reverberatory furnace, and an excess of sulphur is thrown in and the doors are closed When combination is complete, the doors are reopened and the heat is raised to dull redness to oxidise the sulphide into sulphate mass, while hot, is thrown into dilute sulphuric acid, allowed to settle, the solution decanted, concentrated, and crystallised The sulphate so produced is of considerable purity copper and copper glance or other sulphurous copper ores are similarly treated Pauffin and Couvert have patented a process for the direct manufacture of the sulphate from the metal (Fr Pat. 399413, 1909) U.S. Pat. 788862, 1905) (See also Walker,

When much iron is present, as in most copper ores and especially in copper pyrites, it would be impossible to separate the copper and ferrous sulphates by crystallisation, because, although copper sulphate crystallises normally with 5 molecules of water, it forms, in presence of ferrous sulphate, crystals isomorphous with that salt and containing 7 molecules of water By carefully adjusting the temperature at which the sulphide is roasted, however, the iron salt may be converted into the oxide while the copper sulphate remains almost unaffected. The iron may be removed by heating the solution of the sulphates to 180° in a copper boiler under pressure Ferrous sulphate crystallises out and is filtered off (Gin, Fr. Pat 328800, 1903) Tho iron may be oxidised and thus separated from the copper by boiling the solution with a little nitic acid. It may also be precipitated as oxide by boiling with copper oxide, or by boiling with lead peroxide with subsequent addition of a little banum carbonate.

Crude copper or the ore may be roasted in air, and then treated with sulphur dioxide to form the sulphate (Gin, Zeitsch. angew Chem.

1903, 566; Eng Pat 5230, 1903)
Darier has patented a process in which cupric chloride is formed by the action of chlorine and water on the metal, and is then decomposed by sulphuric acid, with formation of the sulphate and regeneration of hydrochloric acid (Fr. Pat. 350421, 1904).

When the sulphate is required for purposes

where the presence of iron is not injurious, such liquors, or the mother liquors from which the purer salt has been separated, may be at once crystallised out, with the formation of crystals containing both iron and copper. Much of the 'agricultural copper sulphate' is of this class. The 'Sulzburg vitriol,' prepaied at Buxweiler, also contains both iron and copper. According to Lefort (Compt rend. 26, 185), it consists of CuSO<sub>4</sub> 3FeSO<sub>4</sub>,28H<sub>2</sub>O 'Cupram vitriol,' prepaied at Chessy from zinciferous copper ores, forms blue rhombic prisms, which contain according to Lefort, CuSO<sub>4</sub> 3ZnSO<sub>4</sub>,28H<sub>2</sub>O.

The copper may be separated from the ferrous mother liquors by placing them in vats containing iron plates upon which the copper is

slowly deposited.

Apparatus for the solution of copper oxide in sulphuric acid upon a large scale has been described by Coste (Fr Pat 392617, 1908) If copper be known to contain silver or gold, as is the case with that from the Harz, it is treated with sulphuric acid diluted with its own volume of water, the copper being thus dissolved while the silver and gold are unattacked

Argentiferous copper ones are roasted in a reverberatory furnace, and added in small charges to sulphuric and and digested until the solution contains but little free acid. The solution is then decanted from the precipitated lead and gold, and is concentrated and run into leadlined tanks containing plates of copper, upon which all the silver and part of the antimony and arsenic are deposited, while the greater proportion of the bismuth is precipitated as a basic sulphate, and the iron is reduced to the ferrous condition The liquor is then crystallised, the mother liquors being used for treating a fresh quantity of ore Copper sulphate is obtained of great purity and in considerable quantity in the refining of silver by precipitating it upon plates of copper from its solution as sulphate (v Silver)

An electrolytic process for the production of the sulphate consists in using a solution of sodium sulphate and copper electrodes, a current of carbon dioxide being passed through the liquid. Copper is dissolved from the anode as sulphate, while sodium carbonate is produced at the cathode. These react, regenerating sodium sulphate and precipitating copper carbonate, which is collected and dissolved in sulphuric acid (Kroupa, J. Soc. Chem. 1nd. 1906, 78)

Palas and Cotta have also described electrolytic processes for the production of the salt (Eng. Pat. 9806, 1899, and 17485, 1900)

(Eng Pat 9806, 1899, and 17485, 1900)
The electrolytic production of the sulphate from 'coment copper waters' has been described by Rambaldini (Chem. Zentr. 1909, 1–1675).

It is stated that copper sulphate is sometimes adulterated with ferrous sulphate and Prussian blue to the extent of 90 pc (J. Soc Chem. Ind. 1900. 84)

Copper sulphate crystallises in large transparent blue, doubly oblique rhombic prisms of sp gr 2 28, of the formula CuSO<sub>4</sub>,5H<sub>2</sub>O. According to Poggiale, their solubility in 100 parts of water is:

10°C.  $20^{\circ}$ 30° 40° 50° 36 59 42 31 48 81 56 9 65 83 80° 90° 70° 100° 203.32 156.44 94 60 118.0

When heated, it loses 2 molecules of water at 30°, 2 more at 93°–98°, and at 232° becomes anhydrous, white, and hygroscopic, and combines with water with considerable evolution of heat. At 341° the anhydrous salt begins to decompose (Wanjukow, Chem. Zentr. 1909, if 1124). The sp.gr. of the anhydrous salt is 3606 (Thorpe and Watts). It combines with water in alcohol and other organic liquids with production of a blue colour, and may be used for ascertaining the presence of water in those substances, but the test is not delicate. The anhydrous salt is also soluble in anhydrous methyl alcohol, and produces a blush-green solution (Klepl, J. pr. Chem. 1882, 25, 520)

Copper sulphate absorbs hydrogen chloride with evolution of heat, forming cupit chloride and liberating sulphuric acid—It is therefore used to remove hydrogen chloride from such gases as chlorine or carbon monoxide—A similar

reaction occurs in solution.

When mixed in solution with molecular proportions of potassium and other sulphates, it produces well-defined, crystalline double sulphates. Several basic sulphates are known

The sulphate is the most important of the copper salts. It is largely used in calico printing, principally in connection with potassium dichromate or iron mordants, in black dyeing with logwood, directly or indirectly for the preparation of most pigments containing copper, and to prevent rot in timber. In agriculture the crude sulphate containing ferrous sulphate is used to a considerable extent to prevent smut in seeds. The seeds are soaked for some hours in a weak solution of the sulphate, and are sown within 24 hours.

A 10-20 pc solution of copper sulphate, preferably mixed with lime, is applied to vines with great benefit. A small quantity is found in the vines and must, but the tannin and sulphur introduced before fermentation appear to remove it in most cases.

Kaisten has stated (v. J. Soc. Chem. Ind. 1896, 367) that attacks of illness resembling dysentery have been caused by a wine which contained copper in such quantity as to give a visible deposit on steel in 12 hours. Its presence was due to spraying the vines with a copper salt.

An effective wash for vines is prepared by boiling 25 parts of sodium carbonate and 25 parts of resin in 100 parts of water, and then diluting and adding copper sulphate (J. Soc. Chem. Ind. 1899, 155)

Copper sulphate is used in preparing copper ferror yande, a solution of which, in potassium citrate solution, is used as a toning-bath for photographs (Ferguson's Copper Toning, ibid. 1900, 465),

Copper sulphate is also used in dyeing to make diazo-colours permanent to light. The dyed fabric may be treated with the salt (Graebling, ibid. 1905, 797), or it may be added to the diazotising bath (Grossmann, Farber-Zeit 9, 328)

Cupro-tetrammonium thiosulphate  ${\rm CuS_2O_3}$   ${\rm (NH_3)_4}$ , has been proposed as an ingredient of detonator compositions, which although less sensitive are alleged to possess advantages over mercury fulminate compositions, as being cheaper, less unhealthy, simpler, and less dangerous to manufacture. The thiosulphate is

made by adding excess of strong ammonia solution to a hot saturated solution of copper sulphate, and thereafter adding an equivalent amount of sodium thiosulphate, dissolved in The salt separates out as the soluhot water tion cools; it is washed with a weak solution of ammonia, and dried at a temperature not exceeding 50° The violet-blue crystals are slightly soluble in water, not hygroscopic, insensitive to light, and very stable positions suitable for various purposes are made by mixing with potassium chlorate, powdered glass, antimony trisulphide and lead thiosulphate (Herz, Zeitsch ges Schiess u Spieng-stoffw 1912, 7, 284; J. Soc Chem Ind 1912, 31, 903)

Potassium copper nitrite K<sub>3</sub>Cu(NO<sub>2</sub>)<sub>5</sub> 18 obtained by mixing cold saturated solutions of copper sulphate and potassium nitrite, adding methyl alcohol, filtering, and adding ethyl acetate to the clear, green filtrate when long crystals of the salt separate Rubidium copper nitrite of similar composition may be obtained In like manner (Kurtenacker, Zeitsch anorg Chem 1913, 82, 204). Basic copper nutrites  $3\mathrm{Cu}(\mathrm{OH})_2\,\mathrm{Cu}(\mathrm{NO}_2)_2$  and  $2\mathrm{Cu}(\mathrm{OH})_2\,\mathrm{Cu}(\mathrm{NO}_2)_2$ 

are also known

Cupric natrate Cu(NO<sub>3</sub>)<sub>2</sub> may be prepared by dissolving copper or the oxide or carbonate in nitric acid. The solution at temperatures above 20° deposits dark-blue crystals containing 3 molecules of water, which melt at 1145° and boil at 170° with evolution of nitric acid and formation of a green basic salt. This basic salt formation of a green basic salt may also be prepared by boiling the solution of the nitrate with copper or copper hydrate, or with a little alkalı (v. also Copper carbonates for an application of the basic mitrate)

The anhydrous salt may be obtained by the action of nitric anhydride on the hydrated salt It is a white, deliquescent powder, decomposing at 155°-160° (Guntz and Martin, Bull Soc chim

1909, 5, 1004)

Copper nitrate is used to a slight extent in dyeing and calico printing, and a solution, prepared by mixing solutions of copper sulphate and calcium nitrate, is used in viticulture (Gouthière et Cie and P Ducancel, Fr Pat. 395806, 1908)

Cupric sulphide CuS occurs as covelite or ındıgo copper in blue flexible plates, in Vesuvian lava, in Chile, and in the copper-mines of Mansfeld It may be prepared by heating cuprous sulphide with sulphur at a temperature not above the boiling-point of sulphur, by digesting cuprous sulphide with cold strong nitric acid, or by precipitating a copper solution with sulphu-

retted hydrogen  $D_4^{25}$  4 68. On the large scale it is obtained as a paste by precipitating a solution of the sulphate with sodium sulphide. This paste is used in calico printing for the development of anılıne black

The preparation and use of copper sulphide for thermo-couples has been described (Eng Pat 11300, 1905).

Rieder has used (Zeitsch. Elektrochem 1902, 370) an electrolytic method for the pre-

paration of this compound

A brownish-red persulphide of copper has been obtained by Bodroux by adding a solution of calcium pentasulphide to a solution of copper acetate at 0° (Compt. rend. 130, 1397).

Copper acetate v. Metallic acetates, ACETIC ACID.

Copper arsenite v. Scheele's green. ait. ARSENIC.

Cupric phosphate is of no technical interest. A bulliant green colour containing a basic phosphate, prepared by heating a mixture of copper acetate, sodium phosphate, and ammonia, has, however, been used in calico printing (Bourcart, Mon Sci [3] 4).

Phosphorus combines in several proportions with copper, and produces true alloys, which in

many cases are of great value.

Heyn and Bauer state that the phosphorus exists in the alloy as Cu<sub>3</sub>P and Cu<sub>5</sub>P<sub>2</sub> (J Soc. Chem. Ind. 1906, 1047) The latter compound has been obtained by Rubénovitch by the action of phosphine on copper sulphate (Compt rend 127, 270)

Copper silicide (Cuprosilicon) CuaSi is obtained when copper and silicon are heated together in the electric furnace (Vigouroux, Compt 1end 1896, 122, 318, Lebeau, sbid. 1906, 142, 154) It is now manufactured in Germany and America by this process (Steinhart, Eng and Min J 1899, 67, 710), and is used for purifying and hardening copper, and for adding to tin- zinc-, and aluminiumbronzes to increase their tensile strength and hardness

Cuprosilicon can be prepared pure by heating together 17 parts silicon and 9 parts copper in hydrogen, and removing the excess of silicon by solution of sodium carbonate. It is silverwhite, with a metallic lustre, and is haid and The sp gr is 758, and it is attacked by chlorine and aqua regia (Vigouroux, Compt. 1end 1906, 142, 87, see also Philips, Métallurgie, 1907, 4, 587, and Lebeau, ibid 141, 828)

Copper carbonates. The normal salt has not been prepared, but several basic carbonates are known, and used as blue and green pigments Basic copper carbonate occurs native as malachite Cu(HO)<sub>2</sub> CuCO<sub>3</sub>, and as azurite or chessylite Cu(HO)<sub>3</sub> 2CuCO<sub>3</sub> When ground, these minerals

form a fine but expensive pigment

An anhydrous basic carbonate is precipitated on addition of a solution of sodium carbonate to a hot solution of copper sulphate or nitrate. (For a complete description of all the known basic carbonates of copper, see Pickering, Chem Soc Proc 1909, 188 Cf Dunnieliff and Lal, Chem Soc. Trans. 1918, 113, 718) Commercial basic carbonates of copper differ considerably in composition: the amount of carbon dioxide present is below that required for malachite or azurite. A definite basic salt is known of the composition 2CuCO<sub>3</sub>,5Cu(OH)<sub>2</sub>.

Under the names Verditer green, Verliter blue, Bremen green, and Bremen blue, this salt is largely prepared for paper staining, &c According to Habich (Technologiste, 17, 413), the following processes are in use. A hundred parts of old copper sheathing from which impurities, oxide, &c, have been removed by digestion in dilute sulphuric acid, is cut into pieces and mixed with a paste formed by moistening a mixture of 99 parts potassium sulphate and 100 parts common salt, and the mixture is stirred occasionally for some months to ensure thorough exposure to the atmosphere The action appears to consist in the production of cupric chloride,

which, in presence of the metal, becomes converted into a basic chloride, and finally, by the action of the oxygen, into an oxychloride. the oxidation be incomplete, the subchloride is not completely oxidised, and, as it, when subsequently decomposed by alkali, gives an orangered precipitate of suboxide, the pigment would be lowered in value. The oxychloride may also be similarly prepared from a mixture of 100 parts copper, 60 parts common salt, and 30 parts strong sulphuric acid diluted with three times its volume of water; or by treatment, with free atmospheric exposure, of copper with a solution of cupric chloride in hydrochloric acid.

To 100 kilos. of this thick magma of oxy-

chloride, which has been washed by decantation, a concentrated solution containing 7 kilos copper sulphate and 40 kilos concentrated soda solution (32°-36°Bé) is added. The mixture is vigorously stirred and poured at once into 150 kilos of soda solution (20°Bé.). The precipitate is washed, passed through a fine hair sieve, and dried spontaneously or at a temperature below 25°. If hot air be used in the drying, it must be quite free from acid or sulphin gases produce the finest colour, desiccation must be perfect

Habich recommends the following process for making a verditer which has a very different composition from the above A solution of copper oxide in nitric acid is treated with potassum carbonate, which is added in portions until most, but not all, the copper has been preci-The green precipitate is washed and introduced into a solution of copper nitrate whereby it is converted into a heavy green insoluble basic nitrate. This is digested in a solution of potassium zineate (formed by dissolving zinc in caustic potash solution) A dark-blue pigment, of great 'body' but little weight, is thus produced It contains zinc and copper, apparently combined as a double oxide or as 'copper zincate,' and a small quantity of basic

copper nitrate

Verditer may be prepared by agitating a solution of copper nitrate with chalk. The washed pasty precipitate is mixed with 8-10 p c. of freshly burnt lime with production of a fine The precipitate without velvety blue pigment

addition of lime is green

According to Gentele, the following process adonted at Bremen, Cassel, &c; 225 lbs is adopted at Bremen, Cassel, &c; 225 lbs sea salt and 222 lbs blue vitriol, both free from iron, are mixed dry and ground between millstones with water to a thick paste paste is mixed in strata with 225 lbs of clean copperplate cut into pieces about 1 inch square, in wooden chests made without nails, and the mixture is digested for about 3 months with the maximum exposure to air, the whole being well mixed and exposed about once a When the action is complete, the undissolved metal is removed and the precipitate is washed with a minimum of water, filtered and thrown into a tub To 180 lbs of the magma 12 lbs of hydrochloric acid (13°Bé) is added, and the mixture is stirred and left for 24 or 36 hours. Six volumes of this solution is mixed with 15 volumes of caustic alkali (19°Bé) followed after an interval by 6 volumes of water. The mass is well mixed and left for 36-48 hours, and is then well washed by decantation, filtered,

exposed for some time in a moist condition to the air, and finally dried (v. also Copper monoxide'

COPPER-GLANCE or Chalcocite, Native cuprous sulphide Cu<sub>2</sub>S, crystallising in the orthorhombic system. Excellent twinned crystals were formerly found in abundance in the neighbourhood of Redruth in Cornwall (hence the name redruthite) and Bristol in Connecticut, usually, however, the mineral is found as compact masses. It is iron-black with metallic fustre, but, on exposure to light, it soon becomes dull with a powdery black coating It is soft (H 2½) and sectile, and can be readily cut with a knife; sp gr 5.7 It occurs in veins of copper ore, and is often of importance as an ore, especially when it contains small amounts of Isomorphous with copper-glance is the mineral stromeyerite (Ag, Cu)2S, which has been found in considerable quantities in the Altai Mountains in Siberia

COPPER PAINT v COPPER

COPPER PYRITES or Chalcopyrite. A sulphide of copper and iron CuFeS<sub>2</sub>, containing when pure 34.5 p.c. of copper, and the most important of the ores of copper It has a characteristic brassy-yellow colour with metallic lustre, and on the surfaces often displays a brilliant iridescent tarnish (peacock-copper-ore). It often occurs together with, and intimately intermixed with, iron pyrites, from which it can be distinguished by its deeper colour and lower degree of hardness, copper pyrites (H  $3\frac{1}{2}$ -4) is readily scratched with a knife, giving a greenishblack powder, whilst iron pyrites (H. 6-6½) is scratched only with difficulty or not at all It occurs in mineral-veins and in bedded deposits, and by its alteration gives rise to many secondary copper minerals Crystals are tetragonal with inclined hemihedrism, but only rarely are they distinctly developed, sp gr 4 2 L. J. S.

COPRA and COPRA OIL v. COCO-NUT

COPROLITES. Concretionary mixtures of calcium phosphate and calcium carbonate, derived from the excrements of certain extinct fishes and reptiles Formerly much used in the manufacture of superphosphate of lime (v FERTILIZERS)

COPROSMA. The bark, and more especially the roots, of the C grandiflora, C linariifolia, and C areolata, which belong to the natural family of the Rubiaca, and are widely distributed in New Zealand, possess tinctorial property (Aston, New Zealand, J Sci Tech 1918, 1, 3), and being related to madder probably contain either alizarin itself or an allied colouring matter. Thus an alcoholic extract of the C grandiflora is coloured purple by alkali, and becomes yellow on addition of acid. From the acid solution, by means of ether, an orangeyellow crystalline substance can be isolated in small amount

COPYING or INDELIBLE INK PENCILS. Unlike iron-gall copying-inks, which will only yield good copies for a relatively short time after writing, solutions of aniline dyestuffs produce writing from which copies may be taken at any subsequent period. In copyingink pencils the aniline dyestuff, usually methyl violet, is incorporated with graphite, kaolin clay or other basic material. The preparation of pigments for this purpose was claimed by Petit (Eng. Pat. 4090 of 1874), and their composition was first described by Viedt (Dingl. poly J 1875, 216, 96) At the present time these pencils are seldom employed for copying purposes, and then chief use is as a substitute for ink, since they produce a writing which cannot be erased so readily as the marks of a lead pencil Hence they are frequently described as indelible pencils, although the description is only relatively correct Lehner (Ink Manufacture, 1902, p 125) gives the composition of four kinds of these pencils made by Faber in Bayaria aniline dyestuff ranged from 255 to 50 pe, graphite from 24 5 to 37 5 pc, and kaolin clay from 12 5 to 50 p c

Specimens of these pencils examined by Mitchell (Analyst, 1917, 42, 1) had the following composition .-

Origin	Mois- ture	Residue insol, in water or alcohol	D <b>y</b> est uff	Loss on ignition (gra- phite, &c )	Ash (kaolin, &c)

Pigments used in copying-ink pencils may be classified into four main groups-viz (1) those composed of graphite and dyestuff only, (2) those in which the dyestuff has been incorporated with approximately equal proportions of kaolin and graphite, (3) those in which the kaolin is largely in excess; and (4) those in which the graphite predominates The dyestuff is usually methyl violet, but copying-ink pencils in which red or blue aniline dyes are used are also sold

The copying properties depend not only on the proportion of the dyestuff, but also on the influence of the basic material. Pencils in which a large proportion of alumina is present yield only faint copies, even when the pigment contains a large amount of the dyestuff Although methyl violet is usually regarded as a very fugitive dyestuff, experiments have shown that under certain conditions the writing done with these pencils is more permanent than writing done with ordinary ink

C A M CORAL is the calcareous substance secreted by many varieties of five kinds of organisms, viz. (1) Actinozoa, the principal constituents of coral reefs, (2) Hydrozoa, the large common corals known as millepores; (3) Bryozoa, delicate corals in various forms, resembling mosses, branches, thin filamentary deposits, or

lowly organisms, mostly of very minute size; (5) Nullipores, which, although closely resembling millepores, are veritable algae or sea-weeds; they may be readily distinguished from the millepores by the absence of perforations

Coral is simply a secretion corresponding to the bone of vertebrates or the shell of mollusca, and is composed almost entirely of calcium carbonate derived from sea-water and from the food of the coral-making polyps

Ordinary coral is somewhat harder than . limestone or marble, and, when tapped with the hammer, gives out a ringing sound clearer than is clicited from ordinary calcium carbonate. The sp gr of 15 specimens examined by Silliman, averaged 2 523

Small and variable quantities of magnesium carbonate, calcium sulphate, calcium fluoride, alkaline chloride, silica, and oxide of iron are found in corals

The red coral, Corallium subrum, varies in colour from crimson to rose, the latter being the rarest and, therefore, the most prized It is gathered from the rocky bottom and shores of the Mediterianean, and it occurs most abundantly at a depth of 25-50 feet, although, according to Dana, it may be found as deep as 1000 feet Forchhammer found 2.1 pc magnesia in Corallium rubrum, and 6 36 in Isis According to Trommsdorff, the red pigment of coral is a resin soluble in oil of turpentine, and, after removal from the coral by this solvent, is easily soluble in alcohol and ether, but insoluble in caustic potash. In a red madrepore, Vauquelin found a red colouring matter, which was turned violet by alkalis. Moseley has described in some corals and allied organisms a red colouring matter (Polyporphyrin) which is insoluble in water, glycerol, alcohol, ether, and in strong solutions of ammonia and potash It is soluble in moderately strong sulphuric, nitric, or hydrochloric acids. For the formation and distribution of coral and coralreefs, &c v Corals and Coral Islands, J. D Dana: more solid masses (in the Palæozoic limestone formations this species of coral abounds); (4) Edinb 1880, 505 See also Forchhammer, Foraminifera, chambered shells belonging to J Pharm. Spencer, 1904.

It is now known that the materials constituting coral-reefs sometimes undergo remarkable chemical changes, and that the calcium carbonate is largely replaced by magnesium carbonate or calcium phosphate. In 1846 J D Dana and B. Silliman showed that the rock of an upraised coral-reef in the Pacific contained as much as 38 pc. of magnesium carbonate. The deep boring made in the Atoll of Funafuti in 1897-8, yielded a series of cores, of which a chemical examination was made by E W Skeats and Hart Smith in the laboratories of the Royal College of Science It was found that down to the depth of 637 feet dolomitization had only gone on to a small extent, the proportion of magnesium carbonate never exceeding 16 pc, but the lower portions of the core were very nich in the magnesium salt, containing from 30 to 43 pc, the rock thus becoming almost a true dolomite A large collection of coral limestones obtained by Alex Agassiz, from reefs in the Pacific, was subsequently examined by Skeats, who showed that they contained varying amounts of magnesium carbonate up to nearly 42 pc Specimens from Christmas Island in the Indian Ocean gave similar varying results, percentages of magnesium carbonate up to over 43 p.c. being found A coral limestone obtained by boring at Key West, Florida, yielded to G Stieger, in the laboratories of the U.S. Geological Survey, over 14 p c of magnesium carbonate

Coral reefs that have been covered by deposits of guano are found to have their carbonates largely replaced by phosphates Thus the rocks of the coral reef known as Christmas Island in the Indian Ocean have been largely worked for the deposits of calcium phosphate, and Teall has shown that Clipperton Atoll in the North Pacific contains rocks with as much as

38½ p.c. of phosphotic acid (For changes in the chemical composition of coral rock, see Dana and Silliman, Amer J Sci 2, 1 1846, 189; Judd, Chemical Examination of Materials from Funafuti in 'the Atoll of Funafuti,' Phil Trans 1904, 362-389, Skeats, The Chemical Composition of Limestones from Upraised Coral Islands, Bull Mus Comp Zool Harvard, vlu 1903, 53-126, Teall, Quart Journ Geol Soc liv 1898, 230-232)

CORALLIN, CORALLINPHTHALIN, PHE-NOLCORALLIN v AURIN

CORDIALS and LIQUEURS are spirituous compounds flavoured with essences obtained from fruits, herbs, spices, or other substances, usually sweetened with sugar or glycerol, and often strongly coloured They are manu factured and used to a much greater extent in France and other European countries than in the United Kingdom, and although there is no essential difference between them, the term 'cordials' is by many restricted to British, and 'liqueurs' to the foreign preparations.

The spirit in the best qualities of liqueur is derived from the grape, but grain and other spirit is frequently employed, especially in cordials; but, whatever the origin of the spirit, it should be highly rectified and neutral in character, so as not to impair the flavour of the finished product. The alcoholic strength of cordials and liqueurs varies greatly, but, on the average, they contain from 30 to 40 p.c. of alcohol, or 50 to 70 p c. of proof spirit. The sugar must be pure, and is added in the form of a

clear syrup.

The principal flavouring ingredients employed are (a) those used solely on account of their essential oils, as aniseed, bitter almonds, caraway, juniper berries, mint, lemon-peel, orange blossom, &c; (b) those valued for their bitter principles as well as their essential oils, as cinnamon, cloves, curaçoa apples (a kind of orange), gentian, ginger, orange-peel, sweet calamus, wormwood, vanilla, &c, and (c) fruits, chiefly cheries, pineapples, raspberries, and strawberries. The flavourings are obtained either by digesting the flavouring ingredients (bruised or cut up) with alcohol and distilling the mixture to obtain an essence, or by filtering the alcoholic extract to form a tincture, or by simply expressing and clearing the juice of fruits or digesting the latter for a more or less prolonged period in spirit

Artificial essences simulating the above flavourings are frequently employed, but their use in beverages is questionable, since it seems probable that their physiological action differs from that of the natural flavouring substances

which they are intended to imitate.

The colouring matters most commonly used are as follows "Red, amline red, brazilwood, cochineal, cudbear, and sandalwood, yellow, saffron and turmeric, blue, indigo, chlorophyll (from nettles, parsley, spinach, &c) and mixtures of blue and yellow colourings, violet, and brown, a solution of buint sugar or caramel (v Liqueurs)

CORDIERITE v IOLITE

CORDITE v Explosives.

CORDYLITE (or Barium-parisite). Carbonate and fluoride of cerium-metals and barium (CeF)<sub>2</sub>Ba(CO<sub>3</sub>)<sub>3</sub>, containing Ce<sub>2</sub>O<sub>3</sub>, 23 72, and (La,Di),O<sub>4</sub>, 25 67 p.c. It occurs as small, pale wax-yellow, club-shaped hexagonal crystals in syenite-pegmatite at Narsarsuk near Julianehaab in south Greenland, sp gr 431 It is isomorphous with, and closely iclated to, parisite.

CORIOFLAVINE v ACRIDINE DYESTUFFS. CORIOPHOSPHINES v ACRIDINE DYESTUFFS. CORK. Cork is derived from the bark of two evergreen species of oak tree, the cork oak, Quercus suber (Linn) and Q occidentalis (Gay) The former yields the best cork, and grows mostly in those countries bordering on the Mediterranean up to the 45° lat The latter occurs on the Atlantic seaboard of Portugal, Spain, and

France up to 48° lat

The cork tree is from 30 to 60 feet high, and 3-4 feet thick. It grows slowly and reaches the age of 150-200 years. The tree has the peculiarity of throwing off its outer bark when it reaches a certain age, and then reproducing it. It is this that makes the cork industry possible. The chief countries in which cork is produced are:

1 Spain Particularly the province of Catalonia Here the best cork is grown

Seville is the chief market.

2 Portugal Centres Lisbon and Oporto

3 Algeria Here the cork trees form great forests, those belonging to the State were some years ago fully 600,000 acres in extent

- 4 Southern France and the Pyrenean district Large forests of Q suber exist in the more mountainous parts, but in the low-lying 'Landes' the tree is Q occidentalis, which grows as far north as Belle Isle
- 5 The Adratic coast. Some is produced in the Austrian provinces, but it is of inferior quality.

6 Sicily, Sardinia, and Corsica also yield cork of good quality.

For an account of the cork industry in Sardinia, see J Chem Soc Ind 1919, 38, 352 R. From U.S. Com. Rep. July 25, 1919

Speaking generally, the cork tree seems to thrive best on dry granitic and sandy soils, and not to do well in damp or limestone soils

The complete bark of the cork tree consists

of two layers

(1) The dry dead bark, comprising the epidermis and the cork proper, with the meso-

(2) The green living skin which clothes the wood immediately under the dry back. This may be looked upon as the active cork-producing layer, and contains bast fibres and the endodermis

The epidermis on one-year-old twigs is green and smooth, but in the second year between it and the green under-skin irregular white waxy masses are formed, these represent the beginning of the cork formation and increase from year to year, changing gradually into cork proper. At the end of the third year the epidermis dries up and clacks

Barking the trees. This is the most important operation in the management of a cork forest, because on the care with which it is carried out depends the life of the trees and the

regularity of the slabs produced.

In barking, the workman takes a special tool and makes a cut round the stem above and below the portion of bark to be removed. A vertical cut or cuts are made so that the bark may be stripped off the tree, in which operation the shaft of the tool is used as a lever. Care must be taken not to bruise the green underskin, the real producer of the cork

The first barking produces so-called 'virgin cork,' which is of little value, as it has not elasticity enough for use as bottle corks. It was formerly used for the production of Spanish

black, but of late years it has been employed in the manufacture of ground cork.

During the first year of growth the tree produces from 3 to 5 mm. of cork, but afterwards less, the mean for the first 9 years being about 2 1-3 mm., giving a total thickness of 20½ mm. After 9 or 10 years, when barking usually occurs, the growth is slower, but where thicker cork is required, the period is of course longer. The first stripping usually takes place on the 15-20 year-old tree. The best cork is yielded by trees of from 50 to 100 years old. Those growing in the mountainous districts yield a smaller quantity but better quality of cork.

After the cork bark has been removed from the tree, it is stacked and weighted with heavy stones to flatten it, and when dry it is scraped with an iron tool to remove the epidermis. The cork is then immersed for 5 or 6 minutes in a tank of boiling water, when it swells, and, according to the quality, retains this swelling more or less permanently. The water also removes tannin, vegetable acids, and their salts. In Spain the cork is occasionally passed through a fire, whereby it is superficially blackened, acquiring, it is supposed, by this treatment especially good qualities or 'nerve'

After steeping, the plates are placed in heaps, weighted, and by hydraulic presses compressed

into bales and bound with hoop iron

Chemistry of cork. ('ork extracted with hot water under pressure, yields gallic acid, colouring matters, iron and magnesium salts. By extraction with alcohol it yields 'cerin,' or cork wax  $C_{32}H_{20}O$ . Siewert examined the alcoholic extract and isolated from it 'decaciylic acid'  $C_{10}H_{18}O_2$ .

The composition of cork has been further studied by Kugler (Arch Pharm 1884, 217), Gilson (*ibid* 1890, 690), and Hy Ingle (J Soc Chem Ind 1904, 1197)

Suberine, according to Kugler, is a real fat, which cannot be entirely extracted by solvents, because they do not penetrate the material

sufficiently

Gilson saponified cork from Q suber with 3 p.c. alcoholic potash, and isolated from the filtrate 44 p.c. of fatty acids, consisting of Phellonic acid  $C_{2\nu}H_{3\nu}O_{2\nu}$ , mp. 95°-96°, a monobasic acid giving a violet colour with zine chloude-nodine solution; yield 8 p.c. Suberinic acid  $C_{1\gamma}H_{3\rho}O_{3\nu}$ , a semi-fluid sticky substance; 36 p.c. Phlononic acid  $C_{12}H_{4\rho}O_{3\nu}$  fine white needles, m.p. 120°-121°; in small amount

Gilson considers suberine not to be a true fat, but rather a mixture of complex esters and possibly condensation products of different acids.

Treated with iodine solutions cork does not give the cellulose reaction, and there is some dispute as to whether cellulose or a pentosan is the carbohydrate present in cork. Gilson, from microscopic examination, considers that cellulose is present.

Cork also contains certain aromatic compounds, tannin and the aromatic aldehyde of wood, hadromal, besides coniferin and vanillin.

Treated with strong nitric acid, cork produces suberic acid (CH<sub>2</sub>)<sub>8</sub>(COOH)<sub>2</sub>, oxalic acid, and other products. Strong sulphuric acid charsit, but it is little affected by hydrochloric acid. Chlorine, bromine, and iodine cause cork to shrink, the two former first bleaching it—Ignited

it burns, swells up, and forms a charcoal called Spanish black

Physical properties—The sp gr of cork is variously given from 0 12 (Rollmann) to 0.24 (Muschenbroek), on the average 0 16

The uses of cork depend on its compressibility, elasticity, imperviousness to liquids, its lightness, its stability to weathering, &c It is used in making stoppers, mats, soles, linings, springs for heavy waggons, as anti-vibratory and sound-deadening materials

Waste cork is granulated by suitable machinery, sifted, and then ground to powder. The finest dust is mainly used in the manufacture of linoleum. Slightly coarse cork is used for the manufacture of cork carpet, but in both cases the binding material is prepared linseed oil.

Still coarser cork, of the size of peas, mixed with a proportion of fine, is employed in the manufacture of mats, insulating materials for water and steam pipes and cold storage chambers, packing, artificial corks for bottles, &c

In order to bind the particles of cork together are employed (1) collodion, used for bath mats and stoppers. The granulated cork of various grades in suitable proportions is mixed with the solution and the pasty mass pressed into perforated moulds, these are then heated in a suitable chamber provided with a condensing appliance to recover the solvents, ether and alcohol. 'Suberite' belongs to this class The mat is removed from the mould and 'buffed' (sand-papered) on a buffing machine similar to that used by cabinet makers. Cork stoppers are made in a similar manner, and also insulating slabs and tubes for covering steam and water pipes.

(2) Gluten, casem, and glue mixed with only materials and resins and dissolved in suitable solvents, after mixing with the cork (rendered more or less insoluble by means of formalin, tannin, dichromates, lime, &c), have also been used and patented for the production of cork slabs, &c, from granulated cork. The cork of various degrees of fineness is mixed with the cement, subjected to powerful hydraulic pressure in moulds, and in some cases heated up to 200° to harden the albuminous matters of the cement.

(3) Mixtures of cork with silicate of soda and barytes or other pigment have been used for steam-pipe coverings

Slabs of cork have also been made by soaking cork in soap solutions, then drying, treating with milk of lime, again drying and pressing the resultant mass into heated moulds

Another use for cork waste, more or less finely ground, is in the production of floor. In this operation ground cork is mixed with a cement, such as Portland cement, or more often a mixture of cork and calcined magnesia is mixed with a solution of magnesium chloride and the pasty mass spread on the floor and allowed to harden, other salts, such as lead acetate, are sometimes added

Cork dust is also used as a packing for the hollow spaces between the walls of cold-storage chambers, round the pipes of ice plants, &c, no binding materials being employed Mixed with pitch, granulated cork is used as the filling between the outer and inner soles of boots,

especially American. It forms a warm, water-proof and resilient layer

Granulated cork of various degrees of fineness is also mixed with the paint used to coat iron surfaces where there is danger of the condensation of moisture, such as in the cabins of steamers, in breweries, factories, laundries, and the like

CORROSION OF METALS. By the term 'coriosion'is generally understood the disintegration of a metal through oxidation. Usually a skin of oxide is formed which more or less protects the underlying metal from attack Copper, zinc, lead and aluminium are cases in point. Iron,1 on the other hand, is exceptional, in that, when oxidised by exposure to ordinary atmospheric influences, a pulverulent, hygioscopic mass of oxide, known familiarly as fust, is produced, which not only fails to protect the underlying metal, but actually accelerates further corrosion For this reason, and also because non is of such enormous commercial importance, the various problems associated with the corrosion of non have received wide consideration and been made the subject of numerous researches; only in very recent years have systematic attempts been made to investigate the corresivity of the other commercial metals

Corrosion of iron. It is impossible here to review or discuss the voluminous literature which has appeared on the subject during recent years, and for particulars, including bibliography, the reader is referred to Friend's Corrosion of Iron and Steel (Longmans and Co., 1911), and to The Corrosion and Preservation of Iron and Steel, by Cushman and Gardner (McGraw-Hill Book Co., New York, 1910)—It will suffice here to give a short account of the questions at issue

Conditions essential to the corrosion of non—Before passing on to consider the various theories that have been offered to account for the mechanism of corrosion, it is important to have a clear conception of a few of the fundamental facts. These may be briefly summarised as follows—

- I Liquid water, alone, both at ordinary temperatures and at the boiling-point, is without any appreciable action upon iron. In the course of time the metal frequently becomes very slightly tarmshed, but no trace of rust-formation can be detected
- 2 Water vapour is without visible action upon iron at ordinary temperatures upwards to about 300°C. At 350°C, and somewhat above, tarnishing occurs owing to a superficial layer of ferrous oxide being produced. At still higher
- 1 The word 'iron' is, both here and in the sequel, used in its broadest sense to cover wrought iron, steel, and cast iron

temperatures a protective layer of ferroso-ferric oxide is produced, which, however, is not rust.

3. Dry air or oxygen has no visible action upon iron at ordinary temperatures. It is not until the metal is raised to about 220°C, that a pale yellow tint is acquired, which, as the temperature rises, becomes successively straw-These 'temcoloured, purple, and finally blue pering' colours, as they are termed, are due to the formation of thin layers of oxide, and are consequently not produced in vacuó (Roberts, Trans Inst Mech Eng 1881, p 710), but are produced in perfectly dry air, such as that obtained by prolonged desiccation over phosphorus pentoxide (Friend, J. Iron Steel Inst. 1909, n 172).

4. A mixture of water vapour and air is without action on iron at ordinary temperatures. This was demonstrated by Dunstan and his coworkers (Trans. Chem. Soc. 1905, 87, 1548), who further showed that if, under the above conditions, liquid water is allowed to condense on the surface of the metal corrosion proceeds rapidly

From the foregoing it is evident that the rusting of iron is not an example of direct aerial oxidation, but that the presence of both liquid

water and air or oxygen is essential

Theories of rusting -- Now although all ordinary nons readily corrode when exposed to the combined action of distilled or natural waters and air, it is of considerable academic importance to inquire whether or not a pure specimen of iron will corrode when exposed to perfectly pure air and water. In 1888 Crum Brown (J Iron Steel Inst 1888, n 129) summarised buefly the most important facts then recorded on the corrosion of non and supported, though he did not originate, the then current idea that the action is primarily the result of acid attack—the acid, in most cases of aerial oxidation, being carbonic According to this theory the metal is first attacked by dissolved carbon dioxide (carbonic acid) giving ferrous carbonate, or bicarbonate, and hydrogen ferrous salt is then oxidised by atmospheric oxygen, and the basic ferric carbonate potentially formed is, in presence of water, converted into hydrated ferme oxide (rust). As the carbon dioxide is thus wholly eliminated at the end of the cycle, it may be supposed to renew its attack on the iron

This theory received vigorous support from Moody, who proved by a very ingenious experiment (Proc Chem Soc 1907, 23, 84) that rust is formed by the action of oxygen upon iron in solution and not by its action upon the metal In other words, the rusting of iron is preceded by its solution Moody further satisfied himself, as the result of a careful series of experiments (Trans Chem. Soc 1906, 89, 720), that water and oxygen alone are quite insufficient to induce rusting In experiments where iron had remained bright for many weeks in contact with pure air and water, the introduction of a minute quantity of carbon dioxide at once determined rusting. The experiments at once determined rusting The experiments of Friend (J Iron and Steel Inst 1908, ii 16; Proc Chem. Soc. 1910, 26, 179) led to the same conclusion.

On the other hand, Whitney, in 1903 (J. Amer Chem Soc 25, 394), applying modern electrochemical theory to the process, expounded the

diametrically opposite view that water and air alone suffice to establish rusting According to modern views, the action of an acid on a metal is ascribed to an exchange of electric charges between the hydrogen ions of the acid and the electrically neutral atoms of the metal, the hydrogen being deposited on the metal in the molecular state, and the metal atoms passing into the solution as metal ions. Inasmuch as pure water is regarded as being to some small extent ionised into hydrogen ions and hydroxyl ions, it is to that extent, electrochemically speaking, an acid, and when iron is immersed in it, there should be a deposition of hydrogen on the iron and an equivalent formation of iron ions The water round the iron now contains ferrous ions and hydroxyl ions, or in other words, is a dilute solution of ferrous hydroxide. If oxygen has access to the ferrous hydroxide solution, hydrated ferric oxide will be formed and deposited as rust

Such in outline is Whitney's theory, apart from the detailed application of Nernst's theory of electrolytic solution pressure, which he also introduces. The explanation just given for the action of pure water on pure and physically homogeneous iron, involves the deposition of hydrogen as a film of gas on the immersed portion of the metal As this film would prevent further contact between the metal and the water, it is supposed that it slowly dissolves in the water and escapes by diffusion, or is oxidised by the dissolved oxygen, so enabling the action to continue This theory received considerable support from W H Walker and his co-workers (J Amer. Chem Soc 1907, 29, 1251), who concluded that they had 'substantiated the work of Whitney, and shown that non does dissolve in pure water in the absence of carbon dioxide and oxygen

Dunstan, Jowett, and Goulding (Trans. Chem Soc 1905, 87, 1548).

It may be added, in passing, that the names of Cushman (The Corrosion of Iron, Bulletin No 30, U.S. Dept of Ague 1907), Tilden (Trans Chem Soc 1908, 93, 1358), and of Heyn and Bauer (Mitt Konigl Materialprufungsamt, 1908, 26), must be added to those who believe that iron will corrode in the presence

of pure water and oxygen

Nearly all the experiments just referred to were carried out with iron of ordinary com-mercial purity. This circumstance made it possible for supporters of the 'acid theory' to ascribe the rusting in absence of carbonic acid, to the presence of acidic substances generated from impurities in the iron itself Lambert and Thomson (Trans. Chem Soc 1910, 97, 2426) found that carefully purified iron remained unchanged when exposed for several months to purified air and water Any specimen of commercial iron, or of iron prepared with fewer precautions than the immune sample, rusted quite readily in the same circumstances. From their experiments, the authors concluded that whilst pure non will not rust in pure air and pure water, iron will do so if it contains only a small amount of impurity, even if the impurity is neither acid in itself nor likely to give rise to acid.

From the foregoing it is evident that opinions widely differ as to the chemistry of corrosion. Academically, therefore, the problem still awaits solution In actual commercial practice, however, since neither water, air nor iron itself, is ever quite pure, it may be safely postulated that corrosion will result whenever these three are

brought into contact.

The Mechanism of Corrosion —Aitchison (J. Iron and Steel Inst, 1916, I., 77) has outlined an attractive theory according to which, in the case of a perfectly annealed specimen of pure iron, a difference of potential exists between the crystals of ferrite and the amorphous, intercrystalline material, thereby leading to corrosion. Any potential difference between the crystal grains themselves, due to strain, in a less perfectly annealed specimen will add to this effect, the total corrosion being the sum of the two actions. In the case of iron containing carbide the main differences of potential will lie between the carbide and ferrite, the latter functioning anodically and oxidising away. The case of steels containing alloying metals is interesting. Potential difference exists between the carbide and solid solution, the latter acting as anode If the alloying element is associated entirely with the carbides, as in the case of small quantities of W, V, and Mo, they do not decrease corrosion Ni, on the other hand, enters the solid solution, reducing its solution pressure and hence the potential difference between it and the carbide, thus hindering corrogion

The ferroxyl indicator The study of the susceptibility of non to rust, and especially of the localisation of susceptibility, has been aided considerably by a device due to Cushman (lc and J. Iron and Steel Inst 1909, 1–33) and Walker (J Amei Chem Soc 1907, 29, 1257) The iron to be studied is fixed in a jelly made of agar-agar, in which small quantities of phenol-phthalein and potassium ferricyanide have been incorporated. Wherever the iron is being attacked, blue ferrous ferricyanide (Turnbull's blue) appears, whilst the second electrode in the circuit declares itself by the pink colour developed from the phenol-phthalein. The pink colour indicates the presence of hydroxyl ions

· The chemical nature of rust -Rust is a pulverulent, hygroscopic mass, ranging in colour from brown to red, and consisting of iron oxidised more or less completely to hydrated ferric oxide As a rule, the browner the rust the greater is the extent of hydration ferrous oxide is generally present also, particularly if the original metal has not been completely oxidised away. This ferrous oxide has a blackish appearance and may be found in the innermost layers close to the metal (see analyses by Moody, Trans. Chem Soc. 1906, 89, 726, Tilden, ibid. 1908, 93, 1358; Gaines, Chem. News, 1910, 101, 205; Steel, J Soc. Chem Ind. 1910, 29, 1141, Rust also contains free water in addition to that chemically combined with it, and it readily absorbs carbon dioxide from the air These two properties serve to render it an active stimulator of corrosion, for the carbon dioxide dissolves in the moisture yielding carbonic acid This attacks a portion of the iron converting it into ferrous carbonate, which in turn is oxidised by the air to rust. The liberated carbon dioxide is now free to attack further portions of iron in a sımılar manner.

Graphitisation is a form of corrosion to which cast iron is particularly liable, the mass becom-

ing so soft as to be readily cut with a knife The metallic iron is more or less completely oxidised, mainly to ferrous oxide Frequently portions of this latter have been washed or dissolved away, the remainder collecting within the pores of the now isolated mass of graphite. Examples are afforded by Berzelius (Traité de Chimie, 1831, vol 111 ), Rennie (Min. Proc Inst Civil Eng 1845, 4, 323), Draper (Chem. News, 1887, 56, 251), Le Naour (J. Iron Steel Inst. 1898, 1 526), Holgate (Gas World, 1913, 58, 479), and Of these Berzelius drew attention to the cast-iron cannon balls raised at Karlskrona from a ship that had been sunk fifty years previously They had been converted into a soft, porous mass which spontaneously heated upon exposure to air Rennie mentions the case of cast-iron guns reclaimed from the sea in 1822, off Holyhead, after an immersion of about 100 years. When brought out of the water they were quite soft, but upon exposure to the air, they hardened to such an extent that they were used to fire salutes when King George IV passed through Holyhead on his way to Dublin. It was observed that these old guns gave louder reports than any others As a rule, this kind of corrosion does not take place with the purer forms of commercial iron, although a few cases of similar softening are on iccord where wrought iron has been subjected to prolonged immersion in sea water (Lidy, Engineering News, 1897, 39, The percentage of carbon in such cases is, of course, much less than with cast iron, but is frequently much higher than the normal in consequence of the solution and removal of some of the iron

Influence of dissolved substances on rusting. The effect of dissolved salts in the water has received great attention in both the laboratory

and industrial study of rusting

As a general rule, a dissolved salt might be expected to stimulate corrosion by increasing the conductivity of the water If the substance gives an acid solution this action will be all the more marked On the other hand, concentrated salt solutions do not dissolve oxygen to the same extent as pure water, so that if the metal is completely immersed, retardation of rusting might be expected on this account The above conclusions are borne out by the experimental work which has been done. Acids and ammonium salts stimulate corrosion very considerably; sodium chloride stimulates in dilute solutions and retards in concentrated solutions. Generally speaking, as the concentration is increased the corrosivity increases to a maximum (critical concentration), and then, unless interrupted by saturation of the solution, falls practically to zero (limiting concentration). The limiting concentration in certain cases is found to have an extremely low value, eg in alkaline solutions and in chromates and dichromates. Chromates and dichromates, and other oxidising agents are known to render iron passive, and Dunstan and Hill (lc) have shown that alkalis also produce passivity, so that the effects may all be due to this cause In any case there is no doubt that above a small concentration, many substances, such as potassium and sodium carbonates, permanganates, iodates, chromates, and dichromates, borax, &c, will prevent rusting entirely. This property of

the chromates is beginning to find industrial application in the painting of iron work, and the protection of boilers. When more than one electrolyte is present in the water the effects are more complicated and it is found that the concentration of the inhibitor must usually be considerably greater than when it is present alone, if corrosion is to be prevented. An interesting special case is the behaviour of potassium dichromate in the presence of other salts. In such cases the dichromate being an acid salt reacts with the other salt to produce free acid, which destroys the passivity and allows rusting unless the dichromate is in large excess. For practical application as a rust preventive in such cases, potassium chromate which produces no acid is equally effective (Friend and Brown, J. Iron and Steel Inst. 1911, I. 125)

The temperature of a solution exerts an important influence upon its relative corresivity A 3 pc solution of sodium chloride at 10°C, is considerably more corrosive than tap water at the same temperature, but as the temperature rises the relative corresivity falls, until at 21°C the solution is appreciably less corrosive than tap water. The behaviour of sea water, which contains approximately 3 p c of sodium chloride, is of practical interest to the engineer it is considerably more corrosive than fresh water, at 13°C the two waters act similarly; whilst at all higher temperatures sea water is less corrosive than tap water (Friend and Brown, Trans Chem Soc 1911, 99, 1302) In the western part of the tropical Pacific Ocean a temperature of 32°C. is frequently attained; whilst in the Red Sea and Persian Gulf temperatures of 34 4°C and 35.5°C. respectively have been recorded. Such waters, therefore, are much less corrosive than river waters at the same temperature. In the Aictic Ocean, on the other hand, the temperature often hes below 0°C, and such waters are much more corrosive than fresh waters Between these two extremes all grades of temperature occur with corresponding fluctuations in the corrosivities

It is a matter of common knowledge that alkalis, if present in sufficient quantity in solution, will completely inhibit corrosion The merest traces of sodium or potassium hydroxide will suffice to do this provided the solution is protected from neutralisation by the carbon dioxide of the air Upon exposure to the ordinary atmosphere, however, carbonates are produced, and these tend to stimulate corrosion at ordinary temperature unless the concentration of the alkali hydroxide is sufficiently great to yield at least the limiting concentration of alkali carbonate, namely, a 0.25 p.c. solution. An interesting case arises when iron is immersed in alkaline solutions containing dissolved inorganic salts For example, iron will remain untarnished for an indefinite period in a 1 p c solution of potassium hydroxide Upon addition of potassium chloride however, corrosion is readily induced. It is possible, however, to increase the concentration of the alkali to such an extent that corrosion is entirely inhibited, no matter what concentration of chloride be added. The minimum amount of alkali required to inhibit corrosion varies with the nature of the added salt, and rises with the concentration of the same

until saturation of the last-named is reached. It is important to note that when iron corrodes in alkaline solution, the rust invariably takes the form of pitting, being localised at various points on the surface of the metal. When scraped away its interior is found to be dark, consisting largely of ferrous oxide, and the metal is observed to be eaten out or corroded into a small pit The original cause of this pitting is probably the presence of traces of superficial impurity; nevertheless, even the purest forms of commercial iron, such as Kahlbaum's electrolytic metal, readily pit in this manner. This is a point of considerable importance to boiler engineers, masmuch as alkaline feed waters are hable to produce serious trouble. It is not difficult to imagine that a large iron boiler or tank might very well lose several pounds in weight through a uniform superficial corrosion, and not be seriously injured thereby loss of only half an ounce, if localised in the form of a deep pit passing entirely through the metal, might be disastrous. The remedy in such cases appears to lie in raising the concentration of the alkalı until the inhibiting point is reached

Various factors influencing corrosion -1t has already been indicated that the concentration of dissolved oxygen at the surface of the metal has a very important influence on the progress of rusting Practical experience confirms this in many ways Pipe lines conveying water have been known to fail mainly on account of the extreme aeration of the water. Bridge structures always rust most readily near the water level, particularly if the water is in slight motion (see Cobb, J. Iron Steel Inst. 1911, I 170). Iron work which is deeply immersed in water or deeply buried, rusts much more slowly than that which is nearer to the atmosphere The oxygen used up at the metal-water surface, is gradually replaced by diffusion from the airwater surface, and anything which prevents or decreases the rate of diffusion, such as reduction in the size of air-water surface, or covering it with a layer of material impermeable to oxygen, will delay rusting The rate of flow of the water past the metal might be expected to have an influence in this respect, and Heyn and Bauer (Mitt Konigl Material-prufungsamt, 1910, 28, 93) have actually found that slight motion increases the rate of corrosion for both cast iron and steel, especially the former. With an increased rate of flow, however, the corrosion decreased again. At high temperatures, it is naturally found that the tendency to rust is greatly increased although, under many conditions, this may be compensated for by the diminution in the supply of oxygen caused by the lower solubility

Influence of physical condution—It is an experimental fact that two samples of iron may possess precisely the same chemical composition and yet exhibit a marked difference in their powers of resisting corrosive influences. This is attributable to variation in the physical properties of the metals. A series of interesting experiments was carried out by Andrews (Min. Proc. Inst Civil Eng. 1894, 118, 356) on this point, with the object of determining the influence of tensile, torsional and flexional stresses, respectively, upon corrosion. In so far as the first of these, namely, the tensile stress, was

concerned, it was found that the strained portion was cathodic to the unstrained when both were connected in a cell containing sodium chloride solution; in other words, the strained portion resisted corrosion more successfully than the unstrained On the other hand, Hambuechen Bull Univ. Wisconsin, Eng Ser. 8, 1900), after a similar series of experiments, was led to an opposite conclusion. This apparent discrepancy is explained by the work of Richards and Behi (Pub Carnegie Inst, Washington, 1906), which makes it clear that any difference of potential existing between strained and unstrained portions of metal is very small and is greatly influenced in direction by local encumstances Burgess (Trans Amer Electrochem Soc 1908, 13, 17) found that non deformed by stretching beyond the elastic limit corrodes more rapidly than unstrained portions, and this is supported by the work of Heyn and Bauer (J Iron Steel Inst 1909, I 109). As regards the influence of torsional and flexional stress, Andrews found the unstrained portions to be more susceptible to corrosion than the strained Here again the extent of the strain and the local conditions will each exert due influence upon the result

In 1911 Hanemann drew attention to some interesting effects produced by heat treatment upon the resistance of steel to acid attack (Stahl und Eisen, 1911, 31, 1365). He showed that each steel, according to its carbon content, appears to have an optimum quenching temperature, at which a maximum tensile strength is obtained. His results further indicated the existence of a close connection between the tensile strength and solubility of the steel, the steel with the highest tensile strength exhibiting the greatest solubility in acid. From the foregoing it is evident that the physical condition of the metal exerts an important influence upon its corrodibility.

Influence of chemical composition—The chemical composition of non or steel has an important bearing upon its resistance to corrosion. This is most marked in the case of east iron and steel, since these have a wider range of composition than wrought non. The most usual effects of alloying elements may be summarised as follows (Friend, Paper read before Staffs Iron and Steel Inst. Feb. 21, 1914).

1 Some elements, such as sulphur, exist in steels in the form of relatively oxidisable compounds. In mangamferous and cupriferous steels the sulphur is present mainly as the sulphides of copper and manganese. These readily undergo oxidation to sulphureous acids which stimulate corrosion.

2 Not a few elements combine with iron forming alloys or compounds highly resistant to corrosion. Such appears to be the case with phosphorus, nickel, chromium, and silicon.

3 The presence of one element may tend to alter the chemical or physical condition of a second element present in the iron or steel. For example, silicon tends to throw the carbon out of combination with the iron, and effect its separation in the form of graphite. This is a well-known reaction in blast furnace practice, and the consequence is that the corrodibility of the metal is not only influenced by the presence of the silicon per se, but also by the altered condition of the carbon.

4. Alloying elements tend to produce segregation or unequal distribution of the components of the metal during solidification. Serious differences of potential are thereby initiated and the liability to corrode is proportionately enhanced.

In addition to lack of homogeneity in the metal itself it must be remembered that contact with a less electro-positive metal, the presence of small quantities of mill scale (Fe<sub>3</sub>O<sub>4</sub>), or even of rust itself, will cause the iron to become the soluble electrode in a galvanie circuit and thereby hasten its corrosion It is therefore always advisable to avoid making contacts with other metals, or even with other kinds of iron, at points where electrolytic action might take place The fact that non in constant use does not corrode so fast as when at rest has been ascribed to the fact that any oxides formed are quickly removed and do not remain to exercise a galvanic influence

Influence of carbon and manganese—Two of the most important alloying elements in steel are carbon and manganese, and the influence of these upon the corrodibility of the metal has been made the subject of considerable study Hadfield and Friend (J. Iron Steel Inst. 1916, I. 48) summarised their results as follows. I The addition of carbon from 0.03 to 1.63 p.c. to pure iron containing less than 0.2 p.c. of manganese, results in a steadily increasing rate of corrosion both in tap water and in sea water: an initial fall in corrosion with a rapid rise to a maximum with 1.05 p.c. carbon in alternate wet and dry, and a rapid rise in corrosion to a maximum with 0.8 p.c. carbon when exposed to the action of dilute sulphuric acid.

2 The addition of 0.7 p.c. of manganese to the above steels results in a slightly increased corrosion in tap water, sea water, and in alternate wet and dry tests, with a carbon content of up to about 04 to 06 pc. With higher carbon contents the manganese generally affords a slight protection, which is very decided in the wet and dry tests. On the other hand, the presence of the manganese enormously increases the solubility of the steels of all carbon contents m dilute sulphuric acid. This is a point of great commercial importance since in ordinary steels the manganese content is very hable to fluctuate between 0.2 and 0.7 p.c. and it is very evident that the latter are unsuited for acid atmospheres or liquors For example, in large towns considerable quantities of sulphur acids are found in the atmosphere, owing to the combustion of bituminous coal, which, containing a small percentage of non pyrites, leads to the formation of sulphur dioxide, and this dissolving in rain rapidly oxidises to sulphuric acid, giving the rain water an acid reaction. It has been shown that in the industrial quarters of a large manufacturing town this acidity will sometimes represent as much as 90 lbs of sulphuric acid per acre per annum, whilst in the residential quarters it will probably not be more than about 25 lbs The sulphune acid, however dilute, coming in contact with iron-work, accelerates the rusting, and by its corrosive action renders more difficult the protection of the metal

For such districts steels of very low manganese content would appear to be most suitable.

3 By increasing the manganese content to

2 pc. upwards the corrodibility of the steels is greatly decreased in neutral media, although in dilute sulphuric acid the solubility is greatly enhanced.

Numerous other researches on the influence of carbon, nickel, chromium, copper, &c, have been carried out by Bieuil, Chappell, Altchison, Buch Diegel, and others, but for accounts of these the leader is referred to the J Iron Steel Inst.

Relative corrodibilities of wrought iron and steel—The question as to which of the two metals, wrought non or steel, is the more resistant to corrosion is one which has attracted much attention The subject has been discussed by several investigators (see Trans Faraday Soc. 1916, 11, part 2), who point out that the mean result of examining a large number of samples of wrought non and of steel after exposure to corroding influences indicates that the two metals are practically equally resistant. Nevertheless wide divergences exist between the different irons and steels in individual cases This is not necessarily due to any irregularities in the metals themselves, but rather is it attributable to the fact that no one metal can be expected to offer an equal resistance to all kinds of corrosive influences The problem thus becomes one of determining which variety of iron or of steel is the most suitable for any particular purpose. It is conceivable that certain makes of wrought iron will prove most useful in certain circumstances, whilst under other conditions it will prove better to employ Field tests, which are urgently needed to throw light upon these obscure problems, are in progress.

Corrosion of cast iron —Comparatively little research work has been published on the corrosion of east non In 1883 Gruner found that cleaned cast non was less attacked by an and moisture than wrought iron or steel (Compt rend 1883, 96, 195), but was more readily attacked by dilute acids. This latter observation was confirmed in 1915 by Friend and Marshall (J Iron Steel Inst 1915, I 353), working with a mild steel and grey east iron In neutral corroding media there was little to choose between the two metals. The same investigators found (ibid 1913, 1 382) also that a variation in the percentage of silicon between the limits of 1 2 and 2 3 p c exerts no influence per se upon the corrodibility of the The fact that in many cases cast iron objects appear to have a longer life than corresponding ones in wrought non or steel is attributable to the protection afforded by the outer skin formed on the cast iron during casting This may also account for the greater resistance offered by cast-iron pipes to the destructive action of stray electric currents (Brown, Electrical Engineer, New York, 1898, 26, 441)

Acceleration tests—In order to determine what particular variety of iron or steel will resist corrosion most effectively many attempts have been made to employ rapid chemical tests in the laboratory. One of the most usual of these consists in immersing different samples of the metal in dilute sulphuric acid for definite intervals of time and noting the losses in weight Those specimens that dissolve most readily are regarded as most readily corrodible. It cannot be too strongly emphasized, however, that such

tests are of no general value whatever. The only reliable method consists in experimenting with the samples of metal under precisely similar conditions to those to which the metal will be exposed in practice. This, it is true, is a slow process, but the results are sure.

Prevention of rust.—Where the use to which iron is to be put does not admit of any protective coating, it is obviously necessary to consider all the above questions, with a view to providing conditions which shall keep corrosion as slow as possible. The steel plates of a steam boiler, for instance, are subjected to very stringent conditions which often cause extensive pitting, so that special attention has to be given both to the metal of which the boiler is contained and to the feed water An example is described by Huntley (J Soc. Chem. Ind. 1909, 28, 339) of remarkable corrosion in a stand-by borier which could not be prevented by adding alkalis to the water Blisters were found near the water level of the boiler, filled with a liquid which contained ferrous sulphate and sulphuric acid The production of the sulphuric acid was found to be due to the presence of manganese sulphide in the steel. The blister of rust had retained the sulphuric acid, and oxygen passed in to oxidise the sulphide more rapidly than sodium hydroxide to neutralise the resulting acid. In this case, a remedy was effected by the addition of sodium arsenite, which presumably acted as a reducing agent combining with the dissolved oxygen There are various other devices for the removal of oxygen, such as passing the feed water over scrap iron in a closed box, or the addition of an alkaline solution of tannin, which in the boiler forms strongly reducing pyrogallate. The use of dichromates or chromates has already been 1eferred to, although the practice has not yet been widely tested on the large scale Other attempts to protect non have been made by placing pieces of zinc in contact with the metal so that the iron would be protected at the expense of the zine. This practice is not very economical, and usually the effect of the zinc is confined to its immediate locality. In certain circumstances, however, the method is of value. A method of preventing or retaining the corrosion of boilers consists in applying an external current so that the boiler shell is the cathode, an immersed piece of wrought iron the anode, and the boiler-water the electrolyte of 1 to 2 amperes at 4 to 8 volts' pressure is said to show a satisfactory reduction in the extent of the attack on the plates (Harker and Macnamara, J Soc Chem Ind 1910, 22, 1286).

Where conditions permit it, and especially in the case of structural iron work, it is of course a matter of economy to give to exposed iron work a protective coating. The first essential is to provide a coating which shall be as impervious as possible to air and water. Further considerations arise, particularly with regard to the course of events at points where the coating has given way. For small articles a film of vaseline, black lead, or similar material which can be readily renewed is of great practical value. A coating of hot tar or pitch (Angus Smith) has also found wide application. Wire and articles of sheet metal may be protected by means of a coating of a less corrodible metal,

usually zinc or tin. Tin plate finds its widest application in the manufacture of vessels to contain foodstuffs, and other articles for which a long life is not desired. It is less suitable for severe conditions, since at any point where the iron has become exposed a couple is produced in which the more electro-positive iron acts as the soluble electrode and suffers rapid corrosion It is therefore of importance that the tin should be as free from pinholes as possible, and the ferroxyl indicator applied in a thin layer to the surface of the metal is a very valuable indication of the extent to which they exist pinhole is indicated by the development of a blue spot which shows that iron is passing into solution In galvanised or zinc-coated iron the state of affairs is reversed The zinc protects the non first by its own resistance to corrosion, and then when the coating is broken, by the fact that the non is protected at the expense of the more electro-positive zinc. There are several methods now in use for providing the zinc coating in the most suitable form In the hot dip method the iron, after passing through a 'fluxing solution,' is dipped into molten zine The fluxing solution which has for its object the cleaning of the iron surface usually contains hydrochloric acid, and the traces of this which are carried over often have an undesirable effect in producing corrosion of the finished product. In addition to the care necessary to avoid this effect, it is very important to control the bath so that a sufficiently uniform and thick layer of zine shall be produced on the iron Other methods of depositing the zinc are by electrolysis and by exposure to the vapour of zine (Sherardising), and it is claimed that both these methods produce a more resistant coating than the hot dip process. The uniformity of a zine coating can be tested by dipping the metal in a hot concentrated solution of caustic soda (Walker, Proc Amer Soc, Testing Materials, 1909, 8, 430) Pure zinc, under such conditions, is practically unaffected, but in contact with iron, as it would be where there were cracks or pinholes in the coating, a current of hydrogen is produced from the non Tested in this way, hot galvamsed non was found by Walker to be relatively free from imperfections, but wet or electrolytically galvanised was frequently porous, indicating the necessity for careful supervision of the rate of deposition of the zinc so as to obtain the most adherent coating number of other protective devices, mostly patented, depend upon the production from the non itself of a resistant surface layer best known of these is the Baiff-Bower method of producing a fine closely adhering layer of magnetic oxide, by the action of steam on the heated metal. In this way a very uniform and durable coating can be obtained on articles which are not too large When the metal does become exposed, however, the oxide forms with the metal a couple which results in stimulated In the Tatlock process, corrosion of the non the magnetic oxide is obtained by heating in a bath of fused sodium or potassium nitrate Coslett process, which is largely used in bicycle manufacture, depends on the production of an insoluble layer of phosphate by the regulated action of phosphoric acid. These and similar methods of protection are all fairly efficient for for this reason, other things being equal, the

the protection of smaller articles or sheets of iron under not too stringent conditions. where, as is often the case with structural and massive nonwork, the water may contain much soluble foreign matter (often of an acid nature), the progress of corrosion must be carefully watched and checked This involves the use of a protective coat which shall be renewable in situ and easily applied For this reason, a considerable amount of attention is now being paid to the protection of non work by paint.

Paints usually consist of an intimate mixture of pigment and liquid vehicle. As regards the latter it is essential that it should excel in chemical permanence, imperviousness towards air and moisture, electric insulation, chemical mertness towards non, resistance towards physical damage, elasticity, and finally in its drying, hardening or setting power The vehicle most commonly in use is linseed oil, which, upon exposure to an, absorbs oxygen, being transformed into a tough, clastic solid called lmoxyn This oxidation proceeds only slowly in the case of the raw oil as obtained by pressure from Imseed, and in order to facilitate the setting, a substance termed a drier is usually added, which, by some means not thoroughly understood, assists the oil to combine with the atmospheric oxygen. To the same end linseed oil is frequently heated, either in the absence of air or whilst a current of air is blown through, a duer may or may not be added in this case, according to circumstances

The absorption of oxygen by the oil is at first accompanied by a slight expansion, amounting in the case of pure raw ('alcutta oil to about 3 pc at 15°C (Friend, Trans Chem. Soc 1917, 111, 162) Hence when thick layers of paint are exposed to the air the outer layer becomes oxidised most rapidly and by expanding causes the familiar crinkled appearance For this reason the painter prefers to apply his paint in thin layers, so that, upon diving, a smooth and uniform coat results

If the oxidation of the oil stopped at the formation of the solid linexyn the paint film would be very permanent Unfortunately such is not the case. Further oxidation takes place, although very slowly, water, carbon dioxide, and other products being evolved, and accompamed by a simultaneous contraction and embrittling of the film In course of time the contraction becomes so great that the film cracks and peels away. Such old films are a source of danger to nonwork, masmuch as they not only fail to protect the metal, but actually stimulate corrosion (Walker and Lewis, J. Ind. Eng. Chem. 1909, I. 754). Hence when cracking of the paint film has once begun it is desirable to scrape off the old paint and apply an entirely fresh coating. All the drying oils are open to this objection, and attempts have been made to utilise other liquid vehicles, such as nitrated cellulose in amyl acetate, &c

The heating of linseed oil, referred to above, induces a certain amount of polymerisation, reducing its permeability to moisture and generally increasing its protective power when used in paint for iron work. Light greatly accelerates the setting of the oil, but unfortunately it also accelerates its subsequent decomposition;

most permanent paints are those containing black or red pigments, since these absorb the shorter rays of light and prevent them from hastening the destructive oxidation of the linoxyn. As regards the pigments, they should be in a fine state of division in order to admit of thorough incorporation with the oil They should also be insoluble in water, and chemically both permanent and mert. The last-named property is largely dependent upon the solubility and in the case of certain pigments, such as the chromes, a very slight solubility in moisture is not altogether a disadvantage, since the dissolved chromate tends to inhibit corrosion. as already mentioned. This was found experimentally to be the case in the Atlantic City tests carried out under the ægis of Committee U of the American Society for Testing Materials. These tests were begun in 1908 and for details the reader is referred to Cushman and Gardner. Corrosion and Preservation of Iron and Steel (New York, 1910), and Gardner, Paint Technology and Paints (New York, 1911), suffice it to say, however, that paint mixtures containing chromates yielded promising results

It is dangerous, however, to use pigments that are markedly soluble in water, since when these have dissolved out of the paint film by repeated rainfalls, pores are left through which moisture and air readily pass to the metallic surface beneath, hading to serious corrosion.

The chief functions of a pigment consist in (1) offering a support to the Imoxyn, thereby affording a harder and tougher film, proportionately more resistant to mechanical injury, (2) reducing the permeability of the paint film to air and moisture, since the pigmentary particles are themselves impervious to these (There are other functions, but for further details reference may be made to Friend, Iron and Steel Institute Carnegie Memoir, 1918) In the case of acrial iron work, a thick coat of paint protects the underlying metal from attack more efficiently than a thin coat, provided the thick coat is not so heavily laid on as to cause crinkling or running. The best results are obtained by multiple coats, two thin coats being more efficient than one thick one of equal weight The non structures should be painted whilst the scale is still on after loosely adherent flakes and rust have been scraped off. In this case the paint will last rather longer than if applied to the pickled or sandblasted surface and the labour of removing the scale is saved. Rust need not be so carefully removed prior to painting as was formally believed to be necessary

A useful paint for structural non work not exposed to sea-water consists of oil with red lead, Indian red and lamp black, the three pigments being in approximately equal proportions by weight

Almost equally good as the red or white lead paints for protection is a bituminous paint made from pitch, the distillation of which has not been carried too far. This must be absolutely free from free carbon and tai acids or ammonium salts, and if applied hot to the structure to be protected, gives very good results, the colour being the main drawback.

There are many circumstances in which Pitting is, of course, an impossible phenomenon such a bituminous paint is preferable to an oil in the case of a liquid. This leaves us with the paint, as, for instance, in gas works, urinals, or following commercial metals to consider, namely

slaughter houses, where there is much ammonia in the air, which has an extraordinarily destructive effect upon oil paints

Corrosion of non in concrete -In view of the widespread use of concrete reinforced with iron or steel the question of the corrosion of the metal in these circumstances is fraught with unusual importance. Owing to the fact that iron, upon rusting, undergoes considerable expansion (Bauermann, J. Iron Steel Inst. 1888, II 135), it follows that should corrosion of the metal occur when it is embedded in concrete, a cracking of the latter becomes inevitable, more air and water enter, so that corrosion proceeds with an increased rapidity and the structure becomes proportionately weakened If the concrete is well made and the whole is undisturbed by stray electric currents it would appear that ferro-concrete structures may last almost indefinitely. The ingredients of the concrete should not be too coarse, otherwise thorough mixing and good contact will hardly be possible. The mixture must be well punned into position in order to eliminate voids in so far as is possible A sufficient thickness of concrete should be applied, since, if it is too thin, it may crack mechanically and thus admit an and water to the metal Substances likely to contain acids or acid producing constituents should be avoided, such as, for example, coke breeze and slags, which frequently contain dangerous sulphur compounds (see Report of Science Standing Committee of Concrete Inst Mar 9, 1911 Friend, Trans Concrete Inst 1917-18, vol 1x)

Concrete may be advantageously coated with some waterproofing material to render it still more impervious, provided such proofing is entirely free from acid or acid producing substances. This course is specially to be recommended in the case of reinforced concrete structures exposed to the action of sea-water, since the salt exerts a deteriorating effect upon the concrete. For this reason Creighton points out that if beach gravel is used in making the concrete it should first be very thoroughly washed to remove the salt, and furthermore salt should not be added to the concrete during building in cold weather to prevent its freezing (J. Franklin Inst., Nov. 1917.)

(J. Franklin Inst., Nov. 1917) Corrosion of Non-Ferrous Metals --Tho corrosion of non-ferrous metals has not been made the subject of so much study as that of non and steel, nevertheless a considerable amount of useful information has been accumulated The rare or precious metals, such as platinum, midium, and gold, are so resistant to oxidation or corrosion at ordinary temperatures that they may be said, for all practical purposes, not to cornode at all Nickel and cobalt are also very resistant to corrosion, although less so than the foregoing metals. Silver tainishes, particularly in contact with sulphur or sulphureous substances, and is readily pitted or corroded by chlorides such as common salt Mercury or quicksilver likewise tarnishes upon exposure to air, but the layer of oxide tends to protect the underlying metal from attack, if the liquid is kept stationary Pitting is, of course, an impossible phenomenon in the case of a liquid. This leaves us with the aluminium, copper, lead, tin, and zinc, together with their alloys. Such metals as rhodium, ruthenium, &c, hardly concern us here, being rather of the nature of chemical curiosities than otherwise

Aluminium —The study of the corrosion of aluminium has acquired a considerably enhanced importance of late years owing to the ever-increasing use of this metal for air-craft, fittings of sea-going vessels, and for domestic culinary operations

Aluminium tarnishes upon exposure to air, and the layer of oxide, adhering closely to the metal, affords good protection in temperate climes against further corrosion. In hot, tropical countries, where moisture is plentiful, the aluminium corrodes more rapidly, and the coating of oxide, although apparently continuous, may be minutely porous. Aluminium dinking vessels acquire a foul taste in such climates, probably owing to the absorptive properties of this porous oxide layer (Desch, Trans. Faraday Soc. 1916, 11, Part 2).

Aluminum is oxidised by prolonged contact with hot distilled water in the presence of air, the insoluble hydroxide being formed. Scala (Atti R. Accad. Linea, 1913, 22, (1), 43, 95) concludes that this is mainly due to the presence of iron, which passes into pseudo solution in colloidal form as forrous hydroxide and catalytically accelerates the oxidation of the aluminum.

The greater the purity of the metal, and the less its variation in homogeneity, the greater is the resistance of the metal towards corroding influences. Consequently annealed samples are more resistant than those which have not been so treated (Bailey, J. Inst. Metals, 1913, 9, 79). Organic acids, particularly when hot and in the presence of dissolved chlorides, act upon aluminium (Watson Smith, J. Soc Chem Ind 1904, 23, 475), whilst boiling with dilute sodium carbonate solution causes the formation of soluble sodium aluminate, from which the hydrated oxide of aluminium is precipitated on passage of carbon dioxide Both pure and crude alcohol attack aluminium fairly readily, and are rendered turbid thereby (Karpinski, Z Spiritus-industrie, 1912, 35, 660) Hydrogen peroxide in dilute solution readily effects the oxidation of the metal (Droste, Chem Zeit 1913, 37, 1317), as do also dilute solutions of ammonia, sodium hydroxide, and sodium carbonate respectively, in the cold (Hale and Foster, J Soc Chem Ind 1915, 34, 464)

Copper and its alloys —Copper tarnishes upon exposure to moist air at ordinary temperatures, and the skin of oxide thus formed tends to protect the underlying metal from attack Water alone does not appreciably affect copper, and the employment of this metal for kettles for boiling water for culmary purposes is quite Copper differs from iron in that it does not decompose steam, even at red heat cupric oxide heated in steam is reduced to cuprous oxide. Nitric acid readily attacks copper, and the metal oxidises in contact with alkaline solutions. Dilute hydrochloric acid attacks copper in the cold more seriously than nitric or sulphuric acid under similar conditions (Hale and Foster). When embedded in damp concrete copper remains in excellent condition (Gaines, J. Ind. Eng Chem 1913, 5, 766) Sulphur tarmshes copper, and organic acids gradually convert it into basic salts (see Verdigris, &c). Solutions of electrolytes such as sea-water, &c, also attack the metal. [See report of Corrosion Committee J. Inst. Metals, 1919, 21, 87]

The corrosion of an alloy is usually a more complicated process than that of a single homogeneous element, since the different constituents in an alloy do not behave alike towards corroding media. Owing to the corrodibility of non and steel various alloys of copper are used commercially on a large scale for special purposes, as, for example, in the manufacture of condenser tubes, millions of which are in use at any moment by the Admiralty. Consequently a study of the conditions under which corrosion takes place assumes a position of corresponding importance. During the last few years increased attention has been given to this subject, notably by the Institute of Metals, and for full details of the work carried out under their auspices, the reader is referred to Bengough's Reports to the Corrosion Committee, as published in the Journal of the Institute

Much so-called corrosion of metal-work really consists of mechanical abrasion. For example, furnace gases carrying with them fine particles of solid material on passing through metal tubes tends to wear them away. This action is accentuated by the presence of chlorides or sulphur compounds, since these yield with the metal compounds less hard in character, and which are in consequence more easily abraded, or they may even give rise to volatile salts which readily disappear as vapour. This is a common source of trouble with copper and its alloys.

Brass is an alloy of copper and zine, and the resistance offered by it to solutions of electrolytes has been studied by many investigators. The action of chlorides in particular has received attention, notably by Desch and White (J Inst. Metals, 1913, 10, 305, 1914, 11, 235; Desch, J Soc Chem Ind 1915, 34, 258), whose results may be briefly summarised as follows: Corrosion of brass takes place mainly by dezincification, for although both copper and zinc are removed in solution, the proportion of the latter metal in solution and in the flocculent precipitate is much higher than in the alloy Consequently a layer of metal is left, in which the percentage of zinc is much less than in the original alloy, and which has an open, spongy texture that readily yields to oxidation under the influence of air or dissolved oxygen This explains the presence of the layer of cuprous oxide frequently observed on the corroded surface of brass tubes, and which is thus probably not of direct, but of secondary origin. The removal of zinc grains proceeds at first along the boundaries of crystal grains, and in such brasses as exhibit twinning (a-brasses) along the dividing planes between twin crystals.

The presence of iron in solid solution in brass accelerates the corrosion, but small quantities of lead up to 1 pc apparently do no serious harm (Bruhl, J. Inst Metals, 1911, 6, 302) With 2 pc lead a protective layer of basic salts is formed, which tends to retard further action (Desch).

An interesting example of corrosion is afforded by a condenser tube taken from a vessel on the Manchester Ship Canal, and described by Desch The composition of the original metal was Cu, 72 72, Zn, 27 04, Fe, 0 15, and Pb, 0 09 Along the bottom of the tube the metal had been almost completely dezincified, and a transverse section showed that practically only spongy copper remained somewhat higher level the spongy copper extended only partly through the metal, but the boundary between the copper and unaltered brass was perfectly clear

Tin, as is well known, greatly enhances the resistance of biass to attack by sea-water, and for this reason bronzes are in considerable demand for marine work The standard Admiralty alloy for condenser tubes contains Cu, 70, Zn, 29, Sn, 10 The protective influence of the tin appears to be largely mechanical, in that it forms in neutral or faintly alkaline solutions of electrolytes a tough adherent layer of basic salt, which can only be

detached with difficulty

The behaviour of bronzes towards acid solutions has been studied by Giolitti and Ceccarelli (Gazz chim ital 1909, 39, n. 557), who find that their susceptibility to acid attack is intimately associated with microscopical

appearance

When embedded in damp concrete (Gaines, J. Ind Eng Chem 1913, 5, 766) both monel metal and manganese bronze appear to resist corrosion exceedingly well Addition of phosphorus to bronzes increases their resistance to corrosion, and phosphor bronzes, which contain up to 175 pc of phosphorus, have proved very valuable in marine work

Alloys of copper and aluminium, such as those containing up to 10 p.c. of the latter metal, have also proved very resistant to seawater and dilute alkalies, a property that is further enhanced by the addition of nickel (Read and Greave, J Inst Metals, 1914, 11, 169), although, curiously enough, the nickel, if it has any action at all, tends to increase the corrodibility of the alloys in tap water, dilute

mineral acids, and vinegar

Lead—(1) Pure Lead The corrosion of lead of exceptional purity has been investigated by Lambert and Cullis (Trans Chem Soc 1915, 107, 210) The metal, having been prepared in a high state of purity by the method of Stas (Bull Acad roy Belg 1860, 10, 295), was finally distilled in vacuo in quartz tubes at a temperature approximating to 1200° C. Its behaviour towards air, water, and a mixture of oxygen and water was then investigated observed that, if the metal was exposed to air only a short time after distillation, its surface was quickly tarnished in the cold, indicative of slight superficial oxidation If the metal, however, was kept in vacuo for several months, subsequent exposure to air did not cause any appreciable decrease of lustre for several days

Other samples of freshly distilled lead underwent rapid corrosion upon exposure to pure water and oxygen. In the case of totally submerged specimens, white crystals of lead hydroxide were formed, together with a brown deposit, probably consisting of hydrated plumbous oxide Pb<sub>2</sub>O,2H<sub>2</sub>O. When the metal was only partially immersed in the water a bright yellow oxide was formed within half an hour of the admission of oxygen The colour gradually turned to a dull red, the change requiring many months for completion, being accelerated by

exposure to sunlight.

A sample of lead kept in contact with water for 12 months in vacuó presented an undiminished lustre, and no evidence was obtained in other experiments indicative of the slightest solubility of the metal under such conditions Admission of pure oxygen led to no visible corrosion or tainishing for more than a week, and even after six months oxidation had proceeded to such a slight extent that the layer of oxide was suffiattenuated to display interference ciently colours

From the foregoing it is evident that pure, distilled lead behaves somewhat differently towards air or aerated water, according to its 'age,' the specimens that have been most recently distilled proving more susceptible to corrosion than those that have had time to age, although the actual mechanism of the corrosion appears to be the same in either case probably this is due to a difference in the physical character of the metal, and it is in accordance with the behaviour of other substances to suppose that the most unstable form or forms will predominate in the freshly distilled metal, thus giving it a heterogeneous character which gradually settles down to a homogeneous condition of maximum stability

(2) Commercial Lead Although commercial lead is a remarkably pure metal for technical and trade purposes, it cannot be compared with the distilled product of Lambert and It is important, therefore, to study its behaviour towards such corroding agents as are commonly met with in practice This is particularly necessary, since the subject is intimately associated with the national health owing to the extensive employment of leaden pipes for the conveyance of potable waters to private dwellings

The results obtained by early investigators are somewhat conflicting in many of their details (see Summary by Heap, J Soc Chem Ind 1913, 32, 771, 811, 847), but the following facts may be regarded as well established Although Lambert found that pure water exerts no appreciable solvent action upon pure distilled lead in finite time, it is generally agreed that distilled water, freed from air by boiling, readily dissolves commercial lead, and even refined lead. Clowes (Proc Chem. Soc. 1902, 18, 46) found that a sample of very pure lead dissolved to the extent of 0.3 gram per million parts of water, and according to Traube-Mengarini and Scala (Mem R Accad Lincei, 1911, 8, 576), the dissolved metal is suspended in the water in colloidal form Admission of oxygen converts the colloidal metal into colloidal hydrated oxide, the particles of which slowly aggregate to give a crystalline deposit, the liquid becoming turbid Oxygenated waters are thus very corrosive towards lead

The question now arises as to the influence exerted by atmospheric carbon dioxide upon the foregoing reactions Water containing dissolved carbon dioxide has but little action upon lead in the absence of oxygen, and the presence of carbon dioxide in oxygenated waters reduces

their corrosive action by effecting the precipita tion of an insoluble carbonate of lead which protects the metal from further attack. for example, Graham (J. Soc Chem. Ind. 1851, 4, 400) found that pyrophoric lead, which is simply the metal in a state of exceedingly fine subdivision, rapidly renders aerated waters poisonous if carbon dioxide is not present, in consequence of the formation and solution of lead hydroxide, which is soluble to the extent of 1 part of PbO in 10,000 parts of water (Pleissner, Chem Zentr 1907, 11, 1055) The presence of 3 p.c of carbon dioxide, however, prevents the water from becoming poisonous owing to the formation of relatively insoluble lead carbonate, 1 part of which requires 4 million parts of water to effect its complete solution Lead is readily attacked by dilute nitric acid in the cold, much less rapidly by hydrochloric acid, and still less by sulphuric acid under like conditions (Hale and Foster, J Soc Chem Ind 1915, 34, 464). Yorke, in 1834, had already observed that

dissolved salts exert an important influence upon the solubility of lead in waters the most powerful inhibitors are phosphates, such as those of the alkalı metals, small quantities of which almost entirely prevent the solution of lead This is due to the formation of a protective layer of lead phosphate which dissolves in water to the extent of only I part in 7 million parts of water Carbonates and bicarbonates are also very effective, and it has proved a useful procedure to pass certain moorland waters through beds of chalk or limestone to reduce their corrosivity. This does not, in all cases, entirely prevent the solution of lead, since a mere trace of carbonate is not sufficient for the purpose, 4 parts of CaCO<sub>3</sub> or MgCO3 per 100,000 of water being required as a minimum Nevertheless, the procedure is highly beneficial (Thresh, The Examination of Waters and Water Supplies, Churchill, 1913; Liver-eege and Knapp, British Association, Birmingham, Section B, 1913). Birmingham water, which comes chiefly from Wales, is treated at its source with powdered chalk for the same purpose.

The foregoing offers an explanation of the fact that waters which are temporarily hard do not attack lead, in other words, the lead does not pass into solution continuously, since a coat of insoluble carbonate is formed on its surface Permanently hard waters, on the other hand, frequently attack lead rather vigorously Sodium silicate diminishes the corrosivity of water. Dissolved nitrates, particularly ammonium nitrate, attack lead vigorously; but sulphates, chlorides, and acctates, as a rule, much less so Calcium oxide and alkalıs generally have a marked action, and damp concrete may produce serious corrosion (Gaines, J. Ind Eng. Chem 1913, 5, 766). Pure rain water and melted snow resemble distilled water in their activity, but rain waters collected in localities where macadam roads are in common use are laden with calcareous dust, which reduces their activity (Heap). Hence the first rain water from such a district, after a spell of fine weather, may have a comparatively slight action on lead, whilst that which falls after the air has been washed may be expected to act more

vigorously. On the other hand, rain water collected in the neighbourhood of manufacturing cities, is charged with intrates, haloid salts, and sulphur compounds resulting from the combustion of coal, and may or may not be very corrosive according to circumstances

The influence of organic matter upon the solubility of lead in water is obscure It is generally believed that waters derived from moorland and peaty sources are particularly corrosive, and this is usually attributed to the presence of peat acids or of carbon dioxide (Thresh) Experiments carried out by Heap, on the other hand, suggest that such waters, though variable in activity, are considerably less active than pure rain or distilled water. Indeed, both distilled and rain water exhibited m his tests less action on lead after contact with peat, even although their acidity was in some cases increased thereby Water containing certain forms of organic matter yield, after prolonged contact with lead, a flocculent precipitate containing the metal and organic material. This tends to deposit on the lead surface and to form a loosely attached protective layer (Heap)

Rise in temperature in general increases the solubility of lead in water

When sheet lead is immersed in a slightly acid solution of lead intrate or acetate it gradually disintegrates, becoming loose in structure, and ultimately is converted into a spongy crystalline mass, owing to the metal having dissolved and separated out again (see Heller, Zeitsch physikal Chem 1915, 89, 761, Cohen and Heldermann, bid 733, Creighton, J. Amer. Chem. Soc. 1915, 37, 2064). This phenomenon is characteristic both of the purest assay foil and of commercial lead (Desch), and possibly indicates the existence of stable and metastable allotropes (Cohen), the latter of which dissolves and recrystallises as the former. Such a hypothesis is, at any rate, in harmony with the observations of Lambert, to which reference has already been made.

Lead antiques in museums frequently undergo a gradual disintegration, being converted into a white powder consisting essentially of lead carbonate. In such cases chlorides are always present in the powder (Matignon, Compt. 1end 1912, 154, 1619)—Lead that has been immersed in sea-water and dried so that crystals of salt remain attached to the metal undergoes progressive destruction, for which the following cyclo of reactions is suggested

$$\begin{array}{c} \text{NaCl+Pb+O+CO}_2 \xrightarrow{>>} \text{Na_2CO}_3 + \text{PbCl}_2 \\ \xrightarrow{>>} \text{PbCO}_3 + 2 \text{NaCl} \end{array}$$

The sodium chloride thus acts as a catalyser, and is able to effect, in the presence of air and carbon dioxide, the disintegration of indefinite quantities of lead

Tin —Metallic tin remains bright and untarnished for long periods, both in dry and in moist air, at ordinary temperatures. In a piece of tin from an aboriginal cemetery in Florida, Keller (J. Amer. Chem. Soc. 1917, 39, 2354) noticed a number of cavitics lined with small shining crystals, both in the form of thin plates and accular in shape. These consisted of basic chloride SnCl<sub>2</sub> SnO. Water is piactically without action upon tin both in the absence

of, and in the presence of, air Tin is also very resistant to the action of dilute sulphune and vegetable acids, and is thus exceedingly useful for protecting iron or steel from corrosion in the manufacture of articles required for culinary purposes. Caustic soda attacks it, but sodium carbonate, and particularly ammonia, are much less corrosive (Hale and Foster). When alloyed with copper or its alloys it greatly enhances their resistance to corrosion (see Bronze, above), and it exerts a powerful protective influence in other alloys, such as type metal (Meyer and Schuster, Zeitsch angew Chem 1914, 27, 12)

Zinc.—Ordinary commercial zinc readily oxidises in air, and is rapidly attacked by acids Minute quantities of aisenic, antimony, copper, and tin, particularly the first two elements,

accelerate the corrosion of the metal

Zinc is largely used in the manufacture of galvanised iron, and waters passing through galvanised iron pipes or stored in galvanised iron tanks usually give a reaction for zinc. As a rule, however, this is not in sufficient quantities to be toxic.

Boiling water attacks zine (Watson Smith, J Soc Chem Ind 1904, 23, 475), the hydrated oxide of the metal separating out—It is attacked by boiling solutions of sodium chloride, as also by hot dilute solutions of alkalis, such as sodium carbonate, zine hydroxide being produced—The hydroxide does not form a produced—The hydroxide does not form a produced—The hydroxide does not form a produced taken In these cases, but, being readily detached from the metal, exposes fresh surfaces to attack.—Dilute solutions of sodium hydroxide or ammonia corrode zine in the cold, but sodium carbonate acts less vigorously (Hale and Foster See also Report of Corrosion Committee J Inst Metals 1919, 21, 59)—J N F

CORROSION, PROTECTION OF METALS FROM. Of the metals in common use iron (including steel) is not only the most corrodible, but because of its extensive and varied applications under widely diverse conditions, its protection from corrosion constitutes by far the most important case for consideration. With the other common structural metals and their alloys corrosion has in some special cases to be provided against, as in the corrosion of condenser tubes, but, in general, copper, tin, lead, and zine seldom need this attention.

In order to protect the surfaces of iron and steel structures methods based on several

distinct principles are employed

1 Exclusion of the agents causing corrosion air, moisture, or water in the case of submerged structures

This may be accomplished by .-

(a) Coating with an impervious oil film, or asphalt, pitch, &c

(b) The use of paints, varnishes, &c.

(c) Coating with another metal not easily attacked by the corresponding agents

2 By forming a non-corrodible skin consisting of some compound of the metal on its surface, such as the magnetic oxide (Bower-Barff process), phosphide, or nitride

3 By the use of a substance which greatly

reduces ('inhibits') corrosion.

4. Placing the iron in an electro-negative at the same temper condition to another metal, so that the former the use of linseed oil is protected at the expense of the latter, or making the surface to be protected the cathode tough elastic coating.

(negative) and furnishing a continuous current from an external source

It will be seen that there is a wide choice of methods, but practical considerations limit their application. In the case of large structures, ships, bridges, tanks, &c., the large surface, the fixed character of such structures, and the necessity for renewal of the protecting coat, determine the use of some form of paint or vainish paint. Deposition of another metal is applicable to a variety of conditions of use, ranging from the oldinary galvanising for tanks, roofing, &c., to electro-deposition of nickel, as in the case of bicycle parts. For small articles generally, processes of inhibiting, oiling, and formation of a surface compound are alternatives.

Before any system of protection can be properly applied it is essential that the metal surface shall be properly cleaned from dirt, mineral oil, rust (the ordinary ferric oxide  $Fe_2O_3$ ), and mill scale (the black magnetic oxide  $Fe_3O_4$ ). Plates from the rolling mills generally show patches of this oxide. Although it is an excellent protection against rusting when thinly and evenly covering the metal, patches of mill scale may set up active corrosion locally by galvanic action. Further, patches of scale are generally covered with fine cracks through which corrosive agents may pass, and the patch may scale off, carrying any protective composition with it, so that it is essential that all scale shall be removed before coating

Rust and scale may be removed by mechanical means, scraping, who brushing, and sand blasting, the latter being very efficient. Commonly they are removed by pickling the plates in sulphuric acid, 25 p.c. In this acid red rust dissolves, and mill scale is thrown off by penetration of the acid, hydrogen being generated and forcing the scale from the plate. Arsenic in the acid is regarded by many as injurious. The plates should then be washed with water jets under fair pressure (if the plates are immersed in still water a 'gummy' film forms), and then steeped in hot milk of lime to neutralise any acid remaining

Temporary protection from rusting is commonly done by smearing small articles with vaseline or heavy oil Several processes of similar nature, but giving more lasting protection, have been patented, the principle of which is immersion of the metal at temperatures up to a red heat in various oils, and withdrawing while still hot, also spraying of metal hot from the rolls with oil. A layer of slaked lime pasted on is said to be more efficient than smearing with oil, and one patent has been granted for a paste of slaked lime made with a volatile solvent, like naphtha

Asphaltic and coal-tar pitch compositions have great value as preservatives of iron and steel. For many purposes the black colour is prohibitive, but for buried pipes, &c, no better preservative can be employed. In 1848 Dr Angus Smith took out his well-known patent covering the use of pitch. The pipes were preferably first heated, dipped in linseed oil, then heated to 300° F, and dipped in hot pitch at the same temperature. He also mentions the use of linseed oil as an addition to the pitch to keep it of the right consistency, and give a tough elastic coating.

Undoubtedly the finest material for this method of protection is natural asphaltum or bitumen, to which enough heavy mineral oil has been added to give a tough and elastic Pitch from petroleum ('maltha') has much the same characters. The Sabin process consists in dipping in a hot coating mixture like the above, draining, and then heating for two hours in a vertical oven at 400° F Steel water mains up to 5 feet diameter, and in sections weighing 5 tons, have been treated by this process in America, and the United States Navy adopted the process for copper fire mains and flush mains, which are rapidly acted upon by salt water. It has also been employed for the small steel tubing for electric conduits which require an elastic and tough coating.

Heavy coal tar is commonly employed for hot dipping of cast-iron pipes. In practice the process amounts to distillation of the more volatile portions of the tar from the hot pipe, leaving a pitch coating, so that success is largely dependent on the correct dipping temperature. The soft pitch obtainable from tar produced in the low temperature distillation of coal will undoubtedly prove one of the best commercial products in this country. Tar acids and ammonia compounds are both undesirable constituents of tar for this purpose, as both tend to

increase corrosion

The anti-corrosive or protective paints are widely applicable. They may be classified as — 1. Linseed oil paints, containing some direr, and usually also a proportion of varinish

2 True varnish paints (enamels) consisting mainly of resins and oil

3. Varnishes made from a natural resin with a volatile solvent. Each of the above will carry pigment, of which a large proportion is usually iron oxide (Fe $_2$ O $_3$ )

4 Asphalts, or coal-tar pitch, with a certain amount of boiled linseed oil, dissolved in a volatile solvent, such as coal-tar naphtha or petroleum

naphtha

In general, whilst the linseed oil paints are cheaper and easy to apply, they are not so satisfactory as the varnish paints, in which the natural gum or resin reduces the porosity of the film. This has been particularly noticed in the case of coatings for plates submerged in water. Also the more clastic the kind of varnish the better the result Class 3 constitutes an important class of protective compositions specially suited to ship use, where the slow drying ordinary type of varnish can seldom be employed owing to lack of time for drying. The volatile spirit rapidly evaporates, leaving the resin and oil binding the pigment.

Cushman and others, from the results on steel plates in water carrying various pigments in suspension, obtained a classification of these ingredients of paints into 'inhibitors,' 'indeterminates,' and 'stimulators' (Proc. Amer. Soc. for Testing Materials, Vols III to VIII., 1903–1908.) The result is, in part, dependent on the purity of the pigment, but, broadly, zinc pigments, chrome green, Dutch process white lead, and some Prussian blues fall in the 'inhibitor' class; lamp black, other carbon blacks, precipitated barium sulphate (blanc fixe), ochre and bright red oxide, and some Prussian blues are 'stimulators.' Such a classification would

appear to have little value if the pigment particles are thoroughly 'sealed' in the paint medium, but if through porosity, or absorption of water, electrical contact between the pigment particles and the iron is established, the activity of the pigments is probably of the order given, the results certainly suggest an advantage of a first coating with one of the inhibitor class

The most perfect protection with paints is afforded by enamels (varnish paints or 'japans') which have been stoved on to the metal, a good example is seen in cycle frames, &c. The stoving treatment causes the resin and oil to flow into a perfect film, free from porosity, and to set with a fine hard surface. The one objection is the hability to chip with a blow. For under-water work stoved metal is said to show little advantage, and Sabin states that unbaked varnish paints are better.

Coating with another metal less hable to corrosion includes zinc galvansing and tin plating, both of which are carried out by hot dipping the thoroughly cleaned plate in the molten metal. For more special work electrodeposition of copper or nickel (usually on a first coating of copper), and of other metals is occasionally employed. Electro-deposition of zinc is also largely employed for certain classes of malk with a former for the second.

of work, such as frames, &c, for ships
These deposits afford a fair protection, but
even with the best class of nickel plating, as
applied to cycle parts, rusting under wet conditions is found to occur. Should the metal protecting film become broken, so exposing the
iron beneath, in most cases this exposite leads
to more rapid rusting, as the iron is electropositive to the protecting metal, and galvanic
action at its expense is set up. Zinc coatings
are, however, free from this defect, and as long
as a good surface of zinc is still in contact with
the iron, it will be the former metal which is
mainly attacked. Tin plate offers a complete
contrast in this respect.

A special process for applying zine is the sheardising process of Cowper Coles. The cleaned articles are packed in metal vessels with zine dust, a mixture of finely divided zine and zine oxide, and heated for several hours at a temperature below the melting-point of zine. This metal slowly penetiates the iron, and to a far greater depth than with hot galvanising; a hard alloy is formed which is practically non-coirodible, and is capable of being polished.

Processes dependent upon the formation of a protective skin date from the old Bower-Barft process, where the heated non was treated with steam, so that a film of the black oxide (Fe<sub>3</sub>O<sub>4</sub>) was formed. The good surface of 'Russian iron' is due to a similar film, and as long as the film remains intact, protection is excellent, but rusting is accelerated once the film is broken A more recent process is that of Coslett, in which the iron is immersed in a dilute solution of phosphoric acid Later the inclusion of a subsequent dipping in chromic acid was patented by Coslett. Richard and Adams have patented a process in which the article is immersed for from 2 to 20 minutes in a solution made by dissolving 12 lbs of manganous carbonate in boiling phosphoric acid (60 fluid ounces of B P. phosphoric acid to 87 fluid ounces of water).

Another process aims at the production of a

film of nitride of non, the article being heated in a suitable gaseous mixture, such as ammonia, or treating the highly heated metal in a bath of salts which will yield gases capable of forming the nitride.

Protection by 'inhibiting' the corrosive action almost invariably involves dipping in dilute chromic acid

One of the most successful methods of preventing coriosion, especially in the case of boilers and condensers, is that of Elliott Cumberland The galvanic action leading to corrosion is overcome by inserting insulated iron anodes. these being connected to the positive pole of a small dynamo; current always passes from the anode to the part to be protected, which forms the cathode A difference of potential of 6-10 volts is usually employed. In the case of brass tube condensers I ampere per 500 square feet of surface is found to ensure complete pro-In the case of boilers it is found that the hydrogen set free at the cathode plates or tubes is very effective in preventing the formation of a hard scale

Corrosion of Boilers—A serious form of corrosion is to be found in the rusting and pitting of the plates and tubes of high-pressure boilers. Before the adoption of mineral lubricants, it was supposed that the decomposition of the lubricating oils by the superheated steam in the cylinders caused the corrosion owing to the fatty acids liberated, but the same effect has been found with hydrocarbon oils, so that the pitting is evidently not due to this cause

There are several causes which lead to the corrosion found in boilers, amongst which are ordinary corrosion, set up by the carbon dioxide and oxygen which occur naturally in all water, and which act on the metal when the boiler is out of use. This form of corrosion can be prevented by filling the boiler quite full with boiled water rendered slightly alkaline with a little lime and closing air-tight whilst at rest The most frequent cause of corrosion in land boilers is dissolved salts, or free acids and alkalis in the feed water, which become concentrated solutions by evaporation Acid waters, notably those collected in peaty districts, are particularly injurious Nitrates and nitrites, chloride and nitrate of magnesia are salts most hable to cause corrosion. Complete analyses of the saline constituents of the water can alone determine the requisite treatment required to prevent corrosive action. Secondly, galvanic action, induced by the difference in potential between the rust formed by ordinary corrosion and the iron, and also by metallic impurities in the iron and specks of foreign metals deposited upon it This action can be prevented to a great extent by the use of zinc blocks inside the boiler and in metallic connection with the iron of the plates, or by the Cumberland system already described A third cause of corrosion is to be found in the solvent action of distilled water upon the metal of the boiler, the action getting less with increase in the quantity of salts in solution in the water. The fourth cause arises from high local temperatures, often not far below a dull red heat, and then iron decomposes water, forming black magnetic oxide of iron and liberating hydrogen.

 $4H_2O + 3Fe = Fe_3O_4 + 4H_2$ 

Overheating is most likely to be due to deposits or incrustations, and in such cases is checked, or stopped, by the sole use of condensed water, or a properly softened natural water, for the feed JS.S.B.

CORROSION AND FOULING OF STEEL AND IRON SHIPS. AND ITS PREVENTION. In the days of wooden ships the hull troubles that had to be guarded against were the attacks of woodboring animals and the loss of speed due to the growth of weed and shell at and below the water line, but with the launch of the first sea-going vessel built of iron, in 1822, comparatively simple problems became of great complexity, and at the present time the protection of our Navy and mercantile matine from corrosion and fouling is a question of the greatest importance, affecting, as it does, both the life and speed of the vessels

Corrosion.—The troubles due to corrosion are by no means limited to the exterior plates of the ship, but also affect the interior of the

structure, boilers, and condensers

The corrosion of non and steel is brought about by the actions which ultimately result in the conversion of the metal into oxides, and these being accelerated by galvanic actions, which it is almost impossible to climinate in a huge metallic structure like the hull of a modern ship in the presence of sea water, makes prevention far more difficult than in the case of an iron building or bridge

In sea water the process of corrosion is accelerated by the salts contained therein, as these aid the galvanic action set up in the metal by various means, such as impurities in the iron, the presence of mill scale on the plates, high temperature, or even the different stresses imparted to portions of the same plate, whilst in certain waters, such as the mouths of rivers on the west coast of Africa, or in harbours where the water contains much sewage, the sulphates are decomposed by various vegetable and animal organisms with evolution of sulphuretted hydrogen, which greatly increases the corrosion of the metal

The examination of the condition of the bottom plates of vessels that have been at sea for long periods, shows, when the protective paints and compositions have been removed, that three distinct forms of rusting may be distinguished

1 Rust patches, generally near the edges of the plates, consisting of small areas of fine rust, probably caused by moisture on the plate when the protective paint was on. These patches are never thick, and cause but little damage to the plates if all rust be removed before a new coating of paint is put on.

2 Rust nodules are a more localised form of corrosion which has attacked the metal where particles of mill scale have been left on the surface of the new plate, or where small particles of slag or foreign matter have been rolled into the plate during manufacture. These give slight pitting of the plate, but seldom to a serious extent.

3 Rust cones are an accentuated form of rust nodules, and are due to the most local form of galvanic action, caused by the presence of a speck of deposited copper, lead, or other foreign metal, or even a small particle of rust

or mill scale left on the surface of the iron, and covered by the compositions used as protectives and antifoulers. As soon as the sea water penetrates these, galvanic action is set up, water is decomposed, rust formed, and the escaping hydrogen pushes up the composition, forming a blister, the hydrogen escapes and water leaks in, the action becoming more and more rapid, and the blister gradually filling with the product of the action—rust. The blister bursts, but the cone of rust has by this time set fairly hard, and continues to grow from the base, the layers of rust being easily distinguished in a well-formed cone, and when the rust cone is detached, the pitting of the metal at the base of the cone is, as a rule, found to be of considerable depth.

Certain portions of a ship's hull are exposed to special risk of corrosion from galvanic action, owing to the bearings of the sciew shaft and valves for the escape of waste water, bilge, &c, being made of alloys containing copper. In order to prevent this, zinc protectors, consisting of heavy masses of the metal, are placed round all openings where copper or copper alloys are present, and the zinc, being more electro-positive than the iron, places the non in the electronegative condition, so that whilst the non escapes injury the zine rapidly dissolves Cumberland process (vide supra) has been successfully employed in such cases, insulated non anodes being fixed to the hull close to the part to which it is necessary to afford protection

The general procedure for protecting the exterior of the bottoms of non and steel ships from corrosion is to coat them with so-called anti-corrosive or protective paints and varnishes In order that this should be successful, much depends upon the state of the hull at the time

at which the protective is put on

The bottom plates of the newly built vessel are thickly coated, as a rule, with mill scale or magnetic oxide of iron Fe<sub>1</sub>O<sub>4</sub>, which is formed on the surface of the plate during rolling, and which, if it remains perfectly intact, would be an excellent protective, as it forms, indeed, the basis of the Bower-Barff process for the protection of iron, but during the shearing and riveting of the plates this scale gets broken off and exists only in patches, which, if left upon the plate, would excite rapid local galvanic action, owing to the fact that this scale is strongly electronegative to the iron, so that it would need only the exciting influence of the sea water to start the action

In naval vessels, the plates are pickled in dilute sulphuric acid, as already described, until all the scale is removed. In the mercantile marine it is an ordinary practice to launch a vessel without any paint on the hull, leaving the active, but fairly even, justing which ensues to remove the scale, the ship being scrubbed down and then protective compositions painted on when it is docked

This method has the advantage of cheapness, and also of giving a very slightly roughened surface, to which the protective composition adheres firmly, and answers well with tramp steamers and other craft where speed is not an object of paramount importance; but with service vessels and liners, slight as the roughening is, it undoubtedly has an influence on the speed.

The hull of the vessel, being perfectly free from mill scale, and as free as it can possibly be got from the ordinary oxide, is then painted with the protective, but for this to prove effective, the hull must be absolutely dry, a condition which it is exceedingly difficult to obtain, as the big mass of iron is generally a few degrees in temperature below that of the moisture-laden air, and under these conditions a trace of moisture condenses on the surface, which is spoken of as 'sweating' of the metal, and this prevents the proper adhesion of the paint to the metallic surface, and also starts rusting under the paint

Oil paints are the oldest form of protectives in use, and, when the plates are painted when hot and dry, amongst the best and most lasting, but the drying of such paints, being dependent upon the slow oxidation of the boiled oil by au into a resm, requires that a considerable time must clapse between the painting of the ship and the coating becoming hard enough to allow of the anti-fouling composition being painted on over it, and as a rule so short a time is allowed for docking that this is a great drawback

The old paints for this class of work used to consist of red or white lead mixed with boiled linseed oil, but it was shown by M. Jouvin that with the perishing of the vehicle the lead compounds were converted into chlorides and oxychlorides by the sea water, and these were then reduced by the action of the iron of the hull with formation of crystals of lead, which set up galvanic action and led to rapid corresion.

Spirit variash protectives came into use when it became necessary to cut down the time expended in docking, and they owe their rapid drying powers to the fact that, instead of waiting for oxidation to form a resinous mass, as in the drying of boiled oil, a resin is dissolved in a highly volatile solvent, being mixed with boiled linseed oil to give the necessary elasticity, and when this is painted on the hull of the vessel, the rapid evaporation of the solvent leaves the resin and oxidised oil binding the body colour together

Shellac, rosin, kauri, and many other gums and resins are used, whilst the solvents may consist of light hydrocarbons, such as the various grades of solvent naphtha, alcohol, and even fusel oil, but in the Navy very low flash-point solvents have now been discarded owing to the

danger in storage

The drawbacks to the last two classes of protectives are that the solvents employed for dissolving resins and gums are mostly affected by water, with the result that if the plates are not dry, the resins are apt to be deposited in a pulverulent condition, whilst the cold produced by the rapid evaporation of the solvent tends to increase the amount of moisture deposited, which assists in the deterioration of the coating Alcohol variishes have, however, the great advantage that they are not so affected by moisture on the metal, or deposited moisture, since the spirit will absorb a moderate amount of water.

These varnishes also, even when dry, are not impervious to gases and liquids. Under a microscope the coating is seen to be full of minute pores, through which the sea water finds its

way to the iron beneath, and, when once corrosion has been started, the protective coating is gradually forced away from the surface of the iron, exposing more metal to be acted upon The best results are secured by employing several coats of the varnish, and applying it only in weather favourable to the operation, plenty of time being given for the thorough hardening of the material before water comes in contact with it

In most of the various paints red oxide of iron is used to give body and colour to the mixture, and, as it is the same colour as the rust that may form under it, it is very popular with the composition manufacturer, and, providing it be free from acid and soluble sulphates, is unobjectionable, but perhaps a better material would be the mixture of finely divided zinc and zinc oxide, such as is obtained in the Belgian process of distilling zinc, as, even after the varnish had perished, the zinc would afford a further term of protection. After extensive trials the U.S. Naval Authorities adopted an anti-corrosive paint of the following composition gum shellac, 7.9 lbs., turpentine, 0.6 gallon, pinc oil, 0.6 gallon, alcohol, 7½ gallons; dry metallic zinc, 9½ lbs., white zinc oxide, 28½ lbs., the above making 10 gallons.

The protection of the interior surface of the hold of a ship presents some special complexities, as it is exposed to the wear and tear of taking in and discharging cargo and one has to take into consideration such sources of trouble as the action of bilge water, the high temperature, and the presence of foreign bodies such as coal-dust and leakages from cargo There are three classes of protectives used for

the interior portion of a ship

Cements,

Bituminous coatings;

Paints

Although coment is very largely used, yet there are certain drawbacks attached to it which render it by no means the ideal material. It has a certain amount of porosity, so that any corrosive liquid penetrates it and acts on the iron beneath; its rigidity causes it to come away from the metal on any strain being thrown on the latter, variations in temperature having the same effect, and where the coating has parted from the iron, corrosion will start and remain unseen until perhaps too late

Bituminous coatings applied hot are far preferable to cement, but are rather more

troublesome to put on

Fouling of ships and its prevention. The question of the fouling of ships' bottoms is one that has existed from the carliest days, and was of even more importance formerly than it is at the present time, owing to the increase in dock accommodation allowing the more frequent cleaning and painting of the ships; but even now in the case of war the loss in speed during blockading operations, owing to the fouling of the vessels, might prove an important factor in a struggle for supremacy

Fouling consists of various marine growths, both animal and vegetable, which attach themselves to the bottom of the vessel, and by increasing the skin friction whilst the vessel is

in motion, seriously reduce its speed

The nature of these growths needs to be

studied in properly equipped marine biological laboratories, as but little is at present known of the life-history of many of the organisms which are found on a ship's bottom. The main factors, however, are that it is only during the germ or spore period of their existence that they can attach themselves to the bottom of the vessel, and that although the full-grown results are found when the vessel is docked, these growths have taken place in situ

The open ocean and the northern seas are comparatively free from these organisms, but directly inland seas or tropical waters are reached they increase to an enormous extent in variety and numbers, and some harbours, such as the port of Sourabaya, are noted for the fouling influence of their waters. Moreover, it is found that the period of the year exercises a very important influence upon the fouling nature of the water, the spring and early summer being the chief time for these growths to find a lodgment on the bottom of a vessel.

The more common growths are serpulæ, generally called coralline, barnacles, mussels, membranæ, and oysters, usually classified together under the name of 'shell,' whilst at or near the water line are found luxuriant growths of sea grass (Enteromorpha compressa and Zostera marina), and towards the bottom ribbon and other weeds, like the tufted weed or bugula, flourish

Fouling commences with the deposition of a slight slime on the side of the vessel, which is apparently of an albuminous nature, and contains the germs and spores of various marine growths, and is so slight as to escape notice

The first visible sign of fouling on a ship is the appearance of green grass at the water line, and this, in bad waters, will begin to show after a few weeks, whilst the growth will spread downwards from the surface for 5 or 6 feet, but rarely extends below 10 feet, as the growth needs plenty of light and warmth.

It is the most widely distributed form of fouling, and appears in nearly all waters, and, once formed, the grass protects the germs of other growths, and so helps on the general fouling.

In northern waters fouling seldom goes beyond the 'grass,' but in warm climates, especially if long in port, 'shell' soon begins to appear, unless a really good anti-fouling composition is employed for coating the vessel's bottom.

Ships trading to or stationed near the mouths of rivers often show curious results in the kind and extent of the fouling, the marine growths being often killed by the fiesh water, but such vessels foul again very rapidly when once more going to sea, owing to slight deposits of mud and calcium carbonate from the river water.

With wooden ships the necessity of protection against the wood-boring teredo worm as well as fouling led to the adoption of copper sheathing, and when the metal used was of a fairly pure character, it was found to be thoroughly satisfactory, and not only to give complete protection to the vessel, but also to enable it to remain at sea for a very considerable period. The cost, however, was high, and attempts were made to prevent the excessive waste of the copper by using zinc protectors, as advocated by Sir Humphry Davy, but it was soon found

that with the prolongation of the life of the copper plates, fouling again became serious, whilst when later rolled sheets of alloys contaming zinc, such as Muntz metal, were tried, the same trouble again appeared, and it has been clearly proved that the power a copper plate exercises in preventing fouling is inversely proportional to its power of resisting the action of the sea water.

The action of the copper in anti-fouling is that, in the first place, the salts in solution in the sea water act upon the copper with the formation of chlorides and oxychlorides, the former poisonous to all forms of marine life in the germ state, whilst the latter formed a coherent pellicle to which the growths attached themselves and which was torn off during the passage of the vessel through the water by the skin friction, thus enabling it to shed any form of growth that might have attached itself to the plate by a process of scaling

It was found, however, that if the copper were not of the purest, coralline growths very soon attached themselves so firmly through the surface of the skin of copper compounds that it was difficult to remove, and gave points of

adherence for fresh vegetable growths

With the introduction of steel and iron ships, as was natural, attempts were made to utilise the same form of protection from fouling which had proved so satisfactory with wooden ships, and from time to time during the past efforts have been directed to sheathing non ships with copper in the same way soon found, however, that this sheathing set up such severe galvanic action with the hull of the vessel as to be impracticable, and although these attempts were abandoned at a very early period in the mercantile marine, the naval services of several countries have tried its use for service vessels, the generally adopted method being to sheathe the iron hull with wood and to attach to this the copper in such a way as to be insulated from the electro-positive iron, but if water penetrated the insulation was broken The alternative of saturating div wood down with paraffin wax has been suggested

With increase in dock accommodation, the tendency has been more and more towards the use of anti-fouling paints or compositions, which could be painted on over the protective coating of the vessel, and a number of compositions have been placed on the market with

varying success for this purpose

When anti-fouling paints were first manufactured, the only fact at the service of the maker was the experience which had been gleaned from copper sheathing, and on the assumption that the action had been due to the poisonous character of the chloride and oxychloride of copper produced on the plates by the salts in the sea water, compositions were made containing large quantities of corrosive metallic poisons, which, held in a varnish of a more or less lasting character, gave the piotection from fouling for a few months

As has already been pointed out, the action of the copper sheathing was due to two causes: first, the poisonous action of the copper salts on the germ life; and, secondly, the stripping of the pellicle by skin friction when any quantity of growth had formed on its surface, an action

termed 'exfoliation' How important this latter action was may be judged from the fact that when the vessel remained at anchoi in a harbour, the sheathing would last from 10 to 12 years, whilst when on active service the same sheathing would last for only 4 or 5.

Finding that poisons alone gave very unsatisfactory results, the manufacturers of anti-fouling compositions began to make perishable varnishes and grease paints, which should, by the deterioration and wasting of their surface, imitate as nearly as possible the exfoliation of the copper sheathing, and such anti-foulers gave under certain circumstances much more successful results. The idea was that the ship, having been coated with a protective paint or composition to preserve the non, a second or more coatings was put on over the protective, consisting of varnish paints which should slowly yield soluble poisons to the sea water, and in doing so would lead to the disintegration of the varnish surface, which, being washed off, exposed fresh quantities of the poisons to the water

Such compositions proved very satisfactory in the mercantile marine, and all the time that a vessel was actively engaged in going from port to port gave excellent results, but directly these same compositions, which had gained a reputation in the merchant service, were tried on Service vessels, they were found to be as unsatisfactory as those which before had been in use. The reason for this failure is Take the case of a liner trading between New York and England: she is run at a high speed between these two ports for the main portion of her life, remaining in the basin for as short a period as possible in order to utilise to the full her money-earning capacity, for such work it is easy to arrange an antifouling composition, which, with the aid of the skin friction of the vessel, would cause just sufficient wasting of the coating to give the best results. When, however, this is applied to a Service vessel, she probably goes out from dock into the basin and iemains there stationary for perhaps months, and then goes to sea, where she is kept manœuvring at various rates of speed for a considerable period During the period she is in the basin, the composition undergoes practically no wasting, and a thin film of carbonate of lime and mud deposits on the surface, which forms an excellent foothold for any germs and spores that may be in the water, and which, on going to sea, have often advanced too far for the growth to be readily got 11d of

The bad results so obtained led to a composition being put on which wasted with sufficient rapidity to prevent any such deposition in harbour, with the result that when the vessel went to sea, the deterioration being accelerated to an enormous extent by skin friction, the composition was practically all exhausted in a very short time

The most efficient anti-fouling compositions all contain copper or mercury as the poison In some cases soluble salts of these metals are employed with a fairly strong and lasting varnish; in others oxides or insoluble salts are used with varnishes which perish more rapidly on their surfaces and allow the action of the

sea water to convert the compounds into soluble salts.

It is evident that with compositions containing such metallic compounds every attention must be paid to the protection of the hull, as otherwise the formation of soluble salts of copper and mercury might result in the deposi-tion on the iron of these metals by reduction, in which case rapid galvanic action would be set up, and would lead to senous pitting of the plates of the vessel

The compositions of the present day may be

divided into two classes

1 Grease paints containing a metallic poison,

2 Quick-drying varnish paints, also charged with the same poisonous constituents The former class has met with a considerable degree of success, but they have also several very serious drawbacks. As regards the prevention of fouling, they give results not very far removed from the best varnish paints, and in certain waters, such as the Mediterranean, have proved themselves to be excellent antitoulers, but they undoubtedly increase the skin friction of the vessel, and so tend to diminish speed, whilst a second trouble is that, although a varnish paint may often be scrubbed and touched up where fouling has been but slight, with a grease paint the whole has to be removed before recoating, and they are much more costly than the varnish paints, with the result that in the merchant service they are used only to a very limited extent Another drawback to their use is that it is impossible to properly scrape and recoat the vessel during the short period of docking which would suffice for a varnish paint

In the manufacture of varnish paints it is necessary to mix with the solution of gum or resm in a volatile solvent a sufficient proportion of linseed oil to give elasticity to the vehicle, and these paints have been in use in England since about 1870, the greatest advance in them being due to the introduction of the hot process in their manufacture, which enables a more intunate mixture to be made with greater adhesive power and a smoother surface

The rate at which disintegration of these paints takes place is governed largely by the kind of gum used in the varnish, and by the amount of mineral matter introduced as colouring and poisonous material, the solubility of these having a considerable influence on the

rate of disintegration

With a tough and tenacious vehicle, which by itself would undergo but little disintegration under the action of sea water, it is quite possible to use soluble mercury or copper salts, which are liberated only very slowly during the gradual destruction of the varnish On the other hand, if a rosin varnish be employed, insoluble bodies, like the oxides of copper and mercury, the subchloride of mercury, or Scheele's green (copper arsenite), may be used, the oxides and other salts, when exposed to the sea water, being very slowly converted into soluble chlorides.

Many compositions contain arsenic and arsenic compounds, such as sodium arsenite, as these had been found effective as weed killers under ordinary conditions, and it was expected that in a composition they would prevent the

growth of grass at the water line, which, as it caught the eye, gave the impression of the ship being very foul Experience showed, however, that the arsenic had but little effect, and mercury and copper still remain pre-eminently the metallic poisons of the greatest value in anti-foulers. H Williams, Naval Constructor, U.S. Navy, has given the following composition for a paint adopted with great success for naval vessels—grain alcohol, 6 gallon, gum shellac, 13† lbs, turpentine, I gallon, pine-tar oil, I gallon, white zinc oxide, 13‡ lbs, Indian red, 13‡ lbs.; red oxide of mercury, 4‡ lbs. It was found that the cost of this paint was only one-third of the price charged for the proprietary paints

In some anti-fouling varnish paints the poisonous metals themselves have been carried in a very fine state of division, some paints containing very finely divided copper, piecipi-tated from the solution of a copper salt by non or zinc, whilst others contain metallic mercury in a comminuted condition, obtained by adding stannous chloride to the solution of a mercurous salt, these paints, however, show but little advantage over those containing salts of the

One of the most difficult portions of the ship to deal with is what is known as the 'boot top, that is, the portion between the heavy and light load line, as when a ship is discharging cargo the anti-fouling composition over this portion is exposed to the sun and rapidly perishes and peels off, whilst when the ship is again loaded, it is once more immersed, and the alternate action of sunshine and air and sea water perishes the paint at the very spot where it is most likely to be abraded by contact with lighters and barges, the result being that it is often necessary to touch up this portion of the vessel with paint during the voyage, and as good anti-fouling paints are rarely carried for this purpose, this portion of the ship is often painted with ordinary paint, and hence is liable to more damage than other parts of the vessel

**CORROSIVE SUBLIMATE** (Mercuric chloride) v Mercury

CORUBIN v ABRASIVES

**CORUNDUM.** (Coundon, Fr., Kound, Ger., from the Sanskit name korund.) Crystallised alumina ( $Al_2O_3$ ). The crystals belong to the thombohedral system, and are isomorphous with hematite (Fe $_2$ O $_3$ ) They vary considerably in habit, having the form of hexagonal prisms, pyramids, or tables. In some crystals the combination of six faces of the primary rhombo hedron with two faces of the basal plane pro duces a form strikingly similar to the regular octahedron There is no true cleavage, but often the crystals and crystalline masses show a pseudo-cleavage or parting parallel to the basal plane or to one or more faces of the primary thombohedron, due to lamellar twinning on these planes. On these surfaces the lustre is sometimes pearly, but otherwise it is usually vitreous, or inclining to adamantine in character The fracture is uneven to conchoidal; and the sharp jagged edges of the irregular grains give effect to the cutting power of the material when used as an abrading agent. Analyses show the presence of 95-99 p.c. of alumina, with small amounts of ferric oxide, magnesia, silica, water, &c, and sometimes traces of chromium. Sp.gr. 39–41. The crystals are optically unaxial and negative, refractive indices for sodium light  $\omega=17690$ ,  $\epsilon=17598$ . The dichroism is marked. Next to diamond, it is the hardest of minerals, being placed as No 9 in the scale of hardness, on this account it was

formerly known as adamantine spar

A distinction is made between the transparent 'precious corundum' and the dull, opaque 'common corundum,' while a third still less pure variety is known as emery (q v) This division also corresponds with the economic uses of the mineral, 'precious corundum' being used for gem-stones, and 'common colundum' and emery for abrasive purposes The pure, well-crystallised material is perfectly colourless and transparent with a high degree of brilliancy Traces of morganic impurities, however, produce a wide range of colours, which are more vivid in the stones of gemquality, namely red (ruby), orange and yellow ('oriental topaz'), green ('oriental emerald'), blue and indigo (sappline), and violet ('oriental Parti-coloured stones are not amethyst') The colour of common corundum uncommon is usually grey or brown

Corundum is not a widely distributed mineral, but it is found in abundance at certain localities It occurs in igneous and metamorphic rocks, such as granite, syenite, gneiss, peridotite, and serpentine, and in crystalline limestones Material of gem-quality is usually collected as water-worn pebbles in gravels derived from Material for gem-stones and for these rocks. abrasive purposes is not, as a rule, mined in the same localities. Taking first the localities for the gem-varieties, the following may be noted as a few of the most important. The best noted as a few of the most important rubies are obtained from the famous mines near Mogok in Upper Burma, where they occur in a white crystalline marble near its contact with gness, they are mined in this rock and also in its products of decomposition Darkcoloured tubies are obtained with sapphire from alluvial deposits in the provinces of Chantabun and Krat in Stam Stones of good quality have also been mined together with common corundum in Macon Co, North Carohna The best sapphires come from the gem-gravels of Ceylon, other localities of importance are Siam and Kashmir. Dark-blue and greenish-blue sapphires occur abundantly in gravels near Anakie in Queensland, while paler stones of various shades ('fancy stones') are plentiful in the neighbourhood of Helena in Montana

Common corundum as used for abiasive purposes (apart from emery, qv) was formerly mainly mined in the United States; later the Canadian deposits came into prominence; while now the latter are being ousted by the artificial products carborundum and alundum. India has also since remote times produced a certain amount which has been largely used by the native lapidaries. In the United States the corundum deposits extend along the Appalachian Range from Alabama to Massachusetts, reaching their greatest development in North Carolina and Georgia. Here they occur in peridotites near their contact with gneiss. In Canada a belt of corundum-bearing syemites

(nephelme and related alkalme syemites), associated with the Laurentian gnesses, extends for 100 miles across Renfrew, Hastings, and Halburton counties in Ontario, the principal mining district being near Craigmont in Renfrew Co Large rough crystals of corundum are abundant in gness in Madagascar and at Steinkopf in Namaqualand, South Africa More recently, important deposits have been discovered and worked in the Zoutpansberg and Pietersburg

districts in northern Transvaal

The corundum-bearing rock as mined is crushed between hardened steel rolls and the heavier corundum separated in water by means of jigs and concentrating tables. It is sifted into different grades of fineness and used (1) as loose grams, (2) mixed with glue or other soft cement as a coating on paper or cloth; and (3) as corundum-wheels for grinding (a) The last named are of three classes (a) The 'vitrified wheel,' in which the corundum is mixed with clay and baked at a high temperature, with the result that the giains of corundum are set in a matrix of porcelain (b) The 'chemical wheel, in which sodium silicate is the binding material (c) The 'cement wheel' with shellac, rubber, linseed-oil, &c, or magnesium oxychloride Another use for corundum, depending on its hardness, is for the pivot supports for watches (watch-jewels) and other delicate instruments, the poorer qualities of gem-material being used for this purpose Although corundum is the richest ore of aluminium, there are difficulties in its use for the extraction of the metal—It has, however, been used directly in the preparation of aluminium-copper and aluminium-iron alloys.

The artificial preparation of crystallised corundum was first effected by M A Gaudin, m 1837, by decomposing potash alum with charcoal It has since then been produced by a variety of methods, and is now manufactured on a large scale both for use as gem-stones and for abrasive purposes Beautiful crystals of ruby were prepared by E Frémy and Feil, in 1877, by heating a mixture of alumina and redlead with potassium dichromate in a porous fireclay crucible, a fusible aluminate of lead was thereby formed, which was decomposed by the silica of the crucible with the separation of crystallised alumina The crystals so obtained, though of some size, good colour, and perfectly transparent, were unfortunately too thin for cutting as gems A far greater measure of success was achieved by A Verneul in 1902, who has produced fine gems of all colours (v Gems, Artificial) Interesting experiments from a petiological point of view were conducted by J Moiozewicz in 1898, in which he obtained crystallised colundum in silicate magmas supersaturated with alumina Artificial corundum, used as an abrasive under the trade name of alundum (aloxite, adamite), is now manufactured on a large scale at Niagara Falls by fusing bauxite in an electric furnace 'Corubin' is also an artificial colundum, formed as a

by-product in the Goldschmidt thermite process

CORYBULINE, CORYCAVINE v. Corydaline

CORYDALINE AND THE CORYDALIS ALKALOIDS. These alkaloids occur in the loots of the Corydalis tuberosa (DC) (syn C cava, C bulloosa, Bullocapnus cavus), belonging to the Fumariacoæ, and also in some other species of this genus (C ambigua, C vernyi, C nobilis) Corydaline was discovered by Wackenroder, in the year 1826, and forty years later Wicke (Annalen, 1866, 137, 274) described the alkaloid more fully, assigning to it the formula C<sub>18</sub>H<sub>19</sub>O<sub>4</sub>N. An investigation by Additional (Inaug Dissert, Dorpat, 1890) indicated that C cava contained three or four different alkaloids, and the formula C<sub>20</sub>H<sub>27</sub>O<sub>4</sub>N was attributed to the one which is now regarded as corydaline

This base was more completely examined by Dobbie and Lauder (Chem Soc, Trans 1892, 61, 244, 605), and by Freund and Josephi (Annalen, 1893, 277, 1), who respectively ascribed to it the formula ('21H2904N and C22H2704N, the latter being probably the more correct formula. About the same time Freund and Josephi isolated three other alkaloids from ('cava roots, namely bulbocapnine, conycavine, and corybulbine, whilst Dobbie and Lauder described a fifth, conytuberine (l.e. 1893, 63, 485).

Several other corydalis alkaloids have since been isolated, the chief of which are dehydrocorydaline, isocorybulbine, corycavanine, corycavidine, and coryline Gadamei, Ziegenbein, and Wagner have classified the principal alkaloids into the following three groups —

		_	*
(1)	(Corydaline . Dehydrocorydaline Corybulbine .	:	$C_{22}H_{27}O_4N$ $C_{22}H_{23}O_4N$ $C_{21}H_{25}O_4N$
	(150Corybulbine	:	$\mathrm{C_{21}H_{25}O_{4}N}$
(2)	{Corycavine {Corycavamine	:	$C_{23}H_{23}O_{6}N$ $C_{21}H_{21}O_{5}N$
	(Corycavidine . (Bulbocapnine		$C_{22}H_{25}O_5N$ $C_{19}H_{19}O_4N$
(3)	Corytuberine Corydine	:	C <sub>19</sub> H <sub>21</sub> O <sub>4</sub> N C <sub>20</sub> H <sub>23</sub> O <sub>4</sub> N
	(isoCorydine .		CaHaOAN

The alkaloids in the first group are of weakly basic character, those in the third are strong bases, and the members of the second group are intermediate in this respect. All are oxidised by rodine, the first group yielding berbennelike compounds, except in the case of dehydrocorydaline, which is, itself, already such a compound. The third group all contain phenolic hydroxyl, and are therefore dissolved by alkalis

Protopine and two other alkaloids, one of which has the formula C<sub>20</sub>H<sub>17</sub>O<sub>4</sub>N, and is isomeric with berberine, have been found in

Chinese corydalis tubers (C. ambigua), as well as the first three members of Group I (Makoshi, Arch. Pharm. 1908, 246, 381). Eve more alkaloids, including glaucine, have been obtained from parts of C. tuberosa by Haars and by Gadamer (Arch. Pharm. 1905, 243, 154; and 1911, 249, 224).

To separate the chief corydalis alkaloids Gadamer, Ziegenbein, and Wagner extract the ground root with alcohol, distil off the solvent, dilute and acidify the residue with acetic acid. After filtering, the acid filtrate is purified by extraction with ether, then made ammoniacal, and the alkaloids extracted by means of ether. From the ethereal solution, after most of the solvent has been distilled off, a mixture of corydaline, bulbocapnine, corycavine, and corybulbine is deposited; these are separated, in the order given, by successive extractions with boiling alcohol More corydaline is obtained from the mother liquor on further concentration The residue evaporated to dryness is converted into hydrobromides and fractionally precipitated with ammonia, this treatment giving more corydaline, and also corybulbine, isocorybulbine, corycavamine, corycavine, corydine, and bulbocapnine, in the order named Corytuberine remains in the ammoniacal solution, and is obtained by extraction with chloroform after evaporating the solution to a syrupy consistency. To purify the crude corydaline it is converted into the hydrochloride and precipitated, together with some corycavine, from an aqueous solution by addition of alkali; any bulbocapnine present remains in solution, and can be recovered by passing carbon dioxide into the alkaline liquid. The corydaline and corycavine may then be separated by repeated crystallisation from absolute alcohol, corydaline, being the more soluble of the two, accumulates in the later fractions

Corydalis roots have been used in pharmacy, and are credited with antiperiodic properties. The alkaloids have a narcotic effect, but are not employed in medicine. The members of the three groups above-mentioned are closely related in physiological action as well as chemical constitution According to Peters (Arch expt. Path Pharm 1904, 51, 130) and Gadamer (Arch Pharm 1905, 243, 147), the alkaloids of the corydaline group produce paralysis of the spinal cord, and those of the corycavine group stimulate the motor centres, whilst the members of the bulbocapnine group give rise to increased All except corytuberine induce reflex action in flogs narcosis like that due to morphine, and have a prejudicial effect upon the action of the heart It has been suggested that bulbocapnine may be useful as a narcotic in veterinary practice, in the case of animals on which morphine has a stimulating effect.

Group 1. Corydaline  $C_{22}H_{27}O_4N$  crystallises from alcohol in hexagonal prisms, mp 134 5°,  $[\alpha]_D^{20}+317^\circ$  in chloroform or  $+310^\circ$  in alcohol. It dissolves easily in ether, chloroform, carbon disulphide, benzene, or warm alcohol, but is sparingly soluble in cold alcohol, and insoluble in water or alkalis. Corydaline and its solutions are quickly coloured yellow by the action of light or heat. It gives well-crystallised salts The aurichloride (B·HCl)<sub>2</sub>AuCl<sub>3</sub> crystallises from

dilute alcoholic hydrochloric acid as orange-coloured needles, mp 207°, the platinichloride (B·HCl)<sub>2</sub>PtCl<sub>4</sub> forms brown crystals, mp 227°; the hydrochloride B HCl,2H<sub>2</sub>O, columnar crystals, mp 206°–207°; and the ethyl sulphate B·C<sub>2</sub>H<sub>5</sub>HSO<sub>4</sub>H<sub>2</sub>O, large colourless prisms, mp 152 5°.

On exidation with iodine in alcohol corydaline yields dehydrocorydaline, which occurs with it in Corydalis tuberosa (Schmidt, Arch Pharm 1908, 246, 575) Four methoxyl groups are present in corydaline, and the base contains a tertiary nitrogen atom, since it reacts with methyl iodide to form corydaline methiodide B CH<sub>3</sub>L. Oxidised with permanganate, it gives eventually hemipine and meta-hemipine acids, showing the presence of two benzene nuclei in the molecule At the same time, another exidation product, corydaldine C<sub>11</sub>H<sub>13</sub>O<sub>3</sub>N, is formed; and from the constitution of this the presence of an isoquinoline nucleus in the original alkaloid is inferred

On oxidation of corydaline with dilute nitric acid instead of permanganate, dehydrocorydaline is first produced. One of the benzene nuclei is next destroyed, and a yellow dibasic acid, corydic acid C19H17O6N+1H2O, is formed When corydic acid is in turn oxidised with permanganate, it yields first an insoluble, colourless, tribasic acid  $C_{17}H_{15}O_8N$ , coryddic acid, and eventually metahemipinic acid, and a methyl pyridine tricarboxylic acid, which latter on further oxidation is converted into pyridine-2 3 4 6-tetracarboxylic C<sub>2</sub>H<sub>5</sub>O<sub>8</sub>N. The position of the methyl group in the tricarboxylic acid is thus indicated, and from this and the foregoing results the following constitutional formulæ for corydaline dehydrocorydaline are deduced (Dobbie and Lauder, Chem Soc Trans 1892, 61, 605, 1894, 65, 57; 1897, 71, 657; 1899, 75, 670, and 1902, 81, 145) -

This formulation indicates the close relationship shown by these alkaloids with tetrahydroberberine and berberine respectively. The former differs from corydaline only in having a dioxymethylene group substituted for the two methoxyl groups in ring 4, and a hydrogen atom for the methyl group in ring 2. Between the absorption spectra of corydaline and tetrahydroberberine there is also a very close relation; in fact, the only difference is that the general absorption shown by tetrahydroberberine is slightly greater than that of corydaline (Chem. Soc. Trans. 1903, 83, 598)

By reduction of dehydrocorydaline two optically inactive corydalines are produced, r-corydaline, mp 135°, and r-mesocorydaline, mp. 158°-159°, the two compounds being stereoisomeric. The former is obtained when an aqueous solution of dehydrocorydaline hydro-

chloride is treated with platinised zinc and dilute sulphuric acid at the temperature of the waterbath. Its sulphunic acid can readily be resolved by means of brucine into the corresponding l- and d-salts. r-Mesocorydaline is obtained together with its isomeride under milder conditions of reduction, by keeping an alcoholic solution of dehydrocorydaline hydrochloride with zine-dust and sulphuric acid at the ordinary temperature until it is decolourised. The separation of the two bases is easily effected by crystallisation from ether, the r-mesocorydaline alone separating (Gadamer and Klee, Arch Pharm 1916, 254, 295). By means of the camphorsulphonate it can be resolved into active components, but neither the l-form nor the d-form is identical with natural corydaline.

Dehydrocorydalme C<sub>22</sub>H<sub>25</sub>O<sub>4</sub>N occurs in the roots of C tuberosa, C ambigua, C solida, and C verim. From corydalme it is produced by the action of mild oxidising agents, such, as dilute intrie acid. It is a yellow crystalline powder, m.p. 112°-113° (deomp.), and gives crystalline salts, the aurichloride B HAuCl<sub>4</sub> forms red-brown needles, m.p. 219°. It gives a crystalline oxime, m.p. 165°, and, like berberine, unites with one molecule of chloroform, yielding a colourless crystalline compound, m.p. 154°. Haars ascribes the formula C<sub>22</sub>H<sub>25</sub>O<sub>5</sub>N to dehydrocorydaline, and regards the alkaloid as having a keto-structure when in the free state, but as being a quaternary base when in solution (Arch. Pharm. 1905, 243, 165)

Corybulbine was first separated by Freund and Josephi (lc) from commercial corydalme. and more fully investigated by Dobbie and Lauder, who assigned to 1t the formula C21 H25 O4N (Chem Soc Trans 1894, 65, 25) It is soluble in boiling alcohol, from which it separates, on cooling, as a fine crystalline powder, mp 238°-240° It is practically insoluble in water, sparingly soluble in ether and in methyl alcohol, readily in carbon disulphide, chloroform, and hot benzene The solution in chloroform is dextrorotatory,  $[a]_{D}^{20} + 303 \, 3^{\circ}$ . Corybulbine gives well-crystallised salts, the hydrochloride B HCl forms yellowish prisms, m p  $245^{\circ}-250^{\circ}$ oxidation with iodine in alcohol corybulbine gives dehydrocorybulbine C<sub>21</sub>H<sub>21</sub>O<sub>4</sub>N, m p 210°–211°, and on treatment with hydriodic acid furnishes 3 molecules of methyl iodide methylation with methyl iodide in the presence of potassium hydroxide, it yields corydaline, so that it differs from the latter only in containing an -OH group in place of an -OMe group, probably in the isoquinoline nucleus (Dobbie, Lauder, and Paliatseas, Chem Soc Trans 1901, 79, 87)

iso-Corybulbine C<sub>21</sub>H<sub>25</sub>O<sub>4</sub>N, first obtained by Gadamer, Ziegenbein, and Wagner, and subsequently examined by Bruns (Arch. Pharm 1902, 240, 19), crystallises from alcohol in voluminous leaflets, mp 179°-180°, [a]<sub>D</sub>+299 8° in chloroform, and on oxidation with iodine in alcohol yields dehydroisocorybulbine

## C21H21O4N

The latter resembles dehydrocorydaline and dehydrocorybulbine, and its hydriodide reduced with zine and sulphuric acid gives 1-180corybulbine, m.p. 165°-167°. Three methoxyl groups

are present in isocorybulbine (cf. Bruns, idem 1903, 241, 634).

Group 2. Covycavine C<sub>23</sub>H<sub>23</sub>O<sub>8</sub>N was first obtained by Freund and Josephi (Annalen, 1893, 277, 15). It is insoluble in water and in alkalis, sparingly soluble in cold, but more readily in hot absolute alcohol, from which it crystallises in rhombie tablets, mp 218°-219°; the alkaloid is optically mactive. The hydrochloride B HCl,H<sub>2</sub>O forms broad needles, mp 219°, the hydrodide B HI,H<sub>2</sub>O has mp 236°, and the aunichloride B HAuCl<sub>4</sub> has mp 178°-179° (decomp.) With methyl iodide it reacts as a tertiary base, the methiodide produced forming rhombic tablets, mp 218°. Corycavine contains a dioxymethylene group, but no—OH or —OMe group (Ziegenbein, Arch. Pharm. 1896, 234, 523, and Gaebel, idem. 1910, 248, 207)

Conyavamine  $C_{21}H_{21}O_5N$ , like corycavine, contains no methoxyl group, but probably a dioxymethylene group. It is a crystalline base, forming rhombic columns, in p. 149°, and has  $[a]_D^{20}+166°6°$  in chloroform; but on heating at 180°, or by warming with acetic anhydride, it may be converted into an optically inactive modification, in p. 213°–214°, resembling cryptopine (Gadamer, Ziegenbein, and Wagner, Arch Pharm. 1902, 240, 81)

Conjeaviding  $C_{22}H_{25}O_5N$  has been described by Gadamer (idem, 1911, 249, 30). The mixed amorphous alkaloids of C cava on conversion into thiocyanates can be separated into two groups, one giving crystalline thiocyanates, soluble with difficulty in alcohol, the other readily soluble, and amorphous From the second group corycavidine was isolated It is crystalline, and has m p.  $212^{\circ}-213^{\circ}$ ,  $[a]_{D}^{20}+2031^{\circ}$  in chloroform It appears to be corycavamine, in which a dioxymethylene group is replaced by two methyoxyl groups Lake corycavamine, it is converted on heating into the optically mactive form, mp 193°-195° after recrystallisation, the change occurs at 209° Corycavidine crystallises from hot chloroform with ICHCl3 on addition of alcohol It forms a crystalline hydrochloride and nitrate The aurichloride BHAuCl, is a red powder, which sinters at 85° and melts at 170° (decomp).

obtained by Freund and Josephi from the roots of Corydalis cava (Annalen, 1893, 277, 10) It separates from hot absolute alcohol in rhombic needles, mp 199°, [a]<sub>0</sub>+237·1° in chloroform, and yields crystalline salts. The hydrochloride B HCl forms needles, mp about 270°; the hydrodromide B HIs has mp 250°-270°; the hydrodromide B HI, mp 230°-270°, and the platinichloride, mp 200°-230° (decomp). The methicalide B CH<sub>3</sub>I forms shining needles, mp 257°.

Bulbocapnine is insoluble in water, but dissolves in alkalis, and is precipitated from its solutions in these by addition of carbon dioxide or ammonium chloride. Its four oxygen atoms are accounted for by the presence of a methoxyl, a hydroxyl, and a dioxymethylene group (Gadamer and Kuntze, Arch Pharm 1911, 249, 503, 598). Further, 'exhaustive methylation' gives rise to 3:4-dimethoxy-5:6-dioxymethylene-8-vinyl-phenanthrene, which brings

bulbocapnine into close relationship with apomorphine. The same authors have investigated the other members of this group, and assign the following formulæ to the four alkaloids concerned (ibid 641) —

Corntuberine C19H21O4N,5H2O was obtained by Dobbie and Lauder from commercial corydaline by extraction with hot water (Chem Soc Trans 1893, 63, 485) It crystallises from alcohol in fine, silky needles, mp 240°.  $[\alpha]_{\mathbf{D}}^{20}$  +282 6° in alcohol The alkaloid is nearly insoluble in cold water, ether, or chloroform, slightly soluble in benzene, and dissolves readily in hot water or in solutions of alkalis crystalline salts, including a methiodide methoxyl and two hydroxyl groups are present On methylation with methyl sulphate or diazomethane a mixture of two isometic monomethyl ethers is obtained, these correspond with corydine and isocorydine The dimethyl ether of conytuberine is glaucine ('orytuberine in alkaline solution is readily oxidised by air, giving a dark green liquid Its physiological action is very similar to that of anomorphine; and as with bulbocapnine and colydine, the characteristic emetic effect disappears when the two hydroxyl groups are methylated (Gadamer, Arch Pharm 1902, 240, 81, and 1911, 249, 503, 641)

Corydine C<sub>20</sub>H<sub>24</sub>O<sub>4</sub>N was first described by Merck, and later by Gadamer and his collaborators (idem 1902, 240, 81, 1911, 249, 669). It crystallises from alcohol with ½EtOH, mp 124°-125°, or 149° dry, [a]<sup>20</sup><sub>D</sub>+204 3° in chloroform. Three methoxyl groups and one hydroxyl group are present in the alkaloid. Oxidised with rodine, it yields the hydrodide of dehydrocorydine (1<sub>20</sub>H<sub>19</sub>O<sub>4</sub>N HI, which, on reduction, gives i-corydine, mp 165°-167°. From this l corydine is obtained by recrystallisation of the l-bartrate. As shown above, corydine is a monomethyl ether of corytuberine.

isoCorydine  $C_{20}H_{23}O_4N$  is obtained, as already shown, by methylating corytuberine. It crystallises in tablets, mp 185°, and has  $\lceil \alpha \rceil_D^{20} + 195 \ 3^\circ$  in chloroform. Its methiodide has m.p. 213°-214°, and  $\lceil \alpha \rceil_D^{20} + 143 \cdot 3^\circ$ .

COTO BARK. True coto bark is obtained from Bolivia, the Amazons (Brazil), and Vene-It has been considered identical with Winter's bark [from Drimys Winters (Forst)], but its source is really unknown (Jobst and Hesse, Annalen, 282, 191) It comes into the market in long strips about 8 cm broad and 12 mm. thick, and is tough and haid. The colour is cinnamon brown, and a cross section shows numerous yellow spots It has an aromatic odour, and contains cotoin, dicotoin, hydrocotoin and methyl-hydrocotom, resins, tannin, The supply of the true coto bark is limited, so inferior banks, chiefly para-coto bank, are sold These contain little or no cotoin, but instead protocotoin and methyl-protocotoin

Cotoin or Benzoyl-phloroglucinol-mono-methyl ether C<sub>14</sub>H<sub>12</sub>O<sub>4</sub>, is found, together with various

related substances, in true coto back, but not in para coto bark, and has been the subject of much investigation by Chamician and Silber (Ber 24, 299 and 2977, 25, 1119, 26, 777, 27, 409 and 841; 28, 1549), Jobst (N Repert Pharm 1876, xxv 23, Ber 11, 1031), Jobst and Hesse (Ber 10, 249, Annalen, 199, 17), and Hesse (Ber 26, 2790, 27, 1182, Annalen, 282, 191). As a result its constitution has been made clear and a number of its derivatives described.

Cotom can be isolated from true coto bark by extracting the powdered bark with cold ether, distilling off the ether from the extract, and mixing the residue, whilst still hot, with light petroleum, whereupon a resinous-oily mass separates, from which the solution of cotoin can be decanted and the product obtained from it in the form of large yellow crystals. A further quantity can be obtained from the resinous mass mentioned above by boiling it with limewater, and treating the solution obtained with hydrochloric acid, when the cotom is precipitated Cotoin may be recrystallised from alcohol, or hot water, when it separates in yellow prisms, melting-point 130°-131°C. It is difficultly soluble in cold water, readily soluble in hot, is fairly soluble in alcohol, ether, and chloroform, but sparingly soluble in light petroleum or benzene It dissolves in alkalis forming yellow solutions from which it is reprecipitated on acidification As decomposition products of cotoïn, phloroglucinol as also benzoic acid have been obtained

Cotoin has been used pharmaceutically in cases of diarrhora and of phthisis

The diacetul derivative C<sub>18</sub>H<sub>18</sub>O<sub>6</sub>, produced by the action of acetic anhydride, or acetic anhydride and sodium acetate, on cotoin, consists of large prisms, melting-point 94° C. sodium acetate is used in the acetylation, the diacetyl derivative is accompanied by the

commann acctate, melting-point 142°C -

Benzoul cotom, obtained by the action of benzoyl chloride on cotoin, crystallises in prisms, melting-point 110°-112°C

Dibenzoyl-cotom consists of needles, meltingpoint 134°-135°C

Dimethyl-cotoin, obtained by the action of methyl iodide and alkali on cotoin, crystallises from alcohol, and has melting-point 138° C It yields a mono-acetyl derivative, colourless needles, melting-point 150° C, hence the formula

has been proposed for it by Ciamician and

Dibromcotoin C14H10O4B12, which crystallises in large colourless needles, melting-point 116° C, is prepared by the action of bromme on cotom in chloroform solution

Cotom oxime C14H13NO4 crystallises in plates, soluble in alcohol, difficultly soluble in water, and has been prepared by the action of hydroxylamine hydrochloride on a cold aqueous solution of cotom in sodium carbonate

Mono-nitroso-cotom consists of dark red leaflets, or orange-yellow needles (from acetic acid), melting-point 153°-154° C (both forms) The needle variety possibly contains acetic acid of crystalisation (Pollak, Monatsh 1901, 22, 996)

A dilute solution of cotoin in sodium carbonate is capable of coupling with diazonium compounds, and in this way Perkin and Martin (Chem Soc Trans. 1897, 1149) have prepared the following derivatives

Coloin-azo-benzene C14H11O4 C6H5N2 crystallises from acetic acid in orange-yellow needles, molting-point  $183^{\circ}-184^{\circ}$  C , it yields a diacetyl derivative,  $C_{14}H_{9}O_{4}$  ( $C_{2}H_{3}O)_{2}$   $C_{6}H_{5}N_{2}$ , when treated with acetic anhydride and sodium acetate, searlet needles, melting-point  $155^{\circ}$ - $156^{\circ}$ C, on treatment with hot alkalis the acetyl compound is hydrolysed with formation of the free azo compound

Cotom-azo-o-toluene, similarly prepared from diazotised o-toluidine and cotom, orange-yellow needles, melting-point 203°-204°C.

Cotom-azo-p-toluene consists of orange-yellow needles, melting-point 207°-208°C

Hydro-cotoin, which occurs together with cotoin, is a dimethyl ether of trihydroxy-benzoylbenzene, C<sub>6</sub>H<sub>5</sub> CO C<sub>6</sub>H<sub>2</sub>(OH)(OMe)

A number of poly-hydroxy benzophenone derivatives, including products found in coto bark and related to cotoin, have been prepared by W H Perkin and Robinson (Proc Chem Soc, 1906, 305). A G P.

COTTON consists of the long hairs which cover the seeds of various species of Gossymum, a genus of the nat ord Malvacew The botanical classification of cotton is in a confused state, and this is doubtless mainly due to the cultivation of the plant for extensive periods, the large 400 COTTON.

interchange of seed which has taken place between the different countries of production, and the consequent gradual modification of the distinctive characters of the original species.

American cottons.—The ordinary Upland cotton is fairly generally considered to be derived from Gossypium hirsutum (Linn) Some authorities, however, are of opinion that it is derived from G. herbaceum (Linn), whilst others regard these two species as identical Sea Island cotton has usually been regarded as G burbadense, but is considered by Watt (Wild and Cultivated Cotton Plants of the World) to be a hybrid form

Egyptian cottons—The Egyptian cottons probably cannot be referred to any particular species, but are mostly hybrid forms of G burbadense with other species. Most commonly, Egyptian cottons are regarded as G. barbadense, but Watt places them under G. peruvanum (Cav.), which some authorities consider as identical with the former

Induar cottons—With reference to these varieties, G. A. Gammie, of the College of Science, Poona, writes, in his monograph on The Indian Cottons. 'It is clearly evident that we have at the most only one true species of cotton in India, Gossiphum obtust folium, with its two sub-species, G. arboneum and G. herbaceum. All other forms should be treated as derivatives of these.' Other botianists, however, regard the Indian cottons as derived from various distinct species, including G. herbaceum, G. neglectum, G. Wightmanum, and G. arboneum.

Brazilian and Peruvian cottons—Brazilian cotton is generally considered to be the product of G brasiliense (Macf.), and rough Peruvian cotton that of G peruvianum (Cav.)

The cotton plant grows as a shrub or small It is of perennial habit, but, in cultivation, is usually treated as an annual certain districts of Brazil and Peru, however, arborescent forms are grown, which are allowed to remain in the ground for several years the flower-bud first opens, the petals are generally white or pale yellow, but they gradually become darker and redder until the third or fourth day, and then fall to the ground young fruit remains attached to the flower-stalk and enveloped in the calyx, it gradually increases in size, and is known as the 'boll.' When the boll is ripe, it dehisces by from three to five valves, exposing the cotton, which, now that the pressure on it is released, rapidly expands and forms a large fluffy mass As soon as the boll has opened completely, and is quite dry, the cotton is ready to be gathered. The seeds, with the cotton fibre adhering to them, form the product known as 'seed cotton'; this is collected from the ripe bolls, and the cotton (or 'lint'), after being torn from the seeds by the process of 'ginning,' constitutes the law Seed cotton usually concotton of commerce sists of about one-third of its weight of cotton fibre and two-thirds of seeds.

The cotton fibre is composed of a single hollow cell, and, while unripo, has the form of a long narrow tube. As the fibre matures, it becomes more or less flattened, and presents the appearance of a narrow, somewhat opaque ribbon or band, with slightly thickened, rounded edges. The ripe fibre possesses a peculiar characteristic twist. This twist appears to be

an acquired character; it is not present in wild cotton, and is increased by care in cultivation. The number of twists in a given length is very variable, and, as a rule, is, roughly speaking, inversely proportional to the diameter of the fibre, the twist being most numerous in the finest variety (Sea Island) Unripe cotton consists of thin, transparent fibres with little or no twist. Such fibres are known technically as 'dead cotton,' and, being very weak and brittle, they break up in the process of manufacture, thus increasing the amount of waste, and also tending to weaken the yarn or fabric into the composition of which they enter; they also possess the defect of not being able to take dyes satisfactorily.

According to the length of the individual fibres, cottons are classed in commerce as longmedium-, or short-stapled. The long-stapled cottons are 11 inches or more in length, the medium-stapled are about 1 inch long, and the short-stapled are less than I inch The principal long-stapled varieties are Sea Island cotton. Egyptian varieties, and the improved American Upland forms, which have been evolved from the ordinary Upland kinds by continuous selection and careful cultivation The Brazilian and Peruvian cottons vary from about 1 to 11 inches, and are, therefore, either medium- or long-stapled The chief medium-stapled cottons are the ordinary American Upland kinds, and the short-stapled class is represented by the Indian varieties

Sea Island cotton is grown in South Carolina, Georgia, Florida, and the West Indies The fibre is very long, fine, silky, and of a lustrous creamy tint, and this cotton is therefore the most valuable variety. It is used in commerce for spinning the finest and best yarns. Considerable care is required in the cultivation of this cotton, and the yield per acre is usually lower than that of other kinds.

American Upland cottons are produced in enormous quantities in the United States, and are the principal kinds used in the Lancashire spinning industry. They are of longer staple and better quality than the Indian varieties, and are employed for the manufacture of yarns of medium quality.

Egyptian cottons exist in several varieties, most of which yield a fibre of a brownish tint. These cottons are long, strong, and fine, and more lustrous than American Upland, but inferior to Sea Island cotton. Egyptian cotton is preferable to American Upland for the manufacture of goods requiring a soft, smooth finish and high lustre.

The Indian cottons are mostly short and coarse, and are consequently less valuable than American Upland kinds. The chief markets for these varieties are Japan and Germany, comparatively little being imported into the United Kingdom.

Brazilian cotton is harsh and wiry, of medium strength and of good length. One of the varieties grown in North Brazil is a tree cotton, which lives for 8 years or more. The ordinary annual cottons are more largely cultivated and are more productive than the arborescent form, but the fibre of the latter has the longer staple.

Peruvian cotton is chiefly of two kinds,

known respectively as 'rough' and 'smooth.' The former is the product of a cotton tree which is allowed to remain in the ground for from 4 to 6 years; the fibre is well known for its peculiarly harsh and crinkly character, which renders it especially useful to spinners for mixing with wool. 'Smooth' Peruvian is very similar to American Upland cotton, and is used for the same purposes.

The following table gives the approximate length and average diameter of the fibres of the principal commercial varieties. The diathe principal commercial varieties meters of the fibres of any one variety show great variation among themselves, but the figures given under this head are the average of a large number of determinations by various observers, and can, at least, be regarded as

relatively accurate .-

Variety	Usual length	Average diametei
Sea Island American Upland Egyptian Indian Brazilian Peruvian (rough) , (smooth)	 niches 1 6-2 2 0 8-1 1 1 3-1 6 0 6-1 0 1 1-1 4 1 2-1 5 0 9-1 1	mch 0 00064 0 00077 0 00068 0 00084 0 00080 0 00078

Cotton consists of about 83 7 p c of cellulose (qv.), together with 7 p c. of water, 0 6 p c of wax and oil, 1 5 p c. of protein, and about 1 65 pc of mineral matter (ash) (Bull 33, U.S. Dept Agric) The actual composition of The actual composition of

cotton varies with its origin

The wax is present as a thin layer on the surface of the fibre, and renders it incapable of absorbing water readily This substance, to which Schunck (Manchester, Mem Lit. Phil Soc. [III ] 4, 95) has given the name 'cotton wax, resembles other vegetable waxes, such as cerosin prepared from the leaves of the sugar-cane, and the waxes from the leaves of the carnauba palm [Copernicia cerifera (Mait)], and the Laphia palm [Raphia pedunculata (Beauv ) It is insoluble in water, but soluble in alcohol or ether; it melts at 86°, and solidifies again at 80°-82° Puro cotton wax is insoluble in solutions of caustic alkalı, ıt contains C 80 4, H 14 5, O 5 1 crated with this wax is a fatty acid, which was regarded by Schunck as margaric acid, but is more probably a mixture of steame and palmitic acids; it melts at 55.5°, and resolidifies at 50 5°.

The oil in the cotton fibre appears to be identical with that contained in the seed the preparation of the so-called absorbent cotton wool, the wax and oil are removed by boiling the fibre with dilute caustic alkali under pressure, the material is subsequently washed, treated with bleaching powder and hydrochloric acid, again washed, and dried.

The nitrogenous constituents of cotton consist of the remains of the cell protoplasm and

allied substances.

The mineral substances contained in the fibre are chiefly phosphates, chlorides, and sulphates of potassium, sodium, magnesium, and calcium, together with small quantities of iron

and traces of aluminium. If the amount of ash is much more than 2-3 pc, the excess is probably due to the presence of sand and other mechanical impurities.

When cotton is immersed in a strong solution of caustic soda, it undergoes certain remarkable changes, the chief of which is the production of a silky lustre. This phenomenon was discovered by John Mercer in 1844, and has led to results of great commercial importance. The process is now carried out on an extensive scale under the name of 'mercensation' (q v), and is sometimes applied to the yarn and sometimes to the woven The material is either kept in a state fabric of tension during the operation, or is allowed to shrink in the alkaline liquid, and afterwards stretched to its original length before being The process not only produces an washed exceedingly high lustre on the cotton, but also increases its power of absorbing dyes. The structure of the cotton fibre undergoes alteration, the flattened, twisted tube, characteristic of ordinary cotton, swells out, and is thus converted into a hollow, cylindrical form. This change is accompanied by a decrease in length and also by an increase in tensile strength, mercerised cotton being in some cases as much as 50 pc stronger than ordinary cotton Egyptian cotton generally mercerises better than ordinary American cotton

When cotton is treated with a mixture of nitiie and sulphuric acids, it is converted into nitro-cellulose or gun-cotton (v. Explosives). On dissolving gun-cotton in ether, or a mixture of ether and alcohol, the product known as collodion is obtained (v Photography) Nitiocellulose also enters into the composition of

celluloid (q v)

Among the more important works on this subject may be mentioned The Cotton Plant, Bull No 33, Office of Expt Stat US Dept. of Ague, Bowman's Structure of the Cotton Fibre; and Oppel's Die Baumwolle

COTTON BROWNS, SCARLETS, YELLOWS, v Azo- colouring matters, Primuline.

COTTON FLOWERS. Among the various portions of the cotton plant which have been industrially employed must be included the flowers which constitute one of the numerous Indian dyestuffs According to Watt (Dietionary of the Economic Products of India) they are thus used in the Manipur district Gossypetin was first isolated in small quantity from the flowers of the ordinary Indian cotton plant, G herbaccum (Perkin, Chem Soc Trans 1899, 75, 826), and has been more completely studied at a later period (ibid 1913, 103, 650) For its preparation a concentrated alcoholic extract of the flowers is treated with hot water and the mixture digested when boiling with addition of hydrochlone acid for three hours. After removal of tar by filtration the hot liquid on cooling deposits a brownish-yellow powder, which contains a mixture of quercetin and gossypetin These colouring matters are separated by a fractional crystallisation of their mixed acetyl derivatives from acetic anhydride, acetylgossypetin being in these circumstances the least soluble. The acetyl compound is finally hydrolysed by sulphuric acid in the presence of acetic acid in the ordinary manner.

Gossypetin C18H10O8 forms yellow needles,

melting-point 311°-313°, closely resembles quercetin in appearance, and is readily soluble in alcohol, but only very sparingly soluble in water. Concentrated alkaline solutions dissolve it, forming orange-red liquids which on agitation and dilution with water, become green, then blue, and finally assume a dull brown tint. Alcoholic lead acctate gives a deep red precipitate in the cold, passing into dull brown at the boiling-point, and with alcoholic ferric chloride a dull olivegreen liquid is obtained.

Gossypetin like quercetin forms compounds with mineral acids which crystallise in orangered needles, and with alcoholic potassium acetate the monopotassium derivative  $C_{15}H_{9}O_{8}K$  is produced. The hexa-acetyl derivative

C15H4O8(C2H3O)6

forms colourless needles, melting at 228°–230° By fusion with alkali or by dissolving the colouring matter in cold 50 p c aqueous potassium hydroxide and allowing the solution to remain exposed to air for twenty-four hours, with shaking, protocatchiae acid is obtained A phenolic substance also produced by these methods of hydrolysis has not yet been identified

When methylated with excess of methylic rodide and methyl alcoholic potash gossypctim hexanethyl ether C<sub>15</sub>H<sub>4</sub>O<sub>2</sub>(OMe)<sub>6</sub>, colourless needles, melting-point 170°–172°, is produced, and this by hydrolysis with alcoholic potash gives pretocatechia acid dimethyl ether and gossyptiot tetramethyl ether C<sub>12</sub>H<sub>16</sub>O<sub>6</sub>, needles, melting-point 115°–116° By ethylation in a similar manner, gossypctin hexacthyl ether C<sub>15</sub>H<sub>4</sub>O<sub>2</sub>(OEt)<sub>6</sub>, melting-point 144°–146°, can be prepared, and with alcoholic potash yields duthylprotocatechiae acid and gossyptiol tetracthyl ether C<sub>16</sub>H<sub>24</sub>O<sub>6</sub>, melting-point 110°–111° The latter forms an oxime C<sub>16</sub>H<sub>25</sub>O<sub>6</sub>N, melting-point 127°–129°, and when oxidised with permanganate gives gossypctonic acid, yellow needles, melting-point 154°–155° The constitutions assigned both to this latter (1) and to gossyptiol tetraethyl ether (2) are given below—

(1) HO C<sub>6</sub>H(OEt)<sub>3</sub>CO CO<sub>2</sub>H (2) HO C<sub>6</sub>H(OEt)<sub>3</sub>CO CH<sub>2</sub> OEt

and from these that of gossypetin naturally follows —

When an alkaline solution of gossypetin is exposed to air the blue liquid on acidification yields a reddish-brown precipitate which on gentle warming becomes crystalline. Again, if benzoquinone is added to a solution of gossypetin in cold absolute alcohol a similar reaction takes place. On keeping for a few minutes crystals commence to separate, and by then heating to 50° a semi-solid mass is obtained.

Gossyptone C<sub>15</sub>H<sub>8</sub>O<sub>8</sub>, the name assigned to this substance, consists of microscopic needles of a dull red colour, which are difficultly soluble in the usual solvents 1t dissolves in dilute alkalis with a pure blue colouration and its solution in concentrated sulphuric acid is dull brown. Sodium hydrogen sulphite solution reconverts it into gossypetim, Gossyptone possesses strong

dyeing properties, and gives the following shades on mordanted woollen cloth .—

Chromium. Aluminium. Tin
Dull brown. Orange-brown. Orange-red
Iron.
Deep olive.

These, it is interesting to note, are identical with those given in these circumstances by gossypetin itself, and it is accordingly evident that during the dyeing operation oxidation of the latter to gossypitone takes place Until a definite knowledge of the tetrahydroxybenzene nucleus in gossypetin has been obtained the position of the hydroxyl groups in this portion of the molecule can only be conjectured. Existing as it does side by side with quercetin it seems natural to consider that gossypetin is a Again, should gossypitone hydroxyquercetin be a p-quinone, the constitution of gossypetin will be the same as that which Neirenstein and Wheldale have suggested (Ber 1911, 48 3487) for the flavonol (1) which they obtained from quercetone, an oxidation product of quercetin, but the descriptions of the two compounds are not in agreement <sup>1</sup> On the assumption of the necessity for a quinol nucleus in gossypetin a second constitution (2) is however possible -

Again, a third expression (3), representing gossypetin as an hydroxyquercetin, is available, though in this case gossypitone must be regarded as an ortho-rather than a para-quinone:

The glucosides present in cotton flowers have been examined by Perkin (Chem Soc Trans. 1909, 95, 2181), who in the first place employed the Egyptian variety. The Egyptian cottons appear, according to the researches of Messrs Fletcher and Balls, to be derived from natural crosses of brown Peruvian cottons with the Sea Island variety.

A concentrated alcoholic extract of the flowers deposits on cooling a semi-crystalline powder, and this consists mainly of the potassium salts of two glucosides, quereimeritrin and gossypitrin, whereas a third glucoside iso-quercitin is present in the filtrate. A rough separation of the latter from this mixture may also be effected by means of aqueous lead acetate, for in these circumstances the precipitation of isoquercetin does

This compound, more recently synthesised by Neirenstein (Chem. Soc. Trans 1915, 107, 872), is described as melting at 854°-355°, and its hexamethyl ether at 146°-147°.

not occur, at least to any extent The isolation of quereimeritiin and especially of gossypitrin in a pure condition from these flowers is however of too tedious a character to be described here, and for details of the processes involved the original paper must be consulted

Quercimeritrin C<sub>21</sub>H<sub>20</sub>O<sub>12</sub>, 3H<sub>2</sub>O, melting-point 247°-249°, consists of small, glistening, bright yellow plates, insoluble in cold and fairly readily soluble in boiling water. Its alkaline solutions possess a deep yellow tint, with aqueous lead acetate it gives a bright red precipitate, and with ferric chloride an olivegreen colouration Octa-acetylquercimeritrin, needles,  $C_{21}H_{12}O_{10}(C_2H_3O)_8$ , melting-point 214°-216°, is sparingly soluble in alcohol, whereas monopotassium quercimeritiin, a yellow powder, can be obtained by means of alcoholic potassium acetate By hydrolysis with dilute sulphuric acid quereimentiin yields quercetin and glucose according to the following equation -

$$C_{21}H_{20}O_{12} + H_2O = C_{15}H_{10}O_7 + C_6H_{12}O_6$$

and is thus analogous to quercitrin which in this manner is conveited into quercetin and rham-

On wool mordanted with aluminium, tin, chromium, and iron, quereimeritim gives the following shades -

Aluminium. TuChromium Orange-yellow. Bright orange Reddish-brown. Iron Olive-brown

And these results are interesting, because with the exception of the iron mordanted pattern, which is of a rather browner character, the colours thus produced closely resemble those which are given by quercetin itself when dyed in a similar manner. They are widely different from those given by rutin and quercitiin, and mainly as a result of this property there can be little doubt that querementrin is to be represented by one of the two following formulæ .--

Querementin is also present in the flowers of the Prunus emarginata? (Finnemore, Pharm J. 1910, (iv), 31, 604).

Gossypitrin C21H20O13, only isolated with considerable difficulty is more readily prepared from the G neglectum (see below). When crystallised from dilute acetic acid it contains 2H<sub>2</sub>O of crystallisation, and is readily dissolved by hot water, but on boiling this solution yellow needles of the anhydrous substance, melting-point 240°-242°, separate When anhydrous it does not absorb water of crystallisation from moist air, but on boiling with acetone the hairlike needles are broken up into much finer needles, which when dried at 100° possess 1 molecule of water of crystallisation. Such a preparation melts at 200°-202°, and when dried

at 160° on standing in air now absorbs water. Preparations possessing this lower melting-point can be obtained in other ways, and it is accordingly evident that gossypitiin exists in two interchangeable modifications

Gossypitrin dissolves in alkalis with a pale yellow colouration, and gives with lead acetate a deep red precipitate It is almost insoluble in boiling acctone, a property which readily distinguishes it from quereimeritrin, which is fairly soluble in the latter solvent

Acetyl qossyptrin  $C_{21}H_{11}O_{14}(C_2H_3O)_9$ , colourless needles, melting-point  $226^\circ$ – $228^\circ$ , is almost insoluble in alcohol

When hydrolysed with dilute sulphune acid gossypitim yields gossypetin and dextrose according to the equation-

$$C_{21}H_{20}O_{13}+H_{2}O=C_{15}H_{10}O_{8}+C_{6}H_{12}O_{6}$$

The shades given by this glucoside on moidanted wool are as follows .-

Chromium Aluminium  $T'\iota n$ Reddish-Dull Bright Dark brown yellow orange olive; brown.

Gossypitrin reacts, like gossypetin itself, with benzoquinone, and yields in this way a quinone to which the name Gossypitrone C21H18O13, has been assigned This consists of maroon-coloured needles, which possess no definite melting-point, although fusion of the product occurs about 255°-259° By the action of warm dilute sulphurous acid solution it is reconverted into gossypitin, and the same change appears to occur in the dyeing process, for the shades produced are identical with those yielded by this latter glucoside—It is considered probable that the sugar group of gossypitim is attached to its tetrahydroxybenzene nucleus, though until the exact nature of this has been decided, its position is necessarily uncertain

Isoquercitrin  $C_{21}H_{20}O_{12}$ ,  $2H_2O$ , crystallises from dilute alcohol in pale yellow needles, melting at 217°-219° It is sparingly soluble in water, and dissolves in alkaline solutions with a deep yellow tint, but its most interesting property is the fact that with aqueous lead acctate solution it gives a bright yellow precipitate entirely distinct from the deep red deposit which is produced in this manner from

the isomeric quereimeritrin

Again, though more readily susceptible to hydrolysis than the latter glucoside, it yields identical products —

$$C_{21}H_{20}O_{12}+H_{2}O=C_{15}H_{10}O_{7}+C_{6}H_{12}O_{6}$$

Dyeing experiments with isoquercitiin give hades entirely distinct from those given by quereimeritrin, and these, although slightly paler, resemble those yielded by quercitiin.

Aluminium. Chromium Tin. Iron. Golden-Lemon-Brownish-Brownishyellow yellow. yellow. olive.

The properties of this substance indicate that its sugar group is not attached as in querementrin to the phloroglucinol nucleus of quercetin Indeed, it is probably constituted similarly to quercitrin, which, however, contains a rhamnose in the place of the glucose residue Three formulæ are possible for iso-quercitrin, which may be briefly expressed by the statement that the position of the sugar residue in respect to the quercetin group is at | one or other of the points in the following which are marked with an asterisk :-

The aqueous extract of the Egyptian cotton flowers employed in this investigation gave by hydrolysis with acid 186 p.c. of crude colouring matter, and in this approximately 10 pc of gossypetin was present. Dyeing experiments with the flowers in the usual way gave the following shades .-

Chromium Aluminium  $T_{2n}$ Iron. Reddish-Olive-Green-Orangebrown brown. brown. yellow

and these though duller were somewhat similar in character to those given by quereimeritrin In comparison with the shades similarly produced from other natural dyes, they most nearly resemble those of the so-called 'Patent Bark,' a preparation of quercitron bark in which quercetin and no quercitrin is present.

Among the types of cotton flowers there are (a) red, (b) pink, (c) yellow, and (d) white flowered plants. In the offspring of a cross between (a) and (c) there occurs in the second and subsequent generations red and yellow plants which breed pure, whereas in the off-spring of a cross between (a) and (d) all four forms occur which breed pure As a supplementary investigation to that of the Egyptian flowers the petals derived from such pure plants occurring among the offspring of one or other of these crosses have been examined (Perkin Chem. Soc. Trans 1916, 109, 145) (cp. Leake, Proc. Roy Soc 1911, (B), 83, 147)

The types were as follows red flowered, G. arboreum (Linn); pink, G sanguineum (Harsk), yellow and white, two varieties of G neglectum (Tod), usually now treated as one species but originally described as G neglectum and GAs a result it has been found that the red flowers of G arboreum contain isoquercitrin, quereimeritrin and gossypitrin in this case being absent, whereas in the yellow flowers of G neglectum, gossypitrin and isoquercitrin were present, and querementrin appeared to be absent On the other hand, the white flowers of G neglectum and the pink flowers of G sanguineum gave but traces of colouring matter too small for complete identification, though the respective products obtained resembled in their properties apigenin and quercetin An examınation of the ordinary Indian cotton flower, G. herbaceum, available only in small amount, gave the same results as the G neglectum

Gossypetin is also present in the flowers of the Hibiscus sabdariffa or 'red sorrel' of the West Indies, a small shrub which is widely cultivated throughout the hotter parts of India and Ceylon (Perkin, Chem. Soc Trans 1909, 95, 1855) The stems yield the 'Rozelle hemp' of commerce, and this is obtained by tetting the twigs as soon as the plant is in flower. The yellow flowers are just capable of dyeing yellow, but are not used at all in India for this purpose; on the other hand, the red calyces are employed | ing,' which may also occur during the voyage);

for dyeing in an obscure degree in two remote parts of the country (Burkill, Agricultural Ledger, Calcutta, 1908, No. 2, 13).

COTTON SEED OIL is obtained on a large scale from the seeds of the several species of the cotton tree, Gossypium. In the United States, Gossypium hirsutum (Linn), 'Upland cotton,' covered with 'linters,' is extensively cultivated, whereas the plant grown in the Sea Islands and The Indian in Egypt is G barbadense (Linn) variety of cotton seed is generally assumed to be G herbaceum and G arboreum, whilst the South American cotton plants are frequently classified as a separate species, G acuminatum or peruvianum Formerly the seed not required for planting was mostly wasted, as the oil contained therein could not be refined Cotton seed oil was first expressed in this country in the year 1847. Since then the industry has assumed such enormous dimensions that the annual import of cotton seed to this country from Egypt, the East Indies, and South America amounts to more than 600,000 tons, in addition very con siderable quantities of cotton seed oil are imported from the United States, which produce almost 200,000,000 gallons of oil per annum, of which approximately 50,000,000 gallons are exported to Europe

The seed contains, on the average .-

			1	er cen
Oıl .				200
Water				85
Proteins				20 0
Carbohy	drates			32 0
Crude fit	ore			150
Ash				45

The proportion of oil in the seed varies considerably with the origin of the seed. Thus Egyptian seed contains up to 24 pc of oil, East Indian seed on the average only 18 pc, American 'Uplands' and Jamaica seed 23-24 pc; and Brazilian and Peruvian no more than 20-21 p c of oil The seeds consist on an average of 60 p c of kernel and 40 p c of husk.

A distinction must be made between seed which must be decorticated before crushing, owing to the fine 'linter,' which cannot be removed readily, and seed which is crushed in the undecorticated state Undecorticated seeds are chiefly crushed in England, France, and Germany, from Egyptian, Bombay, and also Smyrna seeds, whereas the vast majority of the American 'Upland seed' must be decorticated before being crushed In some European establishments Bombay seed is decorticated before crushing.

The kernels ('meats') are permeated with cells containing a deep-brown colouring matter; hence the clude cotton seed oil running from the hydraulic presses has a ruby-red to almost black colour The depth of the colour of crude cotton oil depends, in the first instance, on the state of freshness of the seed The American seed, which is, as a rule, crushed shortly after having been harvested, yields a crude oil of a much paler colour than that of crude oil obtained ın England, France, and Germany from Egyptıan seed The palest Egyptian crude oil is obtained When the from fresh seed arriving in October. seed is stored it undergoes deterioration ('heathence the crude oil obtained from Egyptian seed in July and August has a very dark colour.

In the American trade three grades of crude cotton seed oil are recognised, viz. 'prime,' 'choice,' and 'off' qualities The crude oil is refined by treatment with a dilute caustic soda solution, at a temperature not exceeding 120° F, whereby the free fatty acids are neutralised; the soap so formed falls to the bottom and carries with it the brown colouring matter, so that the supernatant oil is of a bright-yellow colour. The oil is then washed free from soap, or, in the case of a technical oil, is treated with bleaching powder, to yield the bright-yellow oil of commerce. The first qualities of cotton seed oil which are not bleached with chemicals are used as edible oils, and are consumed in enormous quantities either as such, as a cooking oil, for tinning sardines, table oil, &c. or in the manufacture of lard substitutes, under such names as salad oil, sweet nut oil, butter oil The last-named product is chiefly used in the manufacture of margarine and compound lard

Official methods for analysing cotton seed oil, and tests for determining its behaviour when refined or bleached, have been published by the Interstate Cotton Crushers' Association, U.S.A. (Oil, Paint and Drug Rep., 1913, June 30; 1914,

Cotton seed oil is, at the ordinary temperature, a pale-yellow oil of characteristic, but not unpleasant, taste. At about 12° 'stearine' deposits This 'stearine' would interfere with the use of cotton seed oil as a table oil or salad oil; therefore the 'stearine' is removed on a large scale by cooling the oil to a low temperature, and filtering off the deposit. The filtered oil is known in commerce as 'winter oil' ('demargarinated cotton seed oil'). According to the requirements of the market, it will not 'cloud' at 40° F. or 32° F, or even at 28° F. The sp gr. of cotton seed oil is 0 923–0 925 at 60° F. The saponification value varies from 190 to 193, and its iodine value from 105 to 115.

The solid fatty acids in cotton seed oil consist chiefly of palmitic acid, small quantities of arachidic acid seem to be present, but stearic acid appears to be absent. The liquid fatty acids would seem to consist of oleic and linolic acids only.

Cotton seed oil eminently typifics a semi-drying oil. In the Livache test (see Oils and Fats) it absorbs 5 9 p.c. of oxygen in 24 hours. By blowing air through cotton seed oil at a temperature of about 90°-100°, oxygen is absorbed, with the formation of a small amount of oxidised acids, the acetyl value of the oil rising at the same time considerably. This reaction is used on a large scale in the preparation of 'Blown Cotton Seed Oil' (see Oils and Fats), which is used in considerable quantities is a lubricating oil in admixture with mineral pils, to produce the 'Marine Lubricating Oils' of commerce.

Cotton seed oil hardened by hydrogenation s used as a solid fat in the manufacture of margarine A typical commercial hardened oil melts at about 38°, and has a saponification value of about 196 and iodine value of about 70.

A reliable test for the identification of cotton eed oil, and for the detection of it in other oils ind fats, down to even 1 p.c. (under favour-

able circumstances), is the Halphen colour test, which is carried out in the following manner: 1-3 cc. of the oil is dissolved in an equal volume of amyl alcohol; to this is added 1-3 ce of carbon disulphide, holding in solution 1 pc. of sulphur flowers The test-tube is immersed in boiling water, or, better, in boiling brine, the carbon disulphide being allowed to evaporate off In the course of 5-20 minutes, a deep-red colouration appears, the intensity of which stands in direct proportion to the amount of cotton seed oil in the sample. The reagent which produces the colouration appears to be an impurity in the amyl alcohol, and the test may be rendered more delicate by substituting pyridine for amyl alcohol. In this way as little as 0 25 pc of cotton seed oil may be detected (Gastaldi, Giorn. Farm Chim. 1912, 61, 289) Although the test cannot be used as a quantitative one, yet it must be considered, if positive, as one of the best means of recognising the presence of cotton seed oil qualitatively. A negative Halphen test is, however, no conclusive proof of the absence of cotton seed oil in a mixture, as the colouring matter is destroyed by heating cotton seed oil to 250°, or by keeping it at 200° for some prolonged time, or by 'blowing' it. Hence 'blown cotton seed oils' do not show the Halphen colour reaction.

**COTTON SEED, COLOURING MATTER OF.** Cotton seeds contain, in addition to cotton-seed oil, a phenolic substance gossypol, which remains dissolved in the oil when this is expressed

By extracting the oil with caustic soda and neutralising the solution thus obtained a voluminous precipitate separates which consists of the colouring matter admixed with fatty acids, and the products of its own oxidation. For the isolation of gossypol Marchlewski (J. pr. Chem 1899, 60, 84) employed a partially purified preparation of this character from which the main bulk of the fatty acids had been eliminated. By extraction with ether, repeated crystallisation from glacial acetic acid, and from a mixture of alcohol and 50, c. acetic acid, it was isolated in the form of small yellow prisms.

As the result of analyses of this substance dried in vacuo over sulphuric acid, Marchlewski suggested two formulæ,  $C_{13}H_{14}O_4$  and  $C_{32}H_{34}O_{10}$ , and of these the first is considered preferable. Preparations dried at higher temperatures appeared to suffer alteration as they thus became darker, and had then a lower melting-point.

Thus the gossypol when quickly heated melted , but when previously dried at 125°-130° at 179°-180°. It is easily soluble in the usual organic solvents, and dissolves in sulphuric acid with a cherry-red colouration, a reaction by which its presence in cotton-seed oil can be detected In alkalis, gossypol dissolves with a yellow colouration which rapidly changes to yiolet, and then slowly fades. The ready violet, and then slowly fades susceptibility of alkaline gossypol solutions to air oxidation accounts largely for the impure nature of the crude colouring matter isolated by such reagents from the oil, and it appears that if care is taken in the process, it is possible to obtain a much cleaner material in the first instance. An alcoholic solution of gossypol gives with ferric chloride a dark-green colouration, and with the neutral and basic acetates of lead a deep-yellow precipitate. The analysis of the

lead salt corresponded to C<sub>13</sub>H<sub>12</sub>O<sub>4</sub>Pb. According to Marchlewski, gossypol yields amorphous acetyl and benzoyl derivatives and appears to possess two hydroxyl groups. It contains no methoxy groups, and is not a glucoside dyes iron mordanted material a grey shade, but the product obtained by a careful oxidation of its alkaline solution possesses, it is stated, tinctorial properties of greater importance. Gossypol can be employed on cotton fabrics as a mordant for the basic colouring matters

F E Carruth (Amer Chem J 1918, xi 4, 647) isolates gossypol from the decorticated cotton-seed kernels which have been crushed by rollers before they are 'cooked' in the oil mill From these a considerable amount of oil is removed by percolation with ligroin, and the residue is then extracted with other and the extract evaporated The product is now treated with one-half to one-third its volume of glacial acetic acid, and on keeping for some days, or more quickly by gentle warming, crystals of gossypol acetate separate purification it is dissolved in ether, glacial acetic acid is added, and the solution evaporated until crystallisation commences

To obtain gossypol itself an ethereal solution of the acetate is treated with water, and the ether distilled off. The gossypol thus remains suspended in the water as crystalline crusts, and may be recrystallised from alcohol

A second interesting method consists in adding aniline to an ethereal extract of cotton seed. The solution after warming on the waterbath gradually deposits on standing an orangeyellow microrystalline precipitate, which apparently consists of an aniline salt of gossypol,  $C_{30}H_{29}O_{9}$ ,  $2C_{6}H_{5}NH_{2}$  or  $2C_{30}H_{29}O_{9}$ ,  $5C_{6}H_{5}NH_{2}$ The yield is practically quantitative, and the process may be used to estimate gossypol in extracts of cotton-seed products

To regenerate gossypol from the aniline compound, it is dissolved in hot alcoholic potassium hydroxide, and the aniline removed by steam distillation From the alkaline liquid the gossypol is precipitated on acidification, and may be purified by conversion into the acetate according to the method given above

Gossypol acetate, a molecular compound of gossypol and acetic acid is evidently the substance described by Marchlewski as the free colouring matter It is a comparatively stable substance, and when heated does not evolve acetic acid readily below 180° Its formula determined by alkali titration is

$$C_{30}H_{28}O_9$$
,  $C_2H_4O_2$  or  $C_{30}H_{30}O_9$ ,  $C_2H_4O_2$ 

Hence gossypol itself is  $C_{30}H_{28}O_9$  or  $C_{30}H_{30}O_9$ , and this result is in harmony with other analytical

figures given in Carruth's paper

Gossipol acetonate, C<sub>30</sub>H<sub>28</sub>O<sub>9</sub> (H<sub>3</sub> CO CH<sub>3</sub>, is obtained as glistening crystals when gossypol is dissolved in acctone, and the solution concentrated Like the acetate it is a stable compound, and when heated at 140°-150° it alters but little in weight

Acetyl and benzovl derivatives of gossypol could not be obtained in a crystalline condition, but as a result of their examination the evidence was sufficient to indicate that four or five hydroxyl groups are present in gossypol. When By the interaction of coumarane and benzoyl gossypol is heated to 186°-190° it fuses with the chloride in the presence of aluminium chloride

evolution of vapour, and then solidifies to a black mass On treating the residue with ether a sparingly soluble yellow crystalline compound B. gossypol separates, which is much less toxic than gossypol and melts at about 246°-248°. Again, by fusion with alkali, a second new crystalline substance C. gossypol can be obtained, and this, which is soluble in alkalis with a blue colour is probably closely related to the purple oxidation product of gossypol referred to above

('otton-seed meal which has been submitted to the 'cooking process' loses much of its toxic property, and contains then practically no gossypol By extracting this product with aniline, the aniline compound of D gossypol which crystallises in orange-yellow prisms can be isolated

Alcoholic potash converts this compound into D quesypol itself, yellow crystals, which

darken and soften at about 256°.

From the cooked meal 1 2 p c of the anilmo compound can be obtained These products have not as yet been closely examined.

COUCH GRASS or Triticum, Agropyrum BP. The dried rhizome of Agropyron repens (Beauv) Is frequently adulterated with Cynodon Daetylon or dog grass A common weed in pasture and arable land Used in pharmacy Therapeutic arable land Used in pharmacy value obscure

COUMARANE GROUP Leuco-benzoyl commarane-

according to v Kostanecki and his co-workers is probably the mother substance of the catechin present in Gambier catechu, though the correctness of this view has not yet been fully established Coumarane or hydro-coumarone, the anhydride of o-hydroxyphenyl ethyl mner alcohol--

$$\mathrm{C_6H_4} \underbrace{\mathrm{CH_2\,CH_2\cdot OH}}_{\mathrm{CH_2\,CH_2\cdot OH}}$$

was first prepared by Alexander (Bei 1892, 25, 2409) by reducing coumarone in alcoholic solution with sodium—

$$\begin{array}{ccc} C_{0}H_{4} & O \\ CH & CH_{2} & CH_{2} \\ \hline Coumarone & Coumarane \end{array}$$

It forms a colourless oil, boiling-point 188°-189°, and gives in sulphuric acid solution by addition of ferrie chloride a violet colouration Stoermer and Gohl (Ber 1903, 36, 2873) have obtained coumarane and its homologues by the action of sodium on o-bromo-phenol brom-ethyl esters according to the following equation -

4 benzoyl-coumarane, colourless crystals, meltingpoint 44°-

is produced (v. Kostanecki, Lampe and Marschalk, Ber 1907, 46, 3660), and when reduced in alcoholic solution, the leuco-benzoyl-coumarane above referred to is obtained

COUMARANDIONE, COUMARANONE v.

KETONES.

COUMARANONE GROUP. Though colouring matters derived from coumaranone (ketocumaran) have not as yet been isolated from natural sources, there is some probability of

their presence in certain flowers, and they are not only historically connected with the earlier attempts to synthesise the flavones, but have in certain instances been successfully converted into flavonols.

Coumaranone (1) is obtained (Friedlander and Neudorfer, Ber 1897, 30, 1077) by boiling acetyl o-hydroxyacetophenone bromide (2) with an aqueous suspension of chalk, or by the action of dehydrating agents on phenoxyacetic acid (3)—

(2) 
$$\begin{array}{c} -0 - \text{COCH}_3 \\ -\text{CO CH}_2\text{Br} \end{array} \rightarrow (1) \begin{array}{c} 0 \\ \text{CO} \end{array}$$

$$\begin{array}{c} \text{CH}_2 \\ \text{HOOC} \end{array}$$

(Friedlander, Ber 1899, 32, 1867), and consists of colourless needles, melting-point 97° condenses with benzaldehyde in the presence of hydrochlone acid with formation of benzylidenecoumaranone-

$$C_{\rm CO}$$
 C=CH  $C_6H_5$ 

which was at first considered by Friedlander and Neudorfer (Ber 1897, 30, 1077) to consist of flavone On substituting protocatechnic aldehyde for benzaldehyde these authors obtained the dihydroxy compound-

and this is a strong dyestuff which gives on aluminium mordanted fabrics an orange, and with iron and chromium mordants brown-coloured shades.

The first colouring matter of this group was, however, prepared in 1896 by Friedlander and Rudt (Ber. 29, 878) from chlorogallacetophenone and benzaldehyde-

$$\begin{array}{c} \text{OH} & \text{OH} \\ \text{OH} & \text{OH} \\ -\text{CO} - \text{CH}_2 \text{CI} \end{array} \Rightarrow \begin{array}{c} \text{OH} & \text{O} \\ \text{CO} \end{array} \begin{array}{c} \text{CH}_2 \end{array}$$

$$\rightarrow \begin{array}{c} \text{OH} & \text{O} \\ \text{OO} & \text{C.CH} \\ \end{array}$$

and from the analogous resacctophenone derivative other hydroxy compounds of this group were obtained later. These are of an orange or orange-red colour, as a rule form oxonium salts, and those possessing tinctorial property dye alum mordant a much more orange shade than the flavone colouring matters. There is indeed a close resemblance in this latter respect between these compounds and the colouring matters derived from chalkone-

$$\bigcirc -\text{CO}: \text{CH-CH-C}_6\text{H}_5$$

(Perkin, Chem Soc Trans 1904, 85, 1465), for butem (a tetrahydroxy chalkone obtained from the Bulea frondown) and the 3 4 3' 4' tetrahydroxybenzylidene coumaranone of Friedlander and Rudt give almost identical shades The benzylidene coumaranones dissolve in sulphuric acid with the production of a red or redviolet colouration, and can thus again be distinguished from flavones which in this manner give either colourless or pale yellow solutions

In 1896 Kesselkaul and v Kostanecki (Ber 29, 1886) suggested that judging by its colour reactions the colouring matters of Friedlander and Rudt were not, as these authors suggested, flavone but rather coumaranone derivatives, and the true constitution of these substances became evident on the synthesis of flavone itself by Feuerstein and v. Kostanecki (l.c.) That benzylidenecoumaranones can be converted into flavanol derivatives has been shown by Auwers and Muller (Ber 1908, 41, 4203), and this transformation is discussed under Flavonol.

Coumaranone is also interesting as the source of ox-indigo-

the oxygen analogue of indigotin. This crystallises in yellow prisms, but does not possess any tinctorial value

Analogous colouring matters can be obtained from diketohydrindene (indandione), this also possessing the reactive methylene group, with aldehydes. Thus by heating this compound with protocatechnic aldehyde at 110°-120° v Kostanecki prepared the dihydroxybenzylidene denvative-

which consists of brownish-yellow needles, melting-point 257°, soluble in alkaline solutions with a red-violet colour and gives yellow shades on aluminium mordanted fabrics

From indoxyl also in a similar way Perkin and Thomas (Chem Soc Trans 1909, 95, 798) prepared dihydroxybenzaldehydeindogenide-

crystallising in orange-red needles, and producing with aluminium mordanted fabrics dull scarlet shades

Chalkone or benzylideneacetophenone is readily prepared by the interaction of acetophenone and benzaldehyde (Claisen, Ber 20, 257)—

$$\begin{array}{c} \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{5}} & \mathrm{CO} & \mathrm{CH}_{3} + \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{5}} & \mathrm{COH} \\ \longrightarrow & \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{5}} & \mathrm{CO} & \mathrm{CH}_{2}\mathrm{CHOH} \cdot \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{5}} \\ \longrightarrow & \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{5}} & \mathrm{CO} & \mathrm{CH} & \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{5}} + \mathrm{H}_{2}\mathrm{O} \end{array}$$

It consists of yellow rhombic prisms, melting-point 57°-58°.

When submitted to hydrolysis it is reconverted into the aldehyde and ketone, a reaction which is the reversal of that given above—

which is the reversal of that given above—
$$C_6H_5 CO CH CH C_6H_5 \\ \rightarrow C_6H_5 CO CH_3 + C_6H_5 CH(OH)_2 \\ \rightarrow C_6H_5 CO CH_3 + C_6H_5 CH(OH)_2$$

$$C_6H_5 CO CH_3 + C_6H_5 CH(OH)_2$$

By the employment of hydroxyacetophenones and hydroxybenzaldehydes, in general previously methylated, numerous chalkone derivatives have been obtained by v. Kostanecki and his co-workers. Only one natural colouring matter of this group, known as butein, has at present been isolated, and the synthetically prepared compounds have been more specially interesting owing to their employment for the synthesis of the flavonol group of colouring matters.

of the flavonol group of colouring matters

Ryan and O'Neill by the aid of diacetoresorcinol have obtained dichalkone compounds.

Thus diacetoresorcinol dimethyl ether and
benzaldehyde form dibenzylidendiacetoresorcinol dimethyl ether, and this by the action of
aluminum chloride is demethylated with production of the free hydroxy compound—

It was obtained as yellow crystals melting at  $196^{\circ}$ – $198^{\circ}$ 

Interesting is the fact shown by these authors that by a variation in its method of preparation four distinct varieties of this dichalkone can be produced. Whereas three of these designated as  $\alpha$ ,  $\beta$  and  $\delta$  are stereo-isomers, the fourth or  $\gamma$  variety is structurally related to the other three

When 2-hydroxychalkone is digested at the boiling temperature with alcoholic sulphuric acid, flatanone (dihydroflavone) is produced according to the following scheme:—

and this is the method generally adopted for the synthesis of flavanone derivatives. On the other hand, though as a rule a chalkone only is produced by the interaction of aldehyde and

hydroxyketone, when gallacetophenone dimethyl ether (Woker, v Kostanecki, and Tambor, Ber 1903, 36, 4235) or quinacetophenone monomethyl ether (v. Kostanecki and Lampe, ibid 1904, 37, 773) are condensed with benzaldehyde in the presence of sodium hydroxide the respective flavanones (1 and 2) are thus directly obtained—

On hydrolysis the flavanones yield chalkones, a reversal of the equation given above. The reaction in these cases is not undirectional, and the conversion of flavanone into chalkone, or chalkone into flavanone, is never complete.

Chalkones which contain hydroxyls in the ortho position to one another, in the position 3′ 4′ are powerful colouring matters, whereas flavanones possessing similar hydroxyls are not dyestuffs, as indeed their constitution indicates. During the dyeing operation, employing mordanted woollen material hydrolysis occurs, with subsequent chalkone production, and the shades produced by them are in reality those derived from the latter. Flavanone crystallises in small colourless needles, melting at 75°-76°.

Biomflavanone (1) by elimination of hydrobromic acid readily yields flavone (2)—

and, again, flavanones may be converted into flavonols.

A G P.

COUMARIN 
$$C_0H_6O_2=C_6H_4$$

$$CH \cdot CH$$

$$O = CO$$

$$(1, 2)$$

$$CH \cdot CH$$

$$O = CO$$

was obtained by Vogel (Gilb Ann 64, 161), in 1820, from the tonka bean (the seed of Dipteryx (Coumarouma) odorata, Willd), or from the melilot (Melilous officinalis, Lam), and from the woodruff (Asperula odorata, Linn), but was mistaken by him for benzoic acid Guibort, however, showed that the crystalline odoriferous principle of the tonka bean was distinct from benzoic acid, and named it coumarin. It occurs in Peristrophe angustifolia (Nees), Achylis triphylla (DC), and in many other plants, and is a normal constituent of lavender oil. It is present in plants as a glucoside, which is decomposed by a ferment present in the plant. This ferment is destroyed by alcohol or boiling water (Molish, J Pharm. Chim. 1902, 279).

It was first obtained synthetically by Perkin by heating the sodium compound of salicylaldehyde with acetic anhydride (Chem. Soc. Trans. 1868, 53); or more simply by boiling together salicylaldehyde, acetic anhydride, and dry sodium acetate (*ibid* 1887, 388; see also Tiemann and Herzfeld, Ber 1877, 284) Acetyl coumaric acid is first formed:

$$\begin{array}{c} \text{C}_{\bullet}\text{H}_{4} \swarrow \text{CHO} + \text{CH}_{3} \text{CO} \searrow \text{O} \\ = \text{C}_{\bullet}\text{H}_{4} \swarrow \text{OCO CH}_{3} + \text{H}_{2}\text{O} \end{array}$$

which then parts with acctic acid, yielding coumarin.

$$\begin{array}{c} \mathrm{C_6H_4} \diagdown \mathrm{CH} \cdot \mathrm{CH} \cdot \mathrm{COOH} \\ \mathrm{OCO\ CH_3} \\ = \mathrm{C_6H_4} \diagdown \mathrm{CH} \cdot \mathrm{CH} \\ \mathrm{O-CO} \\ \end{array} + \mathrm{CH_3 \cdot COOH} \\ \end{array}$$

By treating salicylaldehyde (1 molecule) with excess of acetic anhydride (4 molecules) for 6 hours at 180°, coumarin is formed (Reychler, Bull Soc chim. 1897, 17, 517)

Coumarin is also formed in small quantity by heating a mixture of phenol and malic acid with sulphuric acid

$$\begin{array}{c} \text{CH}_2\text{COOH} \\ \text{C}_6\text{H}_5\text{ OH} + \Big|_{\text{CH(OH) COOH}} \\ = \text{C}_6\text{H}_4 \Big|_{\text{O}-\text{CO}} + \text{CO} + 3\text{H}_2\text{O} \\ \end{array}$$

(Von Pechmann, Ber 1883, 2119, 1884, 929, 1649)

It has also been obtained from o-chlorocinnamic acid which is reduced electrolytically to o-chloro-hydrocinnamic acid and then heated with aqueous sodium hydroxide to 250°, when mellotic acid is produced Thionylchloride converts mellotic acid into mellotic anhydride, from which coumarin results by oxidation with bromine vapour at 270°–280° (Moyer, Beer and Lasch, Monatsh 1913, 34, 1665)

Substituted commarins may be obtained by condensing phenols with acetoacetic ester or with malic acid in the presence of concentrated sulphunic acid

'The condensation of acetoacetic ester or malie acid with substituted phenols (containing alkyl, hydroxyl or dialkyl-amino groups) gives good yields if the groups are present in the positions as shown—

The condensation is, however, prevented by the presence of nitro, carboxyl or carbethoxy groups (Clayton, Chem. Soc. Trans., 1908, 2018). It is also very considerably affected by the concentration of the sulphuric acid used

Coumarm forms rhombic crystals melting at 70°, boils at 290°-290 5°; has a pleasant, aromatic odour; is scarcely soluble in cold water, readily soluble in boiling water, very soluble in alcohol and ether. Crude coumarin may be purified by repeated boiling with light petroleum (Claassen, Pharm J 1897, 161).

It dissolves in caustic alkalis, and is reprecipitated on addition of acids If, however, it is heated for some time with concentrated caustic alkali, or better, with sodium ethoxide, a solution is formed from which acids precipitate

This compound can be reconverted into coumain by heating it with acetic anhydride; but when heated alone it is decomposed, yielding phenol and other substances. Reduction of coumarin with zinc in alkaline solution or sodium amalgam in aqueous solution yields mellotic acid as the chief product, with sodium amalgam and alcohol hydrocoumaric acid is formed (Williamson, J. 1876, 587)

On account of the differences shown between coumarin and thiocoumarin, it has been suggested that the two compounds should be represented by the annexed formulæ:

(Clayton, Chem Soc Trans 1908, 524).

The thiocommarin is produced by heating coumarin with phosphorus pentasulphide, and in contradistinction to coumarin is coloured. It also reacts with phenylhydrazine, yielding coumarin phenylhydrazine (with elimination of hydrogen sulphide), which cannot be obtained directly from coumarin itself. For an account of the synthetic benzotetronic acids (hydroxycoumarin carboxylic acids), see Anschutz, Annalen, 367, 174

In Germany, woodruff (Ger Waldmeister) is steeped in white wine, to which it imparts the pleasant aroma of coumain (Maiwein, Maitank) Instead of woodruff, an alcoholic solution of coumain is employed for the same purpose under the name of Maiweinessenz. In larger doses coumain is stated to have a narcotic action

Coumarin has the agreeable odour of asperula, and is used in perfumery for the preparation of asperula essence. It is also frequently used to adulterate extract of vanilla (q, v) (v) Lactones).

COUMARONE C<sub>8</sub>H<sub>4</sub> CH CH. An oil ob-

tained from the coal-tar fraction boiling between 165° and 175° After the pyridine bases and phenols have been removed by acid and alkali. it is obtained as the dibromide on addition of bromine. The dibromide is reduced to coumarone by alcoholic potash and sodium amalgam (Kraemer and Spilker, Ber 1890, 78) It can also be obtained from this source by adding pieric acid to the mixture of oils, whereby the picrate of coumarone crystallises out. This is separated, decomposed by hot water or dilute alkali, and the coumarone obtained by steam The pieric acid is recovered and distillation used for another operation (Ch. Fab. Act. ges. Hamburg, Eng. Pat. 1422, D. R. P. 53793; Ber. 1891, Ref. 233). Coumarone has been synthesised by heating o-hydroxy-ω-chloreinnamene OH C<sub>6</sub>H<sub>4</sub>·CH: CHCl with potash, hydrogen chloride being eliminated (Komppa, Ber 1893, 2968). It has also been prepared by heating phenoxyacetaldehyde with zinc chloride in

glacial acetic acid (Stoermer, ibid. 1897, 1700).

Coumarone boils at 174 0° (corr.) (Perkin,
Chem. Soc. Trans. 1896, 1249). It is unacted

upon by potash or by hydrochloric acid. Sulphuric acid reacts with coumarone in benzene solution, producing a soluble resinous material paracoumarone ( $C_8H_6O)_4$ , which is used to preserve wood and paper. Other polymerides are known. Coumarone is of interest as, when passed through a red-hot tube with benzene, phenanthrene is produced, and with naphthalene, chrysene is produced (Kraemer and Spilker, Ber 1890, 84). The methyl coumarones are present in the coal-tar fraction of b p 185°–195° (Stoermer and Boes, ibid 1900, 3013)

coumarone resins are prepared by treating solvent naphtha with sulphuric acid. They differ from the pitches by their leady solubility in acctone, and from the condensation products of phenols with formaldehyde by their solubility in petroleum spirit and by not yielding phenol when heated with soda-lime at 260°. They differ from the natural resins in being optically inactive, in having a lower melting-point, saponification value and iodine value. They are classified for commercial purposes according to their colour and hardness, those softening above 50° are termed 'very hard,' between 40° and 50° 'hard,' and between 30° and 40° 'medium hard'. For methods of their examination, see Maicusson, Chem. Zeit. 1919, 43, 109–122. Analyst, 1919, 44, 203

122, Analyst, 1919, 44, 203 If coumarone resins are distilled under ordinary or under reduced pressure they yield yellow oils between 150° and 240°, consisting mainly of coumatone, or partially depolymensed paracoumatone, to gether with indene hydrindene and small quantities of phenol By treatment with condensing agents and catalysts these oils again yield resins varying in character with the nature of the catalyst Coumarone oils are not autoxidisable like drying oils, but when mixed with 4-6 pc of driers, such as the resinates of lead or manganese, they yield dry films. The distinctive oxidation process of coumarone oils is to be attributed to indene (E. Stein, Zeitsch angew Chem 1919, 32, 246)

COUPIER'S BLUE v INDULINES.

COVELLITE. Native cupric sulphide, CuS, crystallising in the hexagonal system—Crystals are tare and have the form of thin six-sided plates. Fine large crystals have been found at Butte in Montana—The mineral has a characteristic indigo-blue colour, hence the name indigo-copper (German, Kupperindig)—It occurs in most copper-mines as a blue, earthy coating on other sulphide ores of copper, and is sometimes found in sufficient quantities to be of importance as an ore, eg at Butte in Montana, and Copiapo in Chile—Covellite—containing platinum (as the mineral speriylite, PtAs<sub>2</sub>) is mined in the Medicine Bow Mountains in Wyoming

The juice of cranberries was examined by Mach and Portele in 1888 (Landw. Versuchs. Stat. 1889, 38, 69), who found a litre of the fresh juice to contain (in grammes)

Invert Acidity (as sugar malic acid) Benzoic Tannic acid acid acid Ash Nitrogen 87.1 19.0 0.75 2.2 3.0 0.11

The sp gr. of the juice averaged 1 0591.

The juice will not ferment with yeast, owing, it is said, to the presence of benzoic acid, but this may be due to the poverty of the juice in introgenous matter, for Otto (Bied Zentr. 1899, 28, 284) found that bilberry juice would only ferment vigorously with yeast after the addition of asparagine (about 0 6 gram per litre) or of ammonium chloride (about 0 3 gram per litre) three.

Rising (Bied Zentr 1915, 44, 163) found in cranberries, benzoic, isovaleric, malic and citric acids, fermentable sugars and a glucoside—vaccinin  $\rm C_6H_{11}O_5$  Bz. The amount of sugar varied from 5 7 to 10 4 pc, and that of benzoic acid from 0 108 to 0 455 pc. The keeping qualities of the fruit are dependent upon the amount of benzoic acid present

The pigment of the cranberry consists of an anthocyanin—a compound of galactose with a cyanidin, the chloride of which has the composition  $C_{15}H_{11}O_6CI$  (Will-statter, Sitzungber K Acad Wiss Berlin, 1914, 12, 402).

Classen (ibid 16, 70) isolated a bitter sub-

Claassen (ibid 16, 70) isolated a bitter substance from cranberries, to which he gave the name oiycoccin, and which he found to give reactions similar to those of arbutin  $C_{12}H_{16}O_{7}$ , occurring in the leaves of the red bearberry, Arctostaphylos Uva-ursi (Spreng)

The ash of cranberry junce contains about 3 pc of phosphorus pentoxide and 47 pc of potash

H I

CREAM OF TARTAR v TARTARIC ACID. CREATINE, Methylglycocyamine, Methylguaninoacetic acid H2N C(NH)NMe CH2 CO2H,H2O discovered by Chevreul (Annalen, 1835, 4, 293) m muscular flesh (χρέας=flesh), occurs in human flesh, in the flesh and blood of many warm and cold blooded animals and in urine (Liebig, Annalen, 1847, 62, 257; Gregory, thid 1848, 64, 105; Schlossberger, thid 1848, 66, 80, Voit, Z. Biol 1868, 4, 77; Price, Chem. Soc Trans 1851, 3, Marcet, thid 1864, 2, 406; Folin and Denis, J Biol Chem 1914, 17, 488, Rose, ibid 1911, 10, 265); the amount varies with the species and the organ; the flesh of fowl yields 3 21 pc; of pigeon, 0 825 pc, of ox, 0 697 pc.; of ox heart, 1 375 pc, of herring, 1 324 p c., and of brill, 0 614 p c (Gregory, l c Beker, Zeitsch physiol. Chem 1913, 87, 28; according to Myers and Fine (J Biol. Chem 1913, 14, 9-12) it is constant for a given animal Okuda, 8th Int Cong App. Chem. 1912, 18, 275.

According to Folm (Amer J. Physiol 1905, 13, 45, 66, 117), van Hoogenhuyze and Verploegl (Zeitsch physiol ('hem 1908, 57, 161), Mellanby (J. Physiol 1908, 36, 447), muscular creatine has its origin in the liver. This organ is continuously forming creatinine from substances carried to it by the blood from other organs, and in the developing muscle. This is changed to creatine, until the muscle is saturated with creatine, when the excess of creatinine is excreted by the kidneys. Cf., however, Folin

CREATINE. 411

and Denis (ibid. 493-496 and 500-501) who suggest that creatine is part of living vertebrate protoplasm and the creatine of muscles a postmortem product, and that creatining elimination is a measure of the total normal tissue metabol-18m and independent of any special function of the liver; see also Myers and Fine (abid 1913, 15, 283-285 and 301-304), Inooye (Zeitsch physiol Chem. 1912, 81, 71-79), Ricser (abid 1913, 86, 415-453, and 1914, 90, 221-235), Myers and Fine (abid 1913-14, 16, 169, and abid 1915, 21, 377), Rose and Dimmitt (J Biol. Chem. 1916, 26, 345); Baumann and Hines (L Biol. Chem. 1917, 21, 540). The acceptance of the literature o (J Biol Chem 1917, 31, 549). The creatine is presumably combined with the muscular proto plasm, for though a readily dialysable substance, it does not pass into the surrounding lymph or blood in vitro, nor is it readily obtainable by diffusion from muscular flesh (Urano, Beiti Chem physiol Path 1907, 9, 104) Cf, however, Folin and Denis (J Biol Chem 1914, 17, 499); Leo and Howe (Pro Amer Soc Biol Chem 1912-13, xlin For the origin of urinary creatine, see Benedict and Osterberg (J. Biol Chem 1914, 18, 195), Myers and Fine (ibid. 1913, 15, 301)

In order to extract creatine, the flesh is heated with its own weight of water at 60°, and the juice expressed. The flesh extract is then heated to coagulate the protein, and filtered, the filtrate is treated with basic lead acctate until no further precipitation occurs, and again filtered after removing the excess of lead from the filtrate by sulphinetted hydrogen, when it is evaporated until creatine separates on cooling; this is washed with alcohol and recrystallised from water (Neubauer, Zeitsch anal Chem 1863, 2, 26; 1867, 6, 33). Creatine may be prepared by the decomposition of creatinine zine chloride by means of calcium hydroxide (Benedict, J. Biol. Chem. 1914, 18, 186).

Creatine is prepared synthetically by heating sarcosine with evanamide at  $100^{\circ}$ 

$$CN NH_2+NHMe CH_2 CO_2H$$
  
=  $NH C(NH_2) NMe CH_2 CO_2H$ 

(Volhard, Z. Chem. N. F. 1869, 5, 318, Strecker, J. 1868, 686), or, together with creatinine, by fusing sarcosine with guanidine carbonate (Paulmann, Beilstein Suppl. 1–657)

Creatine forms colourless transparent monoclinic prisms, containing 1H<sub>2</sub>O, which it loses at 100°; it dissolves in 74 4 parts of water at 18°, or in 9810 parts of cold absolute alcohol, and is insoluble in ether (Liebig, Annalen, 1847, 62, 257). Heat of combustion at constant pressure is 4240 calones (Emery, Benedict, Amer J. Physiol 1911, 28–307). The presence of urea, creatinine, or certain salts, raises the solubility of creatine in water and alcohol (Neubauer, lc). The aqueous solution is neutral, and has a bitter, harsh taste.

Creatine is decomposed by boiling baryta water into sarcosine, urea, and methylhydantoin NH  $C(NH_2)$  NMe  $CH_2$   $CO_2H + H_2O$ 

$$= CO(NH_2)_2 + NHMe CH_2 CO_2H$$

$$CO(NH_2)_2 + NHMe CH_2 CO_2H \rightarrow CO$$

$$NMe CH_2$$

$$NH \cdot CO$$

(Neubauer, Annalen, 1866, 137, 294); or by mercuric oxide and water into oxalic acid and

methylguanidine, or by heating with soda-limeinto ammonia and methylamine. Treated with mercum; acetate in presence of sodium carbonate it yields a-methylguanidinoglyoxylic acid NH2 C(NH) NMe CO ('O<sub>2</sub>H,2H<sub>2</sub>O; glistening flakes, m p 203°-204° (Baumann and Ingvaldsen, J. Biol Chem 1918, 35, 277) When potassium hydroxide is added to an aqueous solution of creatine and silver nitrate until the white precipitate first formed just redissolves, the liquid solidifies to a transparent gelatinous mass immediately reduced on heating, or in the course of a few hours at the ordinary temperature addition of potassium hydroxide to a solution of creatino and mercuric chloride precipitates a white crystalline compound (C<sub>4</sub>H<sub>8</sub>O<sub>2</sub>N<sub>3</sub>),Hg,HgO (Engel, Compt. rend. 1874, 78, 1707, 1875, 80, Creatine is converted into creatinine by heating with dilute mineral acids for some hours (Dessaignes, J 1857, 544), or at 117° for 15 minutes (Benedict and Myers, Amer J Physiol 1907, 18, 362), or by boiling down to dryness the solution of creatine to which has been added an equal volume of hydrochloric acid (Benedict, J. Biol. Chem 1914, 18, 192), or by heating with water only in scaled tubes at 100° for 2-3 days (Neubauer, Zeitsch anal Chem 1863, 2, 33) Smoro-dincev (J. Russ. Phys. Chem. Ges. 1915, 47, 1275-9) obtained a double salt of silver nitrate and creatinine, C<sub>4</sub>H<sub>7</sub>ON<sub>3</sub> AgNO<sub>3</sub> (decomposes 188°-191°) on treating pure creatine with silver nitrate in a slightly acid solution

Creatine forms soluble normal salts with the mineral acids (Dessagnes, Annalen, 92, 409), and readily soluble compounds with zine chloride  $C_4H_9O_2N_3$ , $Z_nC_1$ , and cadmium chloride  $C_4H_9O_2N_3$ , $CdC_1$ , $2H_2O$  (Neubauer, *ibid* 137, 300)

Creatine is not usually estimated directly, it is converted into creatinine (q|r), and estimated as such; for the estimation of creatine in urine, r Benedict (J. Biol. Chem. 1914, 18, 192) and Walpole (J. Physiol. 1911, 42, 301), who makes use of the fact that a pale red colour is given by alkaline solutions of creatine and not by creatinine when a trace of diacetyl is added. For its estimation in blood r Greatine wald (Proc. Soc. exp. Biol. Med. 1917, 14, 115). a. Guaninopropionic acid, alacreatine.

## NH2 ('(NH)NH ('HMe'CO2H

from alanine and cyanamide (Baumann, Annalen. 1873, 167, 83), an isomeride of creatine forms, sparingly soluble prisms

The homologues of creatine are prepared by the action of cyanamide on the corresponding amino-acid in the presence of ammonia, e g α-aminocapiocyamine

from leucine and cyanamide (Duviller, Compt. rend 1886, 103, 211, 1887, 104, 1290). According to Duviller (lc) methyl- or ethylamino- acids yield with cyanamide the corresponding creatinine. The creatine is formed only in the case of methylglycocine and β-methylaminopropionic acid, the latter yielding methylaminopropionic acid, the latter yielding met

from a-methylaminopropionic acid and cyanamide, but prepared  $\beta$ -methylguaninopropionic acid NH<sub>2</sub>·C(NH)NMe·[CH<sub>2</sub>]<sub>2</sub>CO<sub>2</sub>H,H<sub>2</sub>O, mp 201°–202°, from cyanamide and  $\beta$ -methylaminopropionic acid, and  $\gamma$ -methylguaninobutyric acid NH<sub>2</sub> C(NH)NMe [CH<sub>2</sub>]<sub>3</sub>CO<sub>2</sub>H, mp 307°, from cyanamide and  $\gamma$ -methylaminobutyric acid.

Formaldehyde and creatine yield the compound C<sub>6</sub>H<sub>11</sub>O<sub>3</sub>N<sub>2</sub>,2H<sub>2</sub>O, decomposing at 250°, and forming a dibenzoyl derivative C<sub>6</sub>H<sub>9</sub>O<sub>3</sub>N<sub>3</sub>Br<sub>2</sub>, mp 265°-266° (Jaffé, Ber 1902, 35, 2896)

Phthalyldicreatine

C<sub>6</sub>H<sub>4</sub>[CO NH·C(NH) NMe CH<sub>2</sub> CO<sub>2</sub>H],

has m.p 212° (Urano, Beit. Chem Physiol Path 1907, 9, 183). Diacetylcreatine

NH C(NHAc)NMe CH, CO, Ac

has m p 165° (Erlenmeyer, Annalen, 1895, 284, 50) M A W.

CREATININE, Methylglycocyamidine

discovered by Liebig in human urine (Annalen 1847, 62, 268), the amount excreted being 26-30 mg per kilo weight of body per diem (Koch, Amer J. Physiol 1905, 15, 1), is also a constant constituent of the unne of horses, cows, dogs, pigs, and rabbits, it is found in muscle (Shaffer and Reinoso, Proc Soc Biol Chem 1910, 7, xxx, Meyers and Fine, J Biol Chem 1915, 21, 383) and occurs in small quantitative of the control o tities in the flesh of fish, about 0.2 p.c. in the case of cod (Poulsson, Chem Zentr 1904, 11 30), for other estimations, see Okuda (8th Int Cong. App Chem. 1912, 18, 275); and traces (0 000098 p.c., Cooper Colls, J. Physiol. 1896, 20, 107) are found in the blood. According to Folin and Denis (J. Biol. Chem. 1914, 17, 487) normal human blood contains 1 mg creatinine and 6-8 mg of creatinine and creatine per 100 grs. blood In domestic animals it is about the same; in birds 0.1 mg creatinine but 11 mgs creatinine and creatine It is probably a normal constituent of all soils (Shorey, J. Amer. Chem. Soc 1912, 34, 99-107, Sullivan, J Amer Chem Soc 1911, 33, 2035-42) and vegetable matter (Oshima and Arizumi, J Coll Agric Tohoku Imp Univ 1914, 6, 17-25)

Under normal conditions, the excretion of creatinine is constant from day to day and hour to hour (Shaffer, Amer J Physiol 1908, 23, 1), it is not affected by diet or exercise (Folin, ibid 1905, 13, 45, 66, 117. Pekelhating, van Hoogenhuyze Verploegh Proc k Akad Wetensch, Amsterdam, 1905, 8, 363. Klercker, Beit Chem Physiol Path 1906, 8, 59) It is now generally regarded as one of the end products of endogenous nitrogenous katabolism, the liver continuously forming creatinine from substances called to it by the blood, cf, however, Folin and Denis (J. Biol. Chem. 1914, 17, 500-501), part of this creatinine furnishes the muscular creatine by the change it undergoes in the developing muscle, v CREATINE; the rest is excreted by the kidneys (Folin, lc, Mellanby, J Physiol 1908, 36, 447; Lefmann, Zeitsch physiol Chem 1908, 57, 476) In cases of fever or starvation, the amount of urinary creatinine is increased, the material wanted for contraction being drawn from the muscular proteids (Pekelharing, van Hoogenhuyze Verploegh, *l.c.*; Leathes, J. Physiol. 1907, 35, 205). In cancer of the liver, the urinary creatinine is diminished and the creatine is increased (Mellanby, *loc.* 

Creatinine is extracted from urine by evaporating to one-third the original volume, decanting from the salts that crystallise out, precipitating with lead acetate and filtering, removing the lead from the filtrate and precipitating the creatinine as the sparingly soluble double salt with mercuric chloride. This is separated, decomposed by sulphuretted hydrogen, and the creatinine crystallised from the filtrate as the hydrochloride (Maly, Annalen, 1871, 159, 279), or by precipitating it as creatinine potassium picrate with subsequent decomposition of the double salt (Folin, J. Biol. Chem. 1914, 17, 463–467, Benedict, ibid. 1914, 18, 184–190)

For extraction from the body tissues and fluids, see Costantino (Chem Zentr 1915, 11, 287, from Arch farm sper 1915, 19, 254-258) Creatinine bears the same relation to creatine as hydantoin to hydantoic acid

and is prepared by boiling creatine with dilute mineral acids for some hours (Liebig, Annalen, 1847, 62, 628) or by heating at 117° for 15 minutes under pressure (Benedict and Myers, Amer. J. Physiol 1907, 18, 362), or by boiling down to dryness with an equal volume of hydrochloric acid (Benedict, J. Biol. Chem. 1914, 18, 192)

('reatinine can be prepared synthetically by heating guanidine carbonate with sarcosine at  $140^{\circ}-160^{\circ}$  (Horbaczewski, J Pharm Chim 1885, 86) A quantitative yield is obtained by heating N-methylglycocyamine with an organic acid (D R P 281051, from J Soc Chem. Ind. 1915, 34, 637)

By heating creatinine with silver nitrate and baryta in excess on the water-bath for about an hour a nearly quantitative yield of methyl guanidine can be obtained (Ewins, Bio-Chem J. 1916, 10, 104). By oxidation with mercuric acetate it yields α-methyl guanidinoglyoxylic acid (Baumann and Ingvaldsen, J. Biol Chem. 1918, 35, 277)

Creatinine forms anhydrous monoclinic prisms soluble in 11.5 parts of water or 100 parts of absolute alcohol at 16° (Liebig, *Le*), and separates on slow evaporation of dilute solutions in square plates containing 2H<sub>2</sub>O (Salkowski, Zeitsch physikal Chem 1880, 4, 133). It is a weak base, displacing ammonia from its salts, and forming soluble salts with the mineral acids (Liebig, *le*), the picrate C<sub>4</sub>H<sub>7</sub>ON<sub>3</sub>·C<sub>5</sub>H<sub>3</sub>O<sub>7</sub>N<sub>3</sub>, m.p. 212°-213°, crystallises in sparingly soluble yellow needles; the acid picrate

C4H,ON3.2C4H3O7N3

has m p  $161^{\circ}$ - $166^{\circ}$  (Mayerhoffer, Wien. Klin. Woch. 1909, 22 [3]); the tartrate

 $(C_4H_7ON_3)_2\cdot C_4H_6O_6$ 

decomposes at  $207^{\circ}$ – $209^{\circ}$ ; the oxalate

 $(C_4H_7ON_3)_2 C_2H_2O_4$ 

is sparingly soluble in alcohol (Poulsson, Chem. Zentr. 1904, 11 30) Creatinine forms characteristic double salts with platinic chloride (C<sub>4</sub>H<sub>7</sub>ON<sub>3</sub>,HCl)<sub>2</sub> PtCl<sub>4</sub>, orange-red plates, m p 220°-225°, with auric chloride

C4H7ON3 HCl AuCl3

yellow crystals, m p.  $170^{\circ}-174^{\circ}$ , with potassium picrate  $\mathrm{C_4H_7ON_3}$   $\mathrm{C_6H_3O_7N_3}$   $\mathrm{KC_6H_2O_7N_3}$ , lemonyellow prisms, 100 parts of water dissolve 0 1806 part of the salt at  $19^{\circ}-20^{\circ}$ , with zinc chloride ( $\mathrm{C_4H_7ON_3}$ ), ZnCl<sub>2</sub>, almost insoluble in alcohol (Heintz, J. 1847, 48, 883), with mercuric chloride 4( $\mathrm{C_4H_5HgON_3}$  HCl) 3HgCl<sub>2</sub>,2H<sub>2</sub>O(Johnson, Proc. Roy Soc 1886, 43, 493)

Creatinine is converted into creatine by the action of cold dilute animonia or calcium hydroxide solutions, or on treatment with iodine (Reichardt, Pharm Zeit 1911, 56, 922); boiling baryta solution converts it into ammonia and methyl hydantoin, with alkaline oxidising agents it yields methylguamidine and oxahe acid, but is comparatively stable towards acid permanganate solutions (Jolles, Bei 1902, 35, 160)

The presence of creatmine in dilute solution or in urine can be detected by (1) Maschke's test (Zeitsch anal Chem 1878, 134), which consists in the formation of a spaningly soluble double compound of creatinine and cuprous oxide, when the suspected solution is heated at 50°-60° with Fehling's solution, as the cuprous oxide is formed by the oxidation of part of the creatinine, it is advisable to add a little glucose to the mixture, the test is sufficiently delicate to allow of the detection of 10000 part of creatinine (2) Weyl's test (Ber 1878, 11, 2175) consists in the production of a ruby-ied colouration, changing to yellow when, to a solution of creatinine, a few diops of 10 p.c. sodium nitroprusside and the same quantity of 10 p c sodium hydroxide or carbonate solution are added acidifying the solution with acetic acid and boiling, the colour becomes emerald green, changing to blue, due to the formation of Prussian blue (Salkowski, Colasanti, Gazz chim ital 1887, 17, 129). Guareschi (Bei 1888, 21, Ref. 372) has shown that this reaction is given by other compounds than creatinine containing the —CO CH,— complex (3) Jaffe's test (Zeitsch physiol Chem 10, 399) is the production of a deep-red colour, when pieric acid and an excess of sodium hydroxide solution are added to the hquid containing the creatinine Chapman (Chem News, 1909, 100, 175) has shown that the colour is due to the sodium salts of aminodinitrophenol (pieramic acid), and diaminonitrophenol formed by the reduction of the pieric acid by the creatinine; if the creatinine is present in excess, reduction to the colourless triaminophenol occurs.

The older methods for the estimation of creatinine were based upon the isolation of the base in the form of its sparingly soluble double salt with mercuric or zinc chloride, and either weighing the precipitate or estimating the metal

or the mtrogen in the compound (Neubauer, Annalen, 119, 35, Salkowski, Zeitsch physiol. Chem. 1886, 10, 113; Grocco, Chem. Zentr. 1887, 17, Kolisch, *ibid* 1895, 1814, Ladd and Bottenfield, Amer. Chem. J. 1898, 20, 869) Edleson (Chem. Zentr. 1909, 1108) recommends precipitating the sulphate in the presence of alcohol and ether, dissolving it in water, and tirrating the solution with standard barrum hydroxide solution, using phenol phthalein as indicator.

The method generally adopted for estimating creatinine in urine is Folin's colorimetric method, based on Jaffé's reaction (Zeitsch physiol Chem 1904, 41, 223) N/2 potassium dichromate solution is placed to a height of 8 mm in one tube of a Duboseq colonmeter; 100 cc of the urine is placed in a 500 c c flask with 10 c c of a 12 pc solution of pieric acid and 5 cc of a 10 pc solution of sodium hydroxide, left for a few minutes and made up to the mark. If x is the length of this solution in the second tube required to give the same colour effect as the 8 mm, of the standard dichromate solution in the first tube, then  $8.1 \times 10/x = mg$  of creatinine in the 10 cc of the urine If a is less than 5, only 5 c c of urine should be used, if a is greater than 13, then 20 cc of urme should be used If creatine is also present in the urine, the amount may be estimated by first determining the creatinine as above, then converting the creatine in another 10 cc of the urine to creatinine by heating it with 5 c c of N/2 HCl on the water-bath for 3 hours or for 15 minutes at 117° under pressure (Benedict and Myers, Amer J Phys 1907, 18, 362), or by boiling down to dryness with an equal volume of hydrochloric acid (Benedict, J. Biol. Chem. 1914, 18, 191-194), The differand estimating the total creatinine ence between the two results represents the amount of creatmene equivalent to the creatine originally present (For precautions to be observed regarding temperature, time, and dilution, in applying this method for the estimation of creatinine, compare Chapman, Chem News, 1909, 100, 175) Folim and Morris (J Biol Chem 1914, 17, 469-473) recommend the use of a standard solution of creatinine instead of a dichiomate solution; see also Folin and Doisy (ibid 1917, 28, 349-356), Gettler (ibid 29, 47) The presence of dextrose, acetone and acetoacetic acid interferes with the final colour reaction and various suggestions have been made for overcoming the difficulty (Graham and Poulton, Proc Roy Soc 1914, B, 87, 212, Greenwald, J. Biol Chem 1913, 14, 87, Rose, J Biol Chem. 1912, 12, 73–80) Morris, J Biol Chem 1915, 21, 201-208, recommends the preliminary precipitation of creatinine as the double potassium picrate See Bauman and Ingvaldsen (ibid 1916, 25, 196-200) for the quantitative precipitation of creatinine with potassium pierate

An isomeride of creatinine, alacreatinine,

was prepared in 1873 (Ber 6, 1371), and other isomerides have been described by Korndorfer, Arch. Pharm. 1904, 242, 620; Schenck,

ibid 1910, 248, 376, and 1911, 249, 463; Schmidt, ibid. 1910, 248, 568; Johnson and Nicolet (J. Amer Chem Soc 1915, 37, 11, 2417) obtained two methyl glycocyamidines somenic with creatinine by the action of methylamine on the ethyl ester of benzoylpscudo-othylthiohydantore acid

Two isomenic nitrosocreatinines were obtained by Dessaignes (Annalen, 1856, 97, 341) and Marcker (ibid 1865, 133, 305) by passing the nitrous fumes from the action of intric acid on assenious oxide into an acid solution of creatinine. The less soluble a-nitrosocreatinine  $C_4H_8O_2N_4$  decomposes at 2103, forming a colourless liquid that quickly solidines to a brown mass from which a new base  $C_7H_{12}O_2N_{10}$  (?) can be extracted, it forms a crystalline nitrate, hydrochloride, and platinichloride, and yields the bromoderivative  $C_4H_7O_2N_4$  melts at 1953 to a brown liquid and decomposes at 2203

According to Kramm (Chem Zenti 1898, 1 37), the yellow colour formed by the interaction of sodium introprusside and sodium hydroxide on creatinine (cf. Woyl, Ber. 1878, 11, 2175), is due to the formation of a nitrosocialization of a nitrosocialization of the yellow alkaline solution and shaking vigorously. According to Schmidt and Hennig (Arch. Pharm. 1912, 250, 345) this is an oxime, they find that on treatment with sodium nitrite in intricacid solution oxime, in p. 193~194°, and "creatinine oxime, which begins to discolour at 250° but does not melt."

The following acyl- and alkyl- derivatives of creatinine have been prepared Benzoylcreatinine C<sub>11</sub>H<sub>11</sub>O<sub>2</sub>N<sub>3</sub>, pale yellow needles, mp 187° (Urano, Beiti Chem Physiol Path 1907, 9, 183), methyl, dimethyl and trimethyl creatinine and salts (Korndorfer, Arch Pharm 1904, 242, 641, Kunze, Arch Pharm 1910, 248, 578–93).

Methyl creatinine HN C | gives an aurichloride, mp. 170°-171°, and dimethyl creatinine gives an aurichloride, mp. 128°-129°

creatinine gives an aurichloride, in p. 128°-129°, and a platinichloride, m.p. 177°-179° According to Kunze the constitution of dimethyl-NMe CH<sub>2</sub>

creatinine is MeN.C. NMe CH<sub>2</sub>; it reacts as a NMe—CO NH—CO

tertiary base; ethylcrcatinine C NEt NMe—CH<sub>2</sub> (Neubauer, Annalen, 119, 50), see Henzerling (Arch Pharm 1910, 248, 594, the platinichloride crystallises in monoclinic plates, mp 197°-211°, ethylcrcatinine hydriodide, mp 217°-219°, diethylcrcatinine platinichloride 201°-202°);

methylamino-a-butyrocyamidine

(Duvillier, Compt. 1end 1882, 95, 456, 96, 1583, 97, 1486, 100, 916, 103, 211, 104, 1290).—For Xantho-, Cruso-, and Amphi-creatinine v Xanthocreatinine. M A W

**CREOLIN.** A disinfectant consisting of an emulsion of coal tar cresols with soap

CREOSOFORM. A condensation product of formaldehyde and creosote Used as an internal antiseptic

**CREOSOL**  $\hat{v}$  CREOSOTE, WOOD TAR

**CREOSOTAL** (Creosote carbonate) is a mixture of carbonates of the phenols present in word creosote, of which the chief are guaracol and creosol

It is produced by heating creosote with a benzene solution of carbonyl chloride (phosgene) under pressure (Heyden, Fig. Pat. 19074, 1890), but is generally prepared by passing phosgene gas through a solution of beechwood creosote in caustic soda solution. The carbonate separates as an oil, and is washed with dilute caustic soda and finally with water

Crosotal is a viscid yellowish liquid, insoluble in water, but soluble in alcohol, chloroform, benzene, &c (Aufrecht, Pharm Zeit 1908, 53, 480) When it is boiled with caustic potash, the odour of crosote is evolved. It is quite odourless, tasteless, and non-initiant in its action upon the mucous membrane, and is therefore much used as a substitute for crosote in the treatment of bronchial affections and pneumonia, especially in children (Weber, Pharm J 68, 115, Toff, ibid 73, 414) The dose for adults is about 60 grains daily, and it is usually given in an emulsion (Haefelin, Pharm Zeit 49, 141)

CREOSOTE or KREOSOTE (from  $\kappa\rho\epsilon\omega s$ , contracted gentive of  $\kappa\rho\epsilon\alpha s$ , meat, and  $\sigma\omega\zeta\dot{\alpha}$ , I save or preserve). Wood tar, and coal tar, when subjected to distillation, yield fractions technically known as 'creosote,' both of which, the latter more especially, find extensive and important uses in the industrial arts

Reichenbach, in the year 1832, applied the term 'kieosote' to a substance derived from wood tar, and which has been found to possess powerful antiseptic properties, shortly afterwards, Runge discovered carbolic acid in coal tar, and the two products were, for a considerable time, regarded as identical, similar compounds, however, have since been procured from other sources, and in order to prevent confusion, it has been suggested to restrict the use of the term 'creosote' to the use in a generic sense as referring to all the phenols and phenoloid bodies derived indifferently from coal, wood, coke-oven, blast-furnace, and shale-oil tars. The enormous extension of the use of creosote oil from coal tar for the preservation of timber has resulted in the terms 'creosote' and 'creosote oil' being used commercially as meaning the heavier distillates from coal tar and coke oventar, the oils from blast-furnace tar being distinguished as 'blast-furnace creosote'

Wood-tar creosote. The tar derived from the distillation of beechwood, when subjected to further distillation, yields certain fractions that are heavier than water, and which, after agitation with solution of caustic soda, and separation from insoluble oils, are boiled with free access of air in order to oxidise various impurities present, the alkaline solution thus obtained is decomposed with dilute sulphuric acid, the crude creosote which separates is again submitted to a similar alkaline and acid treatment, and the product finally distilled, reserving the traction passing over between 200° and 220°

This represents the ordinary 'wood-tar crosote' of commerce It is a complex mixture of phenoloid compounds, the proportions of which are materially influenced by the method originally followed in distilling the beechwood

from which it was obtained.

Wood-tar crossote, when freshly prepared, is a colourless, transparent liquid of an only consistency, and which retains its fluidity at a very low temperature, its sp gr varies from 1 037 to 1 087; it boils at 205°-225°, and dissolves in about 200 parts of water; its odour is strong and penetrating, resembling that of wood smoke, or rather of smoked meat, it refracts light powerfully and burns with a very sooty flame. Wood-tar creosote is powerfully antiseptic, but its power of coagulating albumen has been denied, nevertheless, it preserves animal substances as effectively as carbolic It is less caustic than carbolic acid, and is not poisonous Wood-tar creosote may be regarded as consisting of a mixture of compounds included in several homologous series, chiefly of acid methylic ethers of catechol, and the presence of the following bodies has been established

CS	stablished		
		ormula	Boiling point
1	Monohydric phenols Phenol, carbolic acid C <sub>8</sub> H <sub>5</sub> OH		182°
	Cresols, cresylic acid $\{C_6H_4(CH_4)\}$	(3)OH	203°
	$X$ ylenols or phlorols $\{C_6H_3(CH_3)\}$		220°
2	Ethyl phenol (1-2) $C_6H_4(C_2)$	H <sub>5</sub> )OH nols	203°
	Gualacol or methyl- C <sub>6</sub> H <sub>4</sub> (O	$_{ m H}^{ m CH_3} \}$	200°
	Creosol or methyl- CaH3(CI	${ m P}_{ m OH}^{ m OH}$	219°
	Dimethyl homocate-	I)(OCH <sub>3</sub> ) <sub>2</sub>	214°-128
	Homocreosol or di- methyl guaiacol C <sub>6</sub> H <sub>2</sub> (CF	$I_3)_2\left\{ egin{matrix} \mathrm{OCH}_3 \ \mathrm{OH} \end{smallmatrix}  ight\}$	230°
	Ethyl guaracol(1-3-4)C <sub>6</sub> H <sub>3</sub> (C <sub>2</sub>		
3	Corulignol or pro- pyl guaracol C <sub>6</sub> H <sub>3</sub> (C <sub>3</sub> : Methyl ethers of trihydric phe	H), {OH }	· 241°
J	100	'H <sub>3</sub> )	
	Dimethyl-pyrogallol $C_6H_3$ Of	$\mathbf{H}^{\mathbf{H}_{\mathbf{J}}}$	253°
	Dimethyl - methyl- C6H2(CF	$I_3$ $\left\{ \begin{array}{l} OCH_3 \\ OCH_3 \end{array} \right\}$	265°
	Dimethyl - propyl- pyrogallol (pica- mar)	'UL'	285°
	$\left. \begin{array}{c} Methyl-propyl-pyro-\\ gallol \end{array} \right\} C_{\bf 6} H_{\bf 2} (C_{\bf 3})$	$_{\mathrm{H_7}}$ $\left\{ _{\mathrm{OH}}^{\mathrm{OCH_8}} \right\}$	290°

Of these compounds, phenol is present in have been deprived o extremely small quantity, paracreosol in larger, guaiacol it contained.

and phlorol in notable proportion, but the two principal constituents of creosote are guaiacol and creosol, although not equally present in all varieties, guaiacol, according to Allen, predominates in Rhenish creosote, whilst with Morson's creosote from 'Stockholm tar,' creosol is the chief constituent Homocreosol and cœrulignol are present in small quantity only, but, according to Gratzel, the latter body possesses such energetic and astringent qualities that a single drop placed on the tongue causes bleeding, purified creosote should therefore be absolutely free from this compound, which may be detected by the blue colouration produced by baruum hydroxide

The less valuable portions of wood-tar crossote were found by A W Hofmann to contain the methyl ethers of pyrogallol and its homelogues, these bodies are of interest from the remarkable colouring matters (originally discovered by Runge) which may be derived from them by oxidation, thus, if the sodium derivative of dimethyl-pyrogallol be mixed with the sodium derivative of dimethyl-methyl-pyrogallol and excess of sodium hydroxide and heated in the air, a substance called cupitlonic actal is formed, according to the following equation —

 $(C_6H_{10}O_3)_2 + C_9H_{12}O_2 + 2O_2 = C_{25}H_{26}O_9 + 3H_2O_2$ 

Eupittonic acid has the constitution of a hexamethoxyl aurin  $C_{19}H_8(O(H_3)_8O_3)$  Reichenbach's 'pittical,' called by Wichelhaus 'eupittone,' was a salt of cupittonic acid Wood-tai crosote has been met with adulteriated to a considerable extent with cuide carbolic and cresplic acids, and from the fact that the reactions of these substances closely resemble those of wood crosote, the distinction between the two, especially when in admixture, is attended with some difficulty. Genuine beechwood tai is soluble in solutions of caustic alkalis, and forms a crystalline compound with potassium hydroxide, but not with sodium hydroxide, on the other hand, it is practically insoluble in strong ammonia

An alcoholic solution should give no colouration whatever (blue or red) with baryta water, such colouring indicates the presence of conulignal and other impurities

The composition of beechwood and oak crossotes, freed from hydrocarbons, is given by Béhal and Choay (Compt rend 1894, 119, 106),

as follows ---

			Beech	Beech	Oak

logues			400	32 1	310
Loss			13	24	

Owing to the demand for gualacol for pharmaceutical purposes, wood-tar creosote, as it occurs in commerce, is frequently found to have been deprived of part or the whole of the gualacol it contained.

Methods for the determination of gualacol in wood crossote are given by Béhal and Choay (Compt rend. 1893, 116, 197), M Adrian (Nouv. Rem. 13, 97); L. F Kebler (Amer J. Pharm. 1899, 409)

Pharm. 1899, 409)

Wood-tar crossote is sharply distinguished from the coal-tar acids by its insolubility in absolute glycerol, it is also distinguished from the coal-tar acids by its reaction with an ethereal solution of nitrocellulose, shaken with half its volume of collodion, BP, Calvoit's No 5 carbolic acid coagulates the gun-cotton Morson's crossote does not precipitate the introcellulose from collodion, but mixes perfectly with the ethereal solution; when a mixture of equal volumes of Morson's crossote and Calvort's No. 5 acid is treated with the collodion, the precipitation is very marked.

Creosote from coal tar and other sources. pharmaceutical circles the term 'creosote' is still retained for products of the carbonisation of wood, but, generally speaking, it is recognised in industry as applying to a mixture, consisting principally of hydrocarbons distilled from coal tar, the latter being either of gasworks origin, or from the carbonisation of coal in coke ovens At the time when anthracene was a valuable commercial product, the fraction of coal tar containing this material was usually collected separately, the crude anthracene being removed by filtration, and the oil separated therefrom being placed on the market under the names 'anthracene oil,' 'green oil,' or 'heavy oil' In more recent times many tar distillers have found the recovery of naphthalene unremunerative, and this is especially the case where the crude tar is of such a nature that an appreciable proportion of solid paraffinoid hydrocarbons appears The whole of the anthracene fraction has therefore frequently found its way to the Other distillates of coal tar crossote storage have also been passed into the creosote tanks at various works, including the 'sharp oil' separated during the recovery of crude naphthalene, and the 'middle oils' or 'carbolic oils,' after treatment for the removal of 'tar acids' (crude There is no very serious objection to this development, especially in view of the fact that inclusion of the anthracene fraction results in a mixture containing a large proportion Creosote of this of high-boiling constituents nature is employed in the United States for railway work, and has been exported in recent times to that country in very large quantities by means of 'tankers.' But exception must be taken to the practice that has arisen in some cases whereby the creosote storage has largely assumed the character of a refuse pit for the disposal of various oils, and even tars, that are only marketable with difficulty, such as blastfurnace tar, blast-furnace creosote, water-gas It is probably most satisfactory to tar, &c regard creosote as a fraction obtained during the distillation of coal tar, either of gasworks or coke-oven origin, collected between the light oil fraction and the anthracene fraction; it may or may not include the middle oils, or those portions of them remaining after partial or complete removal of tar acids or naphthalene.

Creosote from coal tar (gasworks). This consists, for the most part, of a mixture of liquid aromatic hydrocarbons with naphthalene.

The naphthalene may be present in such small quantities that the oils retain it entirely in solution, or there may be so much of it, say up to 40 p.c, or more, that the creosote exists as a solid mass at 15°C. Phenolic and basic constituents are also present, together with small amounts of paraffinoid hydrocarbons. The creosote produced from tar that is made in London and the southern districts of England, where Durham and other north country coals are largely carbonised, contains considerably more naphthalene, as a rule, than that obtained in more northerly districts, where Midland coals are retorted On the other hand, the creosote obtained from Midland tar is far richer in tar acids than that made in London. So characteristic are these features that various creosotes are regularly known in the trade as 'Midland creosote,' 'ordinary London creosote,' &c Scotch creosote will be dealt with later. The carbonisation of coal in gasworks has, during the last few years, developed in several directions. It was formerly the custom to work with 'light charges' of coal in the retorts, with the result that a relatively large free-space existed between the surface of the coal and the top of the retort But about 1911 the practice was widely adopted of employing heavier charges, wholeby the 'free space' was greatly reduced The result of this change of procedure was that the volatile products of carbonisation experienced a much more rapid journey to the ascension pipes of the retort, and consequently the changes they underwent, due to thermal decomposition in the free space, were lessened. The effect of this change on the quality of the tar was very noticeable. The quality of the creosote seems to be very similar to that resulting from 'light charge' carbonisation, but there is more of it in the tar The proportion of naphthalene in the crossote is lower, while the proportion of tar-acids is somewhat higher. The average yield of creosote from coal tar is roughly about 20 pc of the latter by volume

Creosote being a mixture of many hydrocarbons, &c, it is not possible to give any definite figures for its physical and other constants, and the more so as it is highly improbable that any two makes are identical. When a sample of good quality is distilled in the laboratory, the main bulk of it usually passes over between 200° and 300° C, the bulb of the thermometer being immersed in the vapour If the anthracene fraction be present there will be a considerable residue at the latter temperature The calorific value is about 16,050 BTh U The evaporating power (in actual practice, 'from and at 212° F.') is 12 0 lbs. The flash-point usually lies about 170°-180° F (closed test). The refractive index of the higher fractions should be above 1.6 (Sage). Determination of the specific heat between 30° and 100° C. gave the figure 0 398. The coefficient of expansion per °F. is about 0.000455. The specific gravity usually lies between 1 030 and 1 080. Creosote generally contains between 0 5 and 0.9 p.c. of sulphur.

Although these figures naturally differ with the various makes of creosote, and can therefore only be regarded as approximate, they, nevertheless, are frequently found useful in industry, and several serve as evidence of admixture of adulterants of a paraffinoid nature, such as have already been mentioned in this article.

Creosote finds its largest application in the treatment of wood, especially railway sleepers, piles, and telegraph poles. Its employment as fuel is being very rapidly developed, chiefly in burners which serve to atomise the liquid, either by direct application of pressure, or by means of steam or air under pressure. Numerous patents have been granted for such burners, and for further information on the subject, consultation of such works as Brame's Fuel may be recommended. The employment of croosote as a fuel for Diesel engines, with or without pilot ignition, is extending, and the 'Diesel Engine Users Association' has recently issued a specification for the quality of oil considered to be best suited for that particular purpose Croosoto oil is (when freed from naphthalene) used in the preparation of disinfectants and sheep-dips. It is also employed for generating artificial light in specially designed lamps such as the 'Lucigen.'

Lamp-black is manufactured by partial combustion of creosote in a limited air supply Recent experiments seem to indicate the possible

value of crossote as a soil steriliser

The best known methods of creosoting timber are perhaps those of Bethel, Boulton, Ruping, Curtis Isaaes, Lawry, Rutgers In some of these processes the croosote is applied under pressure, occasionally after first placing the timber under a vacuum, and at other times the oil is employed at a temperature sufficiently high to boil the sap out of the wood in vacuo.

Many specifications for creosote considered to be best suited for this work have been published; probably the best known is that of Dr. Tidy. The advantages resulting from the creosoting of timber are summarised by Tidy as follows—

Physical —Choking of pores, and thus rendering the material non-absorbent of water.

Brochemical —Inhibition of germ life.

Chemical —Coagulation of albumen by the tar acids

Probably most of the creosote sold for creosoting at the present time is subject to the American 'Maintenance of Way' specification. The most important feature is the insistence on a large proportion of high-boiling oils. It is estimated that in 1913, 35,000,000 gallons of creosote were exported to the United States from the United Kingdom. At various times emphasis has been given to one or more of the following properties of creosote for treatment of timber:

1. Maximum naphthalene content.

2. Minimum naphthalene content.

3 Tar acids.

4. Proportion of high-boiling constituents.

It is considered that the life of railway sleepers is increased five-fold by creosoting. Experiments by J. M. Weiss (USA.) (see J. Soc. Chem. Ind. 1911, 1348), show that coal tar creosote is more efficient as a preservative than is that from water-gas tar, in the proportion of about 6 to 1. Creosote is used for the treatment of wooden paving blocks, for which purpose it is valuable as a preservative and also as a means of rendering the blocks impervious to

water, the absorption of which would give rise to expansion of the wood.

The following are among the tests commonly applied to creosote —

1 Distillation.

2. Liquidity of residue left after distillation.

3 Water.

4. Solid matter (naphthalene, &c.) deposited at  $60^{\circ}$  F

5. Loss on evaporation under specified conditions

- 6 'Absorbent spot'—a drop of the oil being placed on blotting-paper, and examination made for particles of 'free carbon' indicative of adulteration by crude tars
- 7 Taracids
- 8. Specific gravity.
- 9 Colour.
- 10 Fluorescence
- 11 Refractive index—serving to indicate presence or absence of paraffinoid hydrocarbons, or tars containing them.
- 12 Flash point
- 13. Matter insoluble in benzol.

14. Sulphonation

(Cf Sage, J Soc Chem. Ind 1911, 588.)

Creosote from coke-oven tar is very similar

to that from gasworks tar. Oils from low-temperature processes of carbonisation. A great deal of work has been carried out in investigating the products of these systems Some of the processes are The volatile worked under partial vacuum. products of carbonisation are not subjected to the secondary thermal decompositions that are incidental to high-temperature work in horizontal retorts, with the result that the proportion of aromatic hydrocarbons appearing in the oils is very much smaller, the specific gravity of those fractions corresponding to creosote being The content of tar acids is lower than 1 000 very much higher, though there is but little actual phenol From the highest fractions solid paraffinoid hydrocarbons are frequently deposited. Work by Pictet and Bouvier, on the carbonisation of coal at low temperatures and in partial vacuum, points to the conclusion that the primary condensible products are similar to the constituents of certain petrolcums, consisting to a considerable extent of terpenes and naphthenes No solid aromatic hydrocarbons are present. On subjecting these lowtemperature tars to heat by passage through a tube or over red-hot coke, benzene, naphthalene, anthracene, &c, are formed, the resulting oils being very similar to ordinary coal tar creosote. According to Wheeler, 'vacuum' tar is largely a mixture of ethylenic, naphthenic and paraffin hydrocarbons, and homologues of naphthalene, together with phenoloid compounds, chiefly cresols and xylenols. Aromatic solid hydrocarbons are generally absent D. Trevor Jones concludes that the ordinary products of coal tar result from the action of heat on a tar which is formed in the first instance, and which is similar to that obtained under low-temperature conditions. The naphthenes, paraffins and unsaturated "hydrocarbons are decomposed to produce olefines, which are at their maximum at 550° C. The olefines vanish at 750° with the simultaneous appearance of naphthalene and of large quantities of hydrogen. He further concludes that acetylene plays an insignificant part in the formation of coal tar products. Low temperature carbonisation on the large scale yields a very oily tar amounting to 25 or more gallons per ton of coal. This tar is rich in those oils corresponding in distilling range to the creosote of normal tar. In the carbonisation of cannel coal by such processes as much as 50 gallons of tar is obtained.

Creosote from vertical retort tar is characterised by its low content of naphthalene, its high content of tar acids (chiefly higher homologues of phenol), and the large proportion of paraffinoid bodies present, the latter being sufficient to bring the specific gravity below

1.000.

West introduces steam during the process of vertical carbonisation, using continuous vertical retorts. The yield of tar is increased very considerably and reaches 20 gallons per ton. The tar is of low specific gravity and gives a large 'creosote' fraction. The tars evolved during the carbonisation of coal in vertical retorts are not subject to such high temperatures as in the case of horizontal retorts. Consequently these tars resemble, to a certain extent, the low-temperature products already described. Similar remarks apply to the tars from blast furnaces and from power-gas producers, where coal is employed as fuel

Blast furnace creosote. This is sometimes known as 'phenoloid' It resembles vertical retort creosote in many ways. The specific gravity of the hydrocarbons is low, the proportion of tar acids is high, reaching 20-35 p.c., though there is little phenol. The phenoloids from blast-furnace tar, extracted by Watson Smith, contained only 1.33 p.c. of real phenol, boiling at 182°, whereas the tar acids from Lancashire tars yielded 65 p.c. of crystallisable

carbolic acid

The fractions passing over between 210° and 230° contain phlorol and creosol, and those following at a higher temperature, viz 360°, furnish compounds allied to the cupittonic acid obtained from wood tar

This creosote has a very strong and characteristic odour. Blast furnace crossote, and sometimes even the crude tar from which it is distilled, is often mixed with coal tar creosote, and several of the tests generally applied to the latter are employed for the purpose of detecting

this undesirable adulterant

Blast-furnace creosote oil is now produced in large quantities in Scotland. It is employed to a certain extent for creosoting timber, in producing the 'Lucigen' light, and as a liquid fuel. It furnishes from 20 to 35 p c of phenoloid substances soluble in caustic soda, as against 4 to 7 p.c in London coal-tar creosote, and about 16 p.c for Midland and country make. Allen and Angus have secured by patent their use as an antiseptic under the name of 'neosote,' a word signifying 'new preserver' (Eng. Pat. 11689, August 29, 1887) Experiments have shown that the substance compares favourably with carbolic acid, whilst its caustic properties, when applied to the skin, are much less marked. When freshly prepared, the fluid is almost colourless, and bears a great resemblance to wood-tar creosote.

Creosote from producer tar. -In cases where

bituminous coal is gasified a tar is formed, is creosote from which is similar in several respe to the blast-furnace oil. Tar acids and paffinoids are present in large quantity.

Creosote from water-gas tar is characteristy the absence of tar acids. It is usually r in paraffins, of low specific gravity, and m contain anthracene and naphthalene.

Scotch creosote is characterised by its laicontent of paraffinoid hydrocarbons and con

quent low specific gravity.

Employment of creosote oils for lighting Creosote oil has long been employed as a sou of light in the construction of harbours and o door work, where smoke was of little con quence or inconvenience; but when it is wish to burn this oil to the greatest advantage a with the least possible amount of smoke a soot, it becomes necessary to employ lamps constructed that a jet of air or steam, more less superheated, may be introduced in such manner as to ensure more perfect combustic Hartmann and Lucke (D R P 9195, Aug 1879) constructed a lamp specially intended the consumption of creosote oils, in which the is automatically supplied to a dish-shar receptacle, over which is placed a funnel-shar cylinder In the centre of the dish or recepta receiving the oil from its attached reservoir, placed a conical tube, reaching a little abo the surface of the oil, and through which a jet superheated or dry steam may be driven. using the lamp, the dish or receptacle refer to is allowed to fill with oil, it is then ignited its surface, the funnel-shaped cylinder plac over it, and steam cautiously admitted throu the conical tube It will readily be seen th the arrangement closely resembles the 'He path blowpipe,' with the difference that t steam is forced through a body of co bustible fluid, issuing just above its surface, place of air forced through a body or envelo of combustible gas, and issuing at a point position that may be called its surface

The oil thus burns without wick or chimne and affords a light of 180 standard candles, we an hourly consumption of a little over 2 lbs.

creosote.

An apparatus for a similar purpose has be patented by Lyle and Hannay, under the nat of the 'Lucigen' It consists of an oil tank reservoir, fitted with a special burner at the t of a tube, which may be extended to any lengt into this reservoir compressed air is introduc by an indiarubber pipe, so attached as to ma the 'Lucigen' portable. On the compress air being admitted into the oil tank or receptac it forces the oil up through an internal tube, ar escaping at the same time with the oil in t burner, produces a spray which is set on fire. light of about 2000 candle-power is given by t 'Lucigen.' The flame is large, the light w diffused, and the eyes are not dazzled by There is little or no smoke from the flame, a the lamp burns equally well under heavy ra or spray; it requires no lantern, and has parts which can be damaged by rough usa, In the 'Doty' and 'Wells' lights, pressure brought to bear on the surface of the oil or cre sote by means of an air pump, whereby the oil forced through a coil surrounding the lower po tion of the flame, and becomes distilled into ge CRESOL. 419

Creosote oil has also been employed for the injecting into the brick kilns during the burning purpose of illuminating and heating, by direct conversion into permanent gas. A ton of creosote is capable of yielding 13,300 cubic feet of gas, with an illuminating power of 14 candles, a yield of 29,300 cubic feet may be obtained, but of 81 candle-power only; the chief drawback to this method of utilisation is the high temperature necessary to decompose the oils, which results in the production of low candle-power

Employment of creosote as fuel —Creosote oil is extensively used as a fuel, both for marine and stationary purposes and especially for furnaces for heating iron rods for the manufacture of bolts and rivets. From theoretical considerations, it would appear to be eminently adapted to the purpose, I lb. of coal-tar creosote, when effectively burnt, being capable of evaporatmg 11 24 lbs of water, a result which is considerably in excess of that obtained from coal or coke

Various methods have been devised for burning the oil to the greatest advantage These may be briefly summarised under the · following heads :-

1 Injection into the furnace by means of compressed air with 'atomising' apparatus.

2 Injection into the furnace by means of steam with 'atomising' apparatus.

3 Feeding into the furnace by simple gravitation, alone or in combination with coke.

G F Dexter (Journ Gas Lighting, June 29, 1886, 1242-1244), in a table showing the relative calorific values of certain coal-tar distillates, refers to creosote, or heavy oils, as under .

Average formula C<sub>14</sub>H<sub>16</sub>, bp 240° to 270°

and upwards.

Proportionate weight of constituents:

Carbon			0 93913

Hydrogen units		210

Employment of creosote oil as an antiseptic and for the purposes of a cattle wash and sheep

dip (v. DISINFECTANTS).

Creosote oil is also now largely used to absorb benzene from coke-oven gas. The gas, after the extraction of the ammonia, is passed up towers or scrubbers down which a shower of creosote The creosote oil takes up from 3 to 4 p c of benzene, and this is regained by distillation with steam, the creosote being used over and over again until, by the accumulation of dirt and tar, it becomes too viscid, when it is generally run into the tar well. This fact should not be lost sight of when estimating the proportion of creosote in coke-oven tars.

The heavier portions of creosote oil are also used to absorb naphthalene from coal gas; the gas is passed through washers containing the oil. As the oil tends to abstract some of the illuminants from the gas, it is best to add to the oil before use a small proportion of benzene sufficient to saturate the oil so that no more is absorbed from the gas.

The heavier oils are also used as a rough lubricant for brick-making machinery, and for of the bricks to impart a superficial blue colour to them. The creosote acts as a reducing agent on the iron compounds in the clay, and the red colour is changed to blue

A preparation of heavy creosote or anthracene oil with lime is used as a cart or axle

CREOSOTAL. Syn for Creosol carbonate.

CRESATIN. Acetic ester of m-cresol CRESEGOL. Trade name for the mercury-

potassium salt of cresol sulphonic acid CRESOL C<sub>6</sub>H<sub>4</sub>(CH<sub>3</sub>)OH. The three isomeric cresols exist in coal tar (Williamson and Fairlie, Annalen, 92, 319, Ihle, J pr. Chem [2] 14, 442, Tiemann and Schotten, Ber. 11, 767, 783) in about the following proportions. orthocresol,  $35~\mathrm{pc}$ ; metacresol,  $40~\mathrm{pc}$ , and paracresol, 25p.c (Schulze, *ibid*. 20, 410).

The cresols can be separated from the oily,

non-crystallisable mother liquors obtained in the purification of crude phenol by fractionation and crystallisation, by dissolving them in soda lye, freeing the solution from naphthalene or other hydrocarbons by a current of steam, and then fractionally piecipitating with sul-phuric acid. The first fractions, owing to the greater acidity of phenol, contain chiefly cresols, and are further purified by distillation (Muller,

Zeitsch Chem. 1865, 270)

Various processes have been patented for obtaining meta- and para-cresol from crude cresol Raschig (Eng Pat 18334; D. R. P. 112545; J. Soc Chem. Ind. 1900, 37), by repeated fractionation of the crude cresol, obtains a mixture containing 60 p c of meta- and 40 p c This mixture is then sulphonated of para-cresol by means of concentrated sulphuric acid, in which m-cresolsulphonic acid is easily soluble, but the p-compound only with great difficulty. The mixture is allowed to stand for a week, and the crystals of the p-sulphonic acid are removed, or a soluble sodium salt, such as the sulphate, may be added in quantity sufficient to form the sodium salt of the p-cresolsulphonic acid. The latter is separated from the mother liquor, which consists of m-cresolsulphonic acid and a little sodium sulphate The two cresols are obtained from their respective sulphonic acids by hydrolysis with superheated steam. In another process (Raschig, Eng Pat 25269, J Soc Chem. Ind 1900, 1099) the mixture of the two sulphonic acids is subjected to the action of superheated steam at 120°-130°, the mcresolsulphonic acid alone being hydrolysed under these conditions The m-cresol distils off, and on raising the temperature to 140°-160°, the p-sulphonic acid is hydrolysed and p-cresol is obtained. See also Raschig, D. R. PP. 144903, 146752.

According to the Chem Fabr. Ladenburg (D. R P 148703; Chem Soc Abstr. 1904, i. 312) separation of m- and p-cresols, by partial sulphonation, is incomplete The process recommended is to heat crude cresol with sodium hydrogen sulphate at 100°-110°, dissolve the product in water, when p-cresol separates out as an oily layer, the m-cresol alone being sulphonated. Superheated steam, at 180°, is 420 CRESOL

passed in to obtain *m*-cresol, after the *p*-cresol has been separated.

Another process of the same firm (Eng. Pat. 1881; Fr Pat 339880; D R P. 152652; J. Soc Chem Ind 1904, 759) consists in saturating the crude cresol with milk of lime, when the calcium salt of m-cresol, which is much less soluble than that of the p-cresol, separates out. This is filtered off, decomposed with acid, and relatively pure m-cresol is obtained. The crystals of the calcium salt, before decomposition with acid, may be washed with benzene to free them from the last traces of mother liquor Reihm (D. R. P. 53307; Frdl ii 9) separates m-cresol from p-cresol by means of their barium salts.

Rutgers (Fr Pat. 317512; D. R P. 137584 and 141421; J Soc Chem. Ind. 1902, 1410) treats the commercial mixture with anhydrous oxalic acid or an anhydrous acid oxalate By this means, the oxalic ester of p-cresol alone is formed and separates out. This ester is separated and decomposed by water into p-cresol and oxalic acid; the m-cresol is obtained from the mother liquors

Terrisse (D R P 281054) sulphonates the mixture with acid of 60° Bé, at diminished pressure, neutralises with sodium carbonate and drives off the p-crosol in a current of steam. The residual sodium salts are decomposed by sulphuric acid and the m-sulphonic acid then heated with superheated steam, see also Hoffmann Laroche and Co, Fr Pat 454534

Synthetical preparation of oitho- and paracresol -Pure ortho- and para-cresol can be obtained by fusing the potassium salts of the corresponding toluenesulphonic acids with alkali (Engelhardt and Latschinow, Zeitsch Chem 1869, 620), or by diazotising the corresponding For this purpose the toluidine (15 parts) is dissolved in sulphuric acid of sp gr 18 (15 parts) diluted with 500 parts of water, treated with an aqueous solution of potassium nitrite (12 parts), and the product gradually heated with steam. The resulting cresol is then distilled with steam, the distillate treated with soda lye, then with sulphuric acid, and the liberated cresol extracted with ether and finally distilled in a current of carbon dioxide (Tiemann and Schrotter; Ihle (loc cit ))

Orthocresol can also be obtained from carvacrol by treatment with phosphorus pentoxide (Kekulé, Ber 7, 1006). It is crystalline, sp gr 1 0512 at 15 5°, melts at 30° (T. and S; Ihle; Béhal and Choay, Compt rend 118, 1211); boils at 188 5° (B and C), 188° (T. and S) at 191° (corr) (Perkin, Chem Soc Trans 1896, 1182; Fox and Barker 191 8°), is soluble to the extent of 2 5 vols in 100 vols of water, and on fusion with caustic potash is converted into salicylic acid When intrated, it yields dimitroorthocresol (mp 86°-87°) (Nolting and Salis, Ber. 14, 987). Refractive index at 40° ( $\mu_D$ )

1.53719.

Metacresol is prepared by heating thymol (100 parts) with half its weight of phosphorus pentoxide for 10-12 hours until propylene ceases to be evolved, adding the product to 115-120 parts of fused alkali, and further heating the fused mixture for 5-10 minutes to decompose the cresyl phosphate formed. The fused mass is then dissolved in water, treated with ether to

remove any undecomposed cresyl phosphate and other impurities, acidified with hydrochloric acid, and the separated metacresol extracted with ether, and finally distilled in a current of carbon discussed (Figure 1). The second of the second

dioxide (E and L.; T and S).

Metacresol is also prepared from naphthalene 1 3 3'-, 1 3 6-, or 1 3 8- trisulphonic acids, from analogous hydroxy- or amino-naphthalene monoor di-sulphonic acids or from trihydroxynaphthalene, eg 1 3 3'- naphthalene trisulphonic acid together with half its weight of caustic soda and three-quarters of water, is heated for 5 hours at 280°. The product is poured into water, acidified, boiled to expel sulphurous acid, and filtered m-cresol separates out on cooling (Kalle & Co Eng Pat 16559; D R P. 81484; J Soc Chem Ind 1895, 1800; Hoffmann La Roche and Co D. R. P. 247272) It is ordinarily a liquid of sp gr 1 0387 at 15 5°, but can be obtained in crystals, melting at 2 4° (Fox and Barker); it boils at 202° (corr) (P), and is soluble to the extent of 0.53 vol in 100 vols, of water Its aqueous solution is coloured blue by ferric chloude When fused with caustic potash, it is converted into metahydroxybenzoic acid, and on nitiation it yields a trinitro- derivative (m p  $105^{\circ}-106^{\circ}$ ) (Nolting and Salis, Ber 14, 987, 15, 1858) Refractive index at  $40^{\circ}$  ( $\mu_{\rm D}$ )

Paracresol crystallises in prisms, melts at 36° (Barth, Annalen, 154, 358 [B. and C]), 36°-37° (T. and S), and boils at 198° (I.), at 198°-199° (T. and S, B and C), at 202° (corr) (P); and is soluble to the extent of 1 8 vols in 100 vols. of water—Its aqueous solution gives a blue colour with ferric chloride—When fused with caustic potash, it is converted into parahydroxybenzoic acid, and on nitration it yields a dinitro-derivative (mp 85°) (Richter, Annalen, 230, 313;

Nolting and Salis, lc)

The crude cresol, as obtained from coal tar, is only slightly soluble in water, but its solubility in an aqueous solution of potassium cresol, renders its employment as an antiseptic possible. This solution is named solveol (Lacroix-Hunkiabéyendian, J. Pharm. Chim. 28, 34). The crude cresol is also frequently mixed with soaps, and is used in that form for disinfecting purposes (Dammann, D. R. P. 52129; Frdl. i. 538, Holmers, D. R. P. 76133 and 80260, Frdl. iv. 1119 and 1120; Raschig, D. R. P. 87275; Frdl. iv. 1121; Engler and Dieckhoff, Arch. Pharm. 230, 561; 232, 351).

Oxidation with peroxides at a high temperature converts the cresols into the corresponding hydroxybenzoic acids (Friedlander and Low-Beer, D R. P. 170230, J. Soc. Chem. Ind. 1907.

434).

A mixture of nitro- derivatives, obtained by sulphonating coal-tar cresol and nitrating the sodium salt of the resulting cresolsulphonic acid with nitre acid of sp gr 1·2, has been employed, under the names 'Victoria yellow,' 'saffron surrogate,' as a dye for wool and silk; and, although poisonous (compare Weyl, Ber. 20, 2835; 21, 512), has been used as a colouring matter for butter, cheese, &c. By heating crude cresol with sulphur and alkali sulphide, or with alkalipolysulphides, or with a mixture of sulphur and alkalis, at a high temperature, brown sulphur compounds are obtained which are used for dyeing cotton (Farb. vorm.

CRESOLINE YELLOW v. Azo- colouring

CRESORCINOL v. PHENOL AND ITS HOMO-

CRESOSTERIL. Acid-o-oxalic ester of mcrosol

OH CO'H

CRESOTIC ACID CH3 A homologue of salicylic acid and obtained from o-cresol by similar methods to those employed in preparing salicylic acid from phenol; m p 163°-164°.

CRESYLIC ACID. The non-crystallisable, higher boiling portion of the phenols obtained in the purification of phenol (q v.) is, after redistillation, known commercially as cresylic acid or liquid carbolic acid. It is a colourless, only, refractive liquid, does not solidify at -- 80°, has a sp gr 1 044, and consists of 40 p c metacresol, 35 p c orthocresol, and 25 p c paracresol (Schulze, Ber. 1887, 410). It is much less soluble than carbolic acid in water, ammonia, glycerol, or caustic soda, but more readily so in petroleum spirit It boils at a higher temperature (about 185°-203°), gives a mixture of m-tribromo and o- and p-dibromo derivatives with bromine. It is even more readily acted upon by concentrated sulphuric and nitric acids than carbolic acid (Lunge, Coal Tar and Ammonia, ed 1900, 182, v also Allen, J Soc Chem Ind 1890, 141). Its antiseptic properties are more marked than those of carbolic acid or of either Cf CRESOL. of the three cresols

For a method of estimating phenol in com-mercial cresylic acid, see Fox and Barker (J. Soc.

Chem Ind 1917, 842, 1918, 265 T CRESYL BLUE v. OXAZINE COLOURING MAT-TERS.

CRETAFORM. Oxymethyl cresol tannin. CRISTOBALITE. A native form of silica (SiO<sub>2</sub>) crystallising in the cubic system (pseudocubic) It was first recognised by G. vom Rath in 1886 as regular octahedra up to 2 mm. across, associated with tridymite, in cavities in andesite from the Cerro de San Cristóbal, near Pachuca in Mexico It has since been found in volcanic rocks in the Rhenish district, Central France, and California, and in certain meteorites. The milk-white, translucent crystals are twinned and exhibit optical anomalies, these disappear suddenly at a temperature of 175°, the crystals being then truly cubic; on cooling, the birefringence reappears Sp gr. 234, hardness 6-7, refractive index 149, birefringence 0 0005.

Quartz when heated passes into \$\beta\$-tridymite at 870°, and this in turn passes into  $\beta$ -cristobalite (or metacristobalite, the cubic, optically isotropic modification) at 1470°. On cooling, the latter passes into the birefringent a-cristobalite at 180°-270°. The refractive index of this artificial cristobalite is about 1 484, being slightly higher than that of tridymite (1.477), m.p 1710°. Cubic crystals of silica have also been obtained artificially by heating an aqueous solution of colloidal silica with hydrofluoboric acid at 200° under a pressure of 26 atmospheres. Cristobalite has also been detected in silica bricks. L. J. S.

CRITH. The weight of a litre of hydrogen at 0° and 760 mm pressure—viz 0 0896 gram. CROCEIN, BRILLIANT, ORANGE, SCAR-

LETS, v Azo- colouring matters.

CROCEINE ACID, 2-Naphthol-8-sulphonic acid Used in making croceine scarlet and other dyes.

**CROCIDOLITE.** (Krokydolith, Ger) mineral of the soda-amphibole group, consisting of sodium and non (ferric and ferrous) silicate, NaFe'''(SiO<sub>3</sub>)<sub>2</sub> Fe"SiO<sub>3</sub>. It is known only in a finely fibrous form, its name, in fact, being from κροκύς, κροκύδος, wool. In the trade it is known as blue asbestos, and it is worked for the same purposes as the other varieties of asbestos It is, however, more readily fusible (to a black magnetic glass) than are tremoliteasbestos and scrpentine-asbestos The mineral has been long known from the Asbestos Mountains near the Orange River in Griqualand West, South Africa, where it occurs abundantly as veins, 1 or 2 inches in thickness, in jasperschists The closely aggregated parallel fibres are arranged perpendicularly or nearly so to the walls of the veins, and the material is extracted as slabs It is now extensively mined for commercial purposes (H. F. Olds, Trans. Inst. Mining and Metall. 1899, vii. 122, G. E. B. Frood, The Cape Asbestos Industry, Ann Rep. Govt. Mining. Engineer, Dept. of Mines, S Africa, 1915, and S. African Mining Journal, 1916).

Being an alkali silicate with ferrous iron, crocidolite is especially liable to decomposition when exposed to weathering, sodium is removed, and the iron oxidised and hydrated to form limonite, while the silica is set free. There then results a ferruginous quartz possessing the finely fibrous structure of the original mineral, or, in other words, a pseudomorph of quartz and limonite after crocidolite. This material is coloured a nich golden yellow, and displays a silky lustre, and being at the same time very hard, it is well adapted for ornamental purposes When cut and polished with a convex surface, it displays a cat's-eye effect, and it is extensively used for making knobs, umbrella handles, beads, Such material is known as tiger-eye, though, unfortunately, in the trade the name crocidolite is very frequently misapplied to it. The name pseudo-crocudolite would be more appropriate. In some stones there has been silicification without oxidation, and the indigoblue colour of the original crocidolite has been preserved · material of this kind is known as hawk's-euc The stones have sometimes been coloured artificially by the same processes as adopted in the staining of agate (q v)

L J. S. CROCOITE or Crocoisite. Lead chromate, PbCrO<sub>4</sub>, crystallising in the monoclinic system. The name was originally given in the French form crocoise by F. S Beudant in 1832, from κρόκος, saffron, this was later changed to croconsite, and afterwards to the more correct form crocoite. This mineral is the only chromate of any importance found in nature, and in it the element chromium was discovered. It is found usually as crystals which are bright hyacinthred in colour with a brilliant lustre, the streak is orange-yellow. On exposure to light the crystals soon deteriorate in translucency and

brilliancy Sp gr 60, H 2½-3 Crocoite is a mineral of secondary origin in veins of lead ore and is often associated with gold. It is found at Beresovsk in the Urals (where it was discovered in 1766), Congonhas do Campo near Ouro Preto in Brazil, Luzon in the Philippines, Umtali in Rhodesia, and as very fine crystals at Dundas in Tasmania The mineral has been used as a pigment, being identical in composition with the artificial product chrome-yellow

### CRONSTEDTITE v THURINGITE

CROOKESITE. A selenide of copper, thallium (Tl 16-18 p c ), and silver forming compact masses with lead grey colour and metallic lustre Sp gr 69, H 21-3 It occurs embedded in calcite in the Skrikerum mine, Smaland, Sweden Although a rare mineral it is of interest in being I tions

one of the few minerals containing thallium in

considerable quantity. L. J. S. CROPS. The composition of crops may be regarded from two points of view: (1) the materials they contain, which render them valuable either as food or as sources of some substance of commercial value, (2) the materials they remove from the soil, which must eventually be replaced if the fertility of the land is to be maintained

In Table I, the composition of some of the principal crops grown in the United Kingdom is set out, cereals being excluded because they are dealt with separately The composition of each of these materials shows considerable variations, and the analyses given are either typical or the means of a small number of determina-

[4, Leguminous crops. The leguminous seeds are distinguished by their high protein content. The proteins of the bean and pea and similar seeds have been studied by Ritthausen (Eiweisskorper der Getreidearten, Bonn, 1872) and Osborne (J. Amer Chem. Soc. 1898, 20, 410, Amer. J. Physiol. (1908, 23, 180, &c.) The most abundant of these is the so-called legumin (q v), which, according to Osborne, is a globulin con-Lentils contain a conglutin taining lysine which has been hydrolysed, also some edestin

The leguminous seeds grown in this country contain but a small proportion of oil, which has not received any special examination, the soya bean, however, yields oil up to 20 p c, and is extensively imported from Manchuria and pressed for oil (v. Soya BEAN).

The only carbohydrate in beans, peas, &c, that has received any attention, is the starch, which is abundant and the granules of which possess characteristic shapes The ash of leguminous plants is distinguished by a large proportion of lime, as may be seen from analyses 5-10 in Table II.

Root crops. In these materials, the ether extract contains little, if any, true fat, the mtrogen-containing substances are also very far from being all protein, usually one-half or more of the nitiogen present is combined in various non-protein forms

Potatoes -The characteristic carbohydrate is starch, of which there may be over 20 pc; but sugars (both sucrose and reducing sugars) may be present up to 1 p c, and dextrins or amylans are also present in about the same amount Amongst the nitrogen compounds there are both insoluble and soluble proteins, part of the latter being coagulable by heat or acids, and a large range of amino- bodies, among which tyrosin The non-protein nitrogen has been identified may amount to more than half the total nitro-The darkening of the juice of a fresh potato is due to the black substance formed by the oxidation of the tyrosine under the action of an enzyme, also present in the cells darkening of boiled potatoes is due to some other cause (Ashby, J. Agric Sci. 1905, i. 348). About two-thirds of the ash of potatoes consist of phosphoric acid and potash.

Mangolds.—The characteristic carbohydrate

Aitken, Trans. H & Ag. Soc. 1884, 16.
 Wilson, ibid 1886, 18.

CROPS. 423

present in the mangold is sucrose, which constitutes about 8 p.c of the weight of the root, the total dry matter amounting to about 13 p c. About 0.25 p c of reducing sugar is also present. The variation in the sugar content of mangolds has been examined by Wood (J. Agric. Sci. 1905, 1, 176), who gives the following table.—

Variety	Yield per acre—tons	Dry matter p c	Sugar p c.	Nitrogen p c
White-fleshed globe . , , intermediate Yellow-fleshed tankard . , , , globe . Long red	29 9	10·7	63	0 165
	27 4	12 0	71	0 168
	24 6	13·1	80	0 186
	25 0	13·4	82	0 191
	29 9	13 1	79	0 157

Of the nitrogen in mangolds, only 30-50 p c. is in the protein form, 20-40 p c. is combined as amido or amino-acid and is liberated on hydrolysis as ammonia, while 10 p c. may be in the nitric form

On storage, the mangold loses sugar by respiration, and some of the sucrose becomes changed into reducing sugar, a process which is much accelerated as soon as the temperature rises in the spring (see Miller, J. Roy. Agiic. Soc. 1900, 61, 1902, 63)

1900, 61, 1902, 63)

Sugar beet—In the sugar beet, which has been derived from the same species of Beta as

the mangold, the characteristic carbohydrate is likewise sucrose, which may be present to the extent of 20 p.c. It is always accompanied by a certain proportion of reducing sugars (glucose and maltose), which, in well-grown roots, should not exceed 1 p. c. of the sucrose.

The variations in the amount and nature of the sugars in sugar beet have been subjected to very detailed investigation, for accounts of which the numerous technical works dealing with the beet-sugar industry, should be consulted V Sugar.

The nitiogenous constituents resemble those of the mangold (see Lippmann, Ber 1896, 29, 2645)

Swedes and turnips—In these closely allied roots, the carbohydrates consist of sugars (chiefly reducing sugars, though few data exist) and pectic bodies yielding a mucilage on boiling with water In Wilson's analyses, already quoted, the sugars averaged 4.72 p.c. nitrogen compounds are also largely non-protein, only from 30 to 50 p c. consists of protein. It is generally considered that swedes and turnips grown in the north and especially in the east of Scotland, possess a higher feeding value than the roots grown in the south, analytical data to confirm this opinion are, however, lacking, though it is certain that much larger crops are usually grown in the cooler climate of the north, where the crop can be sown earlier with success.

Ash of crops. In Table II are collected various analyses of the ash of the crops above mentioned

Analyses 8-16 are means taken from Wolff's Aschen-analysen, and have been recalculated to exclude the carbon dioxide present in the ash, as obtained after burning Analyses 1-7 are selected from the Rothamsted records.

Materials removed from the land by average crops. Table III, compiled by Warington from Rothamsted data, shows the amount of the three important constituents—nitrogen, phosphoric acid, and potash, which would be contained in an average crop of the magnitude indicated, and therefore have been removed

from the soil by the crop, except in the case of the nitrogen contained in leguminous crops

A comparison of these figures with the amount of fertilising material usually provided for the crops in question, or the effects of particular manures in field experiments, serves to show that the data contained in Table III. afford no guidance in deciding the appropriate manure for each crop.

The earliest theory of plant manuring, that of Liebig, supposed that the requirements of the plant can best be satisfied by applying to

the land exactly the constituents taken away by a good crop of that particular kind; but the results of the Rothamsted experiments, confirmed by general farming experience, very soon showed that this view was incorrect, because it failed to take into account the enormous amount of plant food contained in the soil, more or less of which would reach the plant according to the method of cultivation and the plant's habit of Moreover, in practical farming the growth supply of manure is largely determined by the place the crop occupies in the rotation and the treatment which has been given to the previous crops. To take an example, wheat and barley withdraw almost the same fertilising materials from the soil, yet all farming experience goes to show that the yield of wheat is chiefly determined by the supply of nitrogen If this element is present in sufficient quantity the wheat plant with its long period of growth is usually able to satisfy its requirements for phosphoric acid and potash from the soil barley, nitrogen is still a most important element in nutrition, but phosphoric acid also exerts a striking beneficial action and is a necessary element in the fertiliser Neither for wheat nor barley need potash be supplied except on very light soils A still more noteworthy example is The table provided by the swede turnip crop shows that an average crop will take away from the soil about 100 lbs of nitrogen, 20 lbs of phosphoric acid and 80 lbs. of potash, yet the usual fertilisers applied to swedes consist almost wholly of phosphatic compounds, with a comparatively small amount of nitrogen and no potash. The majority of the swedes grown in this country receive from 50 to 100 lbs. of phosphoric acid (i.e. about 5 cwt. of superphosphate or basic slag), and the small quantity of nitrogen that would be provided by a light dressing of farmyard manuse or half a hundredweight of sulphate of ammonia. The fertiliser requirements of a crop are in fact conditioned by its specific habit and by the soil (q v) rather than by its composition Certain broad characters may be distinguished. Cereal crops possess considerable powers of obtaining the phosphoric acid and potash reserves in the soil provided they are well supplied with active forms of nitrogen. Leguminous crops rarely require a nitrogenous fertiliser, but respond to mineral fertilisers and particularly to potash, the soil also should be neutral and well supplied with lime. Cruciferous crops are particularly dependent upon an abundant supply of phosphoric acid. Crops elaborating a considerable amount of carbohydrate, e.g. mangolds and potatoes, require potash. In general it may be said that mitrogen promotes leafy development, phosphoric acid maturity, and potash carbohydrate formation and continued growth.

A. D. H.

CROTON OIL is obtained from the seeds of Croton Tiglium (Linn), a tree belonging to the Euphorbiacew, indigenous to the Malabar coast, and cultivated in Southern Asia and China. The seeds contain 53-56 p c of oil

The oil has an amber-yellow, orange, or brown colour, according to its age, it has a nauseous odour, a burning taste, and acts as a very powerful purgative. It blisters the skin and mucous membrane

The chemical composition of croton oil differs so widely from that of all other oils, that its recognition, by means of the 'quantitative reactions' (see Oils and Fats), is easy It contains a considerable amount of volatile acids, hence its Reichert-Meissl value is about 13, its iodine value is 102–106 Saponification value, 210–215, and specific gravity, 0 940 to 0 960. Croton oil is strongly dextro-rotatory (+14 5° to 16.4°).

The variations in the recorded values are mainly attributable to different methods of extraction. Croton oil contains the glycerides of tighe acid, and of butyric, caproic, lauric, myristic and palmitic acids, and probably also olice acid. The vesicating principle is a resinous substance, C<sub>11</sub>H<sub>18</sub>O<sub>4</sub> (Dunstan and Boole, Proc. Roy Soc. 1895, 58, 238).

CROWBERRY (Empetrum nigrum). The

CROWBERRY (Empetrum nigrum). The leaves of the crowberry contain a wax composed of ceryl cerotate, benzoic acid, urson, tannin, dextrose and probably rutin. The anhydrous urson C<sub>10</sub>H<sub>16</sub>O is identical with that obtained from the leaves of Uva Ursi. Empetrum nigrum contains no alkaloids, andromedextrins or glucosides decomposed by emulsion (Van Itallie, Pharm Weekblad, 1918, 55, 709)

CROWN GLASS v. GLASS.

crucibles. A perfect crucible should withstand the highest temperatures without fusion, should bear sudden changes of temperature without fracture, and should be unacted upon by the materials which are to be heated in it. A semi-automatic apparatus for moulding crucibles has been patented by Sims (Eng. Pat. 445, 1888).

1 Wholly or in part derived from the atmosphere,

Clay crucibles are prepared from selected clay; of the Stourbridge clay worked, only about 5 p.c. is available for this purpose. Its plasticity is much increased by exposure for some months in a moist condition to the air. During this process of 'weathering' it becomes disintegrated, and the removal of foreign matter is thereby facilitated. The presence of non pyrites is especially injurious; furnace gases convert it into the oxide which acts as a flux and forms cavities in the crucible Lime is also hurtful, except when in very small quantities and uniformly distributed. Potash and soda are invariably present in clay, and when in small quantity increase the coherence of the crucible without appreciably impairing its power of withstanding the action of heat.

In order to reduce the tendency to crack, and to increase its refractory character, the clay is usually mixed with sand, ground flints, burnt clay (old broken crucibles), graphite or coke These, which are either less fusible than the clay or altogether infusible, form a skeleton which upholds and prevents deformation of the crucibles at temperatures at which the clay would tend to fuse The most refractory crucibles contain the largest proportion of silica.

The clay, which should be of the greatest possible fineness, is well beaten to remove air bubbles and mixed with the proper quantity of the refractory material. According to Berthier (Traité des Essais, 1, 66), when silica is used, it should not be too fine, as the tendency to combine with the clay and thus increase the fusibility would thereby be increased. Crueibles of fine grain are also more liable to fracture.

Small crucibles are usually baked in a kiln, but the large casting pots of Stourbridge clay are not baked until immediately before use When the temperature of the baking is high, the crucible is more liable to fracture on reheating

All clay crucibles are more or less acted upon by litharge, but metals and most ores may be heated in them without danger. Berthier recommends a lining of such material as silica, alumina, or magnesia previously moistened. A lining of chalk renders a crucible less permeable to litharge.

Queneau recommends lining clay crucibles, before drying, with some substance which will resist the chemical reactions for which they are designed and then compressing strongly, drying, and firing (Fr Pat 354319, J. Soc. Chem. Ind. 1905, 1071).

Ciucibles may be rendered non-porous by treating with ferious sulphate solution and firing (Mitchell, U.S. Pat. 894845, J. Soc. Chem. Ind 1908, 886) or by the addition to the clay of chromic oxide, chromites or chrome iron ore, which also renders them much more refractory (Bach, Eng. Pat. 24041, 1903, Klein, U.S. Pat. 787770, Seigle, Fr. Pat. 383593; and Placet, Eng. Pat. 28728, 1896)

The fracture of ciucibles by expansion of

The fracture of ciucibles by expansion of solidifying metal can be prevented by liming with finable material (Colby, U.S. Pat. 830208, J. Soc Chem. Ind. 1906, 934)

Goldschmidt recommends that crueibles for the 'Thermit' process should be lined with a mixture of magnesia or carbotundum and soluble glass (Fi Pat 354597, J Soc Chem Ind 1905, 1114)

Very large crucibles may be built up from cylinders or annular rings of refractory material, provided arrangements are made for tapping the contents without moving the crucible (Reynolds, Eng. Pat. 1004, 1901, Rousseau, Eng. Pat. 7451, 1902)

Stourbridge clay crucibles are made from a mixture of raw ground clay with about one-half its weight of powdered, sifted, old glass pots, from which all adherent glass has been removed, the mixture being made in a disc mill, and kneaded to the proper consistency. Percy gives the composition of the Stourbridge clay used for the best crucibles as silica, 79.25, alumina, 13.57, inon oxide, 1.38, lime, 0.08, magnesia, 0.42, water, 5.11

The following analyses show the composition of certain varieties of cureibles. Nos. 1-7 are by Berthier, No. 8 by Dick, Nos. 9-12 by Brand, and Nos. 13-15 by Mène.—

426 CRUCIBLES.

fracture on sudden change of temperature, but will withstand a very high degree of heat

French crucibles are made from a mixture of 1 part raw Ardennes clay and 2 parts of the same which has been burnt. They are refractory and of fine texture

Cornish crucibles are largely used for copper assaying. They are round, of coarse grain, and of a mottled greyish-white colour. They are kiln-buint, and withstand sudden changes of temperature, but cannot be heated to whiteness Cornish crucibles are now made by the Morgan Crucible Company at Battersea.

London crucibles are of reddish-brown colour and close texture—They will not stand sudden change of temperature, but withstand the action

of litharge fauly well

Silica crueibles may be made of powdered silica, mixed with a highly absorbent substance, e g kieselguhr, saturated with water (Sankey, Eng Pat 3353, 1906, J Soc Chem. Ind 1907, 96) Sand, mixed with a small proportion of cement and water, moulded, dried, and heated to the fusing-point of the sand, forms a very refractory material (Reppey, U S Pat 905295, J Soc Chem Ind 1909, 24) A mixture of sand with a little lime may be used (Berglund, Fr Pat. 366830, J Soc Chem Ind 1906, 1081).

White fluxing pots are made by the Morgan Company from a highly refractory freelay from Rouen (Truchles contaming carbon are now largely used For very high temperatures, crucibles cut from a block of gas carbon or similar material may be employed Clay crucibles may also be filled with a moist mixture of charcoal with starch, treacle, gumwater, or oil, or, for large crucibles, gas tai. The mass is forced with considerable pressure into the crucible and is then cut out, leaving a coating of about \( \frac{1}{6} \) inch in thickness, of the coating is put into the crucible and smoothed with a glass rod. The crucible is then filled with powdered charcoal and heated to redness

Graphite crucibles. For the fusion of metals, plumbago or coke crucibles are of great value, but they are not largely used for assaying. At the Battersea works, the following process of manufacture is employed hand-picked Ceylon plumbago is ground, sifted, digested with dilute sulphuric acid to remove the greater part of the iron, and mixed and kneaded to a stiff paste, with about an equal weight of fine fireclay. The mixture is passed through a pug-mill, and is cut into blocks When required for use, the blocks are again passed through the mill, and made by hand on a wheel or moulded by machinery. They are then dried and baked in saggars These ciucibles may be protected from oxidation by lining them with clay (Woolford, Eng. Pat. 24479, 1898, J. Soc. Chem. Ind. 1900, 52, McDonald, U.S. Pat 828954; J. Soc Chem Ind. 1906, 911)

They are of fine grain, and will withstand the highest temperatures and repeated sudden changes. The graphite is slowly oxidised by metallic oxides or by the furnace gases. To minimise this, the crucible may be coated by dipping in a paste of clay and solution of borax. Any iron which is present in the graphite is liable to become introduced into the melt, and the carbon itself combines with iron or steel (v. Brand, Chem. Zentr. 15, 407; and Dingl. poly. J. 256, 227)

Tar, rosin, &c, may be used to bind the clay and graphite in manufacturing these crucibles (Putz, D R P. 181979; J. Soc. Chem. Ind. 1907, 1030) Digby recommends (Eng. Pat. 3661, 1893) the following composition.—

 Plumbago, 17-mesh granules
 17 parts

 Plumbago, 80 ,
 ,
 2
 ,

 Russian clay
 .
 .
 5
 ,

 China-stone
 .
 .
 5
 ,

 Gas carbon
 .
 .
 2
 ,

The last three ingredients are ground and mixed with water and then the plumbago is added and the crucibles formed, dried at 65° and baked

Salamander crucibles, made by the Morgan Company, contain a much smaller proportion of carbon They withstand sudden changes of temperature perfectly

Lime crucibles are cut from blocks of well-buint (preferably slightly hydraulic) lime.

Magnesia was introduced by Caron as a refractory basic material for making crucibles or for liming reverberatory furnaces for melting and dephosphorising steel Magnesia contracts considerably when heated, it is therefore necessary, before making it into bricks or crucibles, to expose it to a higher temperature than that to which it will be heated. The strongly calcined magnesia is made into a paste with 15-30 pc of raw (slightly calcined) magnesia, and 10-15 p c of water, and is moulded, dried, and baked at a red heat. The highly heated magnesia would not cohere without admixture with the law material Magnesia crucibles are not injured by exposure to the atmosphere Gaudin makes crucibles from a mixture of 1 part magnesia and 1 part bauxite They may also be formed from a mixture of calcined magnesite with from 2 p c to 12 p c of a boron compound (according to the amount of calcium present), moistened, moulded, dried and fired at a high temperature (Rawson and Littlefield, Eng. Pat. 16004, 1900, J. Soc. Chem. Ind. 1901, 992, and *ibid.* 1902, 52). The product is said to resist molten lithage. Porous crucibles for metal refining, are made from a similar mixture with the addition of sawdust (Dobell, Eng Pat 10715, 1897).

Alumina crucibles withstand sudden changes of temperature, and are not affected by the materials fused, even sodium being without action According to Deville's process (Ann. Chim Phys [3] 46, 195), alumina precipitated at low temperature from ammonia alum solution is mixed with an equal weight of powdered marble, and is exposed to the highest temperature of a wind furnace. The mixture so produced, which may be considered as consisting of calcium aluminate, is mixed with its own weight of moist, precipitated alumina, and is made into a crucible, dried and baked (see also Caspar, US. Pat 886111; J Soc Chem Ind. 1908. When the crucible is required to withstand higher temperatures, the amount of the calcium aluminate may be reduced, but the proportion of lime should not fall below 10 to 20 p c.

Bauxite has been used to replace alumina. It is extremely refractory (v. Bauxite, art. Aluminium).

Carborundum crucibles are infusible and

CRYOLITE. 427

resistant to chemical action and have great solidity. They may be made from a mixture of commercial carborundum with sufficient clay to render it plastic (Velter, Fr. Pat 376179; J. Soc Chem. Ind. 1907, 1010; Engels, Eng. Pat 14567, 1901)

A mixture of powdered silica rock or ganister with carborundum or amorphous silicon carbide, may be used. It is mixed with water-glass solution or glue, &c, compressed to shape and heated to the temperature of the electric furnace (Imray and Carborundum Co Eng Pat 19493, 1902; 3308, 1903) (see also Carborundum)

(See further, Kerl, Handb Thonvaaren Ind. 1879, 528-534; and Percy, Metallurgy (Fuel, &c), 1875, 110-141)

an antipyretic.

CRYÖLITE.—(Kryolith, Ger) A native fluoride of aluminium and sodium, found almost exclusively in Greenland, whence it has been sometimes called 'Greenland spar.' The name cryolite, or 'ice-spar' (Eisstein) refers to the general resemblance of the nuneral to ice (κρύσς) and to its ready fusibility in a candle-flame The mineral was discovered by the Danes in 1794, and described in the following year by Schumacher Nearly all the cryolite of commerce is obtained from a single locality at Ivigtut (or Evigtok), on Arsuk-fjord in southwest Greenland This locality was visited by Gresecké, and later by J W Tayler (Quart Jour Geol Soc 12, 140) The cryolite occurs as a large deposit in gness, and contains (especially near its junction with the enclosing rock), a number of metallic minerals, such as galena, pyntes, and chalybite (v. P. Johnstrup, N. Jahrb f. Mm. 1886, 1, Ref. 28, R. Baldauf, Zeitsch. piakt Geol. 1910, xviii 432; O. B. Bøggild, Mineralogia Groelandica, Kjøbenhavn, 1905, O. B. Bøggild, Meddelelser om Grønland, 1912, 1. 107, and Zeitsch. Kryst. Mm. 1913, h. 591. C. P. Bannard, The Combine Min , 1913, h 591 C P Bernard, The Cryolite Mine at Ivigtut, Greenland, Mining Magazine, 1916, xiv 202)

Cryolite is usually found in cleavable translucent masses, of snow-white colour, with a peculiar moist-looking vitreous lustre which renders the mineral easy of recognition. H 25; sp gr. 29-3 Crystals are rare, and their relations have been the subject of much discussion, they are cube-like in habit, and belong to the monoclinic system. There are three perfect cleavages approximately at right angles to one another. Although cryolite is usually white, it is sometimes coloured brown or reddish, and is said to pass downwards, in the Greenland deposit, into a black mass. The black variety loses its colour when heated. Before the blow-pipe cryolite fuses to a white enamel

The composition of cryolite may be represented by the formula 3NaFAIF<sub>3</sub> or Na<sub>3</sub>AIF<sub>6</sub>. This corresponds to 12 8 p.c. Al, 32 8 Na, and 54 4 F. An analysis of the Greenland cryolite

by Chodnev yielded 13 23 p c Al, and 32 71 Na, with 0 83 of  $\rm Mn_2O_3$  and MgO (Verh Petersb. Min Ges. 1845–6, 209). Durnev found in the cryolite of Miask in the Urals, 13 41 p c. Al, 32 31 Na, 0 55 Fe $_2\rm O_3$  and Mn $_2\rm O_3$ , and 0 35 CaO (Pogg Ann. 83, 587) Deville found in the Greenland cryolite 0 018 p c of vanadic acid and a small proportion of phosphoric acid An analysis of cryolite from near Pike's Peak, Colorado, by Cross and Hillebrand yielded Al 12 9, Na 32 4, F 53 55, Fe $_2\rm O_3$ 0 4, Ca $_2\rm O_3$ 0 (Amer. J Sci 1883, xxvi 271)

Cryolite was formerly a rare mineral, but about 1855 it was introduced into Europe commercially, and at once found numerous applications in the arts About 10,000 tons are exported annually from Greenland. By heating finely powdered cryolite with sodium or with magnesium, J Percy and A Dick obtained metallic aluminium (Phil Mag 10, 1855, 364) Deville found that fused cryolite is decomposed by the passage of an electric current, with elimination of free aluminium. At the present time, aluminium is prepared by the electrolysis of bauxite, but the addition of some cryolite is necessary to start the process and to keep it in continuous operation (v. Aluminium)

A wide range of applications was suggested when Julius Thomsen showed in 1850 that cryolite is readily decomposed by heating with calcium carbonate, and that sodium aluminate may be thus obtained

 $Al_2F_6 6NaF + 6CaCO_3$   $= 3Na_2O \cdot Al_2O_3 + 6NaF_2 + 6CO_2$ 

If heated with quicklime, a similar decomposition is effected, of course without evolution of CO<sub>2</sub> The sodium aluminate has been used in the manufacture of alum, and in the preparation of caustic soda for soap making By lixiviation, the aluminate is easily dissolved out, and by the passage of CO2 through the solution, Na2CO3 is obtained, while alumina separates in a gela-The decomposition of cryolite tinous form may also be effected by boiling the finely pulverised mineral with milk of lime By adding an excess of powdered cryolite to the resulting solution the aluminate is decomposed, the alumina being precipitated, while sodium fluoride remains in solution.

$$3Na_2O Al_2O_3 + Al_2F_6 6NaF = 2Al_2O_3 + 12NaF$$

Cryolite can be readily decomposed by the action of sulphuric acid, with formation of sodium sulphate, which can be easily converted into carbonate, but the process, after trial at Copenhagen, has been abandoned in consequence of the inconvenience arising from the evolution of hydrofluoric acid.

 $Al_2F_6 6NaF + 6H_2SO_4 = Al_2(SO_4)_3 + 3Na_2SO_4 + 12HF$ 

The manufacture of soda from cryolite is carried on at Oersund in Denmark, and at Natrona, near Pittsburg in Pennyslvania. The mineral is also employed in the preparation of enamels on iron and for the manufacture of an opaline glass, somewhat resembling porcelain. This glass may be formed by fusing together 100 parts of silica, 35 or 36 of cryolite, and 13 or 14 of oxide of zinc. C. Weinreb has investigated the cause of the milkiness of cryolite glass, and believes that it is due to the presence

428 CRYOLITE.

of aluminium fluoride, which on the cooling of the fused mass, separates in a lighty communited condition, and being distributed through the glass renders it more or less opaque (Dingl poly J 256, 361).

L J S.

cryolithionite. Fluoride of lithium, sodium, and aluminium, Li<sub>3</sub>Na<sub>3</sub>Al<sub>2</sub>F<sub>12</sub>, remarkable in containing a higher percentage of lithium (5 35 p c) than any other mineral. It occurs as large, colourless, rhombic-dodecahedra embedded in the cryolite deposit at Ivigtut in Greenland. Sp gr. 2 77; H. 2½–3; n<sub>Na</sub> 1 3395; in p. 710°. The mineral dissolves in 1350 parts of water at 18°, and from this solution crystallises as cubes.

CRYOSCOPY. So long ago as 1788 Blagden proved that the extent to which the freezing point of an aqueous solution lies below that of water—the depression of the freezing point, as it is called—is proportional to the concentration of the dissolved substance. Nearly a century later, the researches of de Coppet and Raoult showed that when equimolecular proportions of different substances are dissolved in equal quantities of a given solvent, the solutions so obtained have, in general, the same freezing point. It is on these facts that the use of the cryoscopic method of determining the molecular weights of dissolved substances is based.

In comparing the effects of different substances on the freezing point of a given solvent, it is obviously convenient, in view of de Coppet's and Raoult's results, to refer these effects to 1 gram molecule of solute and to some definite quantity of the solvent: in practice, 100 grams of the latter are taken as the standard amount The depression of the freezing point for such a concentrated solution as one containing 1 gram. molecule of solute in 100 grams of solvent cannot be determined directly: it is calculated from the depression observed for a dilute solution, on the basis of the proportionality between depression and concentration An example may be taken to illustrate this point tion containing 0 609 gram of ethyl alcohol in 100 grams of water freezes 0 243° below the freezing point of water; from these data it follows, if proportionality between depression and concentration is assumed, that the depression for a solution containing 1 gram molecule of alcohol in 100 grams of water would  $\frac{0.243 \times 46}{0.609} = 18.4^{\circ}$ Again, a solution 4 276 grams of sucrose in 100 grams of water, freezes 0 237° below the freezing point of water; from these data it follows, as above, that the depression for a solution containing 1 gram molecule of sucrose in 100 grams of water would be  $0.237 \times 342 = 19.0^{\circ}$ . If the depressions pro-4 276 duced by I gram molecule of other non-electrolytes in 100 grams of water are similarly calculated from experimental data, values are obtained which are very close to the figures already quoted. The depression, therefore, for a solution containing I gram molecule of non-electrolyte in 100 grams of water is a constant, independent of the particular solute; the average value of the constant for water, deduced in the empirical way just described, is 18 5°.

For each solvent, a characteristic constant

(k) can be similarly deduced from experimental data. The evaluation of this constant—the 'molecular depression of the freezing point'—is effected, as illustrated above, by the formula  $k = \frac{M}{g} \Delta t$ , where  $\Delta t$  is the depression of freezing point observed for a solution containing g grams of solute in 100 grams of solvent, and M is the molecular weight of the solute

It has been shown by van't Hoff that, on thermodynamical grounds, the molecular depression of the freezing point for any solvent is quantitatively related to the temperature of freezing and to the latent heat of fusion. The relationship in question is  $k = \frac{0.0198T^2}{\omega}$ , where T is the freezing point of the solvent on the absolute scale, and  $\omega$  is the latent heat of fusion per gram of the solvent. The following table shows how far the values of the molecular depression, calculated for various solvents by van't Hoff's formula, are in agreement with those deduced empirically.—

		k	$\boldsymbol{k}$
Solvent		Empirical	('alculated
Water .		$18.5^{\circ}$	$18.6^{\circ}$
Formic acid		$28^{\circ}$	$27.5^{\circ}$
Acetic acid		39°	38 5°
Benzene .		50°	52°
Naphthalene		68 5°	69°
p-Toluidine		53°	51°
Phenol .		75°	74°

The formula  $k = \frac{0.0108 T^2}{\omega}$  is based on the assumption that, when a solution freezes, it is the pure solid solvent which crystallises out. It is not surprising, therefore, that in cases where the crystals separating from the solution contain some of the dissolved substance, eg solutions of thiophene in benzene, the empirical value for the molecular depression, deduced in the usual way, differs considerably from the normal value. In such cases the depression observed is smaller than it would be if the pure solid solvent separated out

When the value of k for any solvent has been ascertained, either empirically by experiments with normal substances of known molecular weight, or indirectly by van't Hoff's formula, it may be utilised in determining the molecular weights of new substances. For this purpose, the formula  $k = \frac{M}{g} \Delta t$  is employed, but now k is taken as known, and M is the quantity to be evaluated. In view of this, the equation may be written  $M = \frac{k}{\Delta t}$ .

It is evident that a determination of the molecular weight of a dissolved substance by the cryoscopic method depends, not on the absolute freezing temperature of the solution, but on the difference between the freezing point of the solvent and that of the solution. This difference can be determined with greater accuracy than can the freezing temperatures themselves. A thermometer with a very open scale, covering only 5°-6°, is employed, and it is convenient, as suggested by Beckmann, to have a reservoir attached to the upper end of the thermometer tube, so that the quantity of mercury in the bulb and stem may be varied according to requirements. This device permits

the use of one and the same thermometer at temperatures, and therefore various solvents. In Beckmann's thermometer, which is the one usually employed in cryoscopic investigations, the scale degree is about 4 cm in length and is divided in hundredths: with the aid of a lens, preferably adapted for sliding up and down the stem, it is possible to estimate 0.001°. The form of the reservoir attached to the upper end of the ordinary Beckmann thermometer is shown in the accompanying sketch. When it is desired to adjust the thermometer for experiments with any given solvent, the bulb is immersed in water of the same temperature as the freezing point of If the top of the mercury thread the solvent

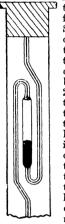

Fig. 1.

should reach a steady position on the upper half of the scale, no further adjustment is needed Should the mercury, after sufficient time has been allowed, extend beyond the scale and into the reservoir, it is necessary to detach a portion This is effected by putting the bulb in water 2°-3° higher than the required temperature, and then gently tapping the upper end of the thermometer until the mercury hanging at the top of the reservoir is separated from the thread. On cooling down again to the freezing temperature of the solvent, the top of the thread should now come to rest somewhere on the upper half of the scale If the quantity of mercury in the bulb and stem is too small, so that when the thermometer is immersed in water of the same temperature as the

freezing point of the solvent, the thread does not reach the scale or appears only on the lowest part of it, the bulb is warmed until the mercury appears at the top of the reservoir. By a throwing movement, some of the mercury at the bottom of the reservoir is jerked up to the top, where it joins the end of the thread. The bulb is then immersed in water 2°-3° above the temperature required, and the final adjustment is carried out in the way already described.

The cryoscopic apparatus commonly employed for the determination of the molecular weight of dissolved substances is that known as Beckmann's. The accuracy of this method, as ordinarily applied, is not great, the error being of the order ±5 p.c. For most laboratory purposes, however, this is sufficient, and it is only when extreme accuracy is required, as in the investigation of very dilute aqueous solutions, that special forms of apparatus have to be employed.

The essential parts of Beckmann's apparatus are seen in the subjoined diagram. A stout glass jar, holding about 1½ litres, is provided with a metal top, at the side of which is a hole for a stirrer, and in the middle of which is another hole capable of holding a large stout test-tube, 3-4 cm. in diameter. The lid and the tube are held in position by springs, as will be evident from the diagram. By means of a cork, there is fitted in the tube another, narrower one, to

hold the liquid under investigation. This tube should preferably have a flat bottom, while the part of it which projects beyond the outer jacket is provided with an auxiliary side tube.

and is itself widened out at the upper extremity The cork with which this inner tube-the freezing tube, as it may be called -is fitted carries the thermometer, and allows also free passage to a stirrer The latter is best made of stout platinum wire, but silver or nickel may be used, provided that the possibility of chemical action is ex-The thermomecluded ter must be fitted in an accurately central position, so that the stirrer may be moved up and down without grating

When a determination of molecular weight is to be made, the freezing tube is charged with a weighed quantity of the solvent, usually 10-20 grams, and the jar is filled with water or a mixture of ice and salt kept at a temperature

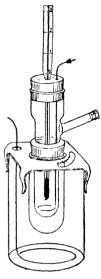

Fig. 2.

4°-5° below the freezing point of the solvent under examination. The freezing tube, with thermometer and stirrer, is immersed directly in the jar, until the temperature has fallen almost to the freezing point. It is then set in the jacket tube and the contents are stirred regularly, while the mercury in the thermometer falls slowly The fall continues until the solvent is more or less supercooled. In the majority of cases, freezing sets in spontaneously before the supercooling exceeds 0.5°, and the liberation of heat results in a rise of the mercury in the thermometer up to a steady maximum position. This is the freezing point of the solvent—the temperature at which liquid and solid solvent are in equilibrium with each other It is advisable, when the thread is rising towards its steady position, to tap the thermometer before taking a reading, and so avoid the possibility of the mercury sticking in the capillary. Should the supercooling exceed 0.5°, crystallisation ought to be initiated, either by stirring very vigorously for a few moments or by introducing a tiny crystal of the solid solvent. Whenever freezing has begun, the solvent must then be stirred with uniform regularity until the constant temperature has been reached.

The freezing point of the solvent having been determined two or three times in the manner just described, a weighed quantity of the solute, enough to give a depression of not less than 0.2°, is introduced, and the freezing point of the solution is then ascertained in the same way as that of the solvent. Subsequent additions of solute are made and the resulting depressions determined as before. One addition, it is true, yields sufficient data for the calculation of the molecular weight of the solute, but it is desirable

CRYOSCOPY. 430

to ascertain also whether the concentration of the solute has any definite and notable influence on the value obtained for its molecular weight It is advisable, further, to redetermine the freezing point of the solvent at the end of such a series of experiments, and so obtain a guarantee that the zero of the thermometer has not changed appreciably during the course of the

Various suggestions have been made from time to time with the object of rendering the simple Beckmann apparatus a more accurate instrument Thus it has been proposed to stir the contents of the freezing tube mechanically instead of by hand The access of atmospheric moisture to a hygroscopic solvent may be prevented by passing a current of dry air into the freezing tube during an experiment, or by using as stirrer an iron ring which is enveloped in platinum foil and is operated electromagne-In this latter case, obviously, communication between the contents of the freezing tube and the outside air can be completely cut off. The same end is attained by employing an ordinary stirrer with a mercury valve. (For a detailed description of these modifications and additions, see Beckmann, Zeitsch physikal Chem. 1891, 7, 323; 1896, 21, 239; 1897, 22, 616, 1903, 44, 169; also Ostwald and Luther's Physiko-chemische Messungen

For the determination of the freezing point of liquids which are obtainable only in small quantities-physiological fluids, for example-Beckmann's apparatus, in its ordinary form, is too large Modifications of this apparatus, suitable for the investigation of blood, urine, &c, have been suggested by various authors (Guye and Bogdan, J Chim. Phys 1903, 1, 379, Burian and Drucker, Zentr Physiol 1910, 23, 772) In these instruments, only 1-2 cub cm. of liquid is required, and it is claimed that the accuracy is of the same order as that attainable with the ordinary Beckmann apparatus this connection, mention ought to be made also of Eykman's apparatus (Zeitsch physikal Chem. 1888, 2, 964, 1889, 4, 497) This con-sists of a small flask, holding about 10 cub cm, into the neck of which is ground a thermometer, graduated in tenths or hundredths of a degree There is no separate jacketing vessel, but the procedure is similar to that followed in the case

As regards the preparation of the cooling bath required in the cryoscopic investigation of aqueous solutions, the usual mixture of ice and common salt solution may be replaced in some cases by a mixture of ice and a solid salt, which gives a steady eutectic temperature suitable for this purpose, with the eutectic temperatures obtained when they are mixed with ice, are alum,  $-0.47^{\circ}$ ; sodium sulphate.  $-0.7^{\circ}$ ; potassium dichromate,  $-1.0^{\circ}$ , potassium sulphate, -1 5°; copper sulphate, --2 0°; otassium nitrate,  $-3.0^{\circ}$ ; zinc sulphate,  $-5.0^{\circ}$ ; barium chloride,  $-7.0^{\circ}$ . Another kind potassium nitrate, of cooling bath was used by Raoult, who surrounded the jacketed freezing tube with ether, and passed through the latter a current of dry air (Compt. rend. 1896, 123, 476; Zeitsch.

of the Beckmann apparatus

any point between room temperature and  $-15^{\circ}$ .

When it is desired to find the molecular weight of a new substance, the question of the most suitable solvent arises. The choice is frequently limited by the solubility of the substance, it may be appreciably soluble in only one or two of the more common solvents. Apart from this, however, there are other considerations which must be taken into account. Extensive investigation has proved that with certain combinations of solvent and solute, the cryoscopic method gives abnormal values for the molecular weight of the dissolved substance. Pre-emmently is this the case when the solvent is water and the solute is an acid, a base, or a salt, in short, an electrolyte; under these circumstances, the value found for the molecular weight of the solute is abnormally low. On the other hand, the influence of substances containing the hydroxyl group (alcohols, acids, phenols, oximes) on the freezing point of hydrocarbons (benzene) and allied indifferent solvents, is such as to lead to abnormally high values for the molecular weight The cryoscopic investigation of solutions of acetic acid in benzene indicates that the formula of the acid is more correctly represented by (CH3 COOH), than by CH, COOH Again, while the molecular weight of alcohol in benzene is nearly normal in dilute solution, the value increases rapidly as the concentration of the alcohol rises The combinations of solvent and solute which lead to abnormally high values of the molecular weight have been studied in detail by various workers (Auwers, Zeitsch physikal Chem 1893, 12, 689, 1894, 15, 33; 1895, 18, 595; 1896, 21, 337; 1897, 23, 449, 1899, 30, 300, 1903, 42, 513, 629, Biltz, *ibid* 1899, 29, 249; Robertson, Chem Soc Trans. 1903, 83, 1425; 1904, 85, 1427; 1005, 27, 1874, 1006, 20, 247; 1447 1905, 87, 1574; 1906, 89, 567). 1617; should be noted that in cases also where the dissolved substance crystallises out along with the solvent, the depression of the freezing point is abnormally small, and the value of the molecular weight calculated therefrom is correspondingly high.

For the cryoscopic determination of the molecular weights of dissolved substances a method of moderate accuracy is sufficient, and an experiment may be carried out with a comparatively small quantity of liquid The case is different with the problem of finding the exact depression of the freezing point for very dilute aqueous solutions—a problem to which much attention has been devoted because of its bearing on the theory of solution It was early evident that the cryoscopic investigation of very dilute solutions involves special difficulties, for the discrepancies between the results obtained by different workers were very considerable Thus the molecular depression for water, based on experiments with sucrose in which the actually observed depressions amounted only to about 0 05°, was found by Arrhenius to be 20 2°, by Raoult, 20·7°; by Jones, 21·8°; and by Loomis, 18·1°, instead of the theoretical value. 18.6°. Subsequent investigations (Nernst and Abegg, Zeitsch. physikal. Chem 1894, 15, 681; physikal. Chem. 1898, 27, 617). By careful Abegg, ibid. 1896, 20, 207; Wildermann, Phil. regulation of the rate at which the air is forced Mag. 1895, 40, 119; Proc Roy. Soc 1896, 251; through the ether, the bath can be adjusted to Raoult, Zeitsch. physikal. Chem. 1898, 27, 617)

have made it clear what conditions must be fulfilled if the freezing point depression for a dilute aqueous solution is to be determined with certainty to 0 001°. It will be sufficient here to indicate these conditions briefly.

As regards the thermometer, it is essential that a telescope be used for reading the position of the mercury, and that the bulb of the instrument be kept at about 0° during the whole of a series of experiments The influence of alterations in the atmospheric pressure cannot be neglected, for it appears that a difference of 1 mm mercury has about the same effect on a Beckmann thermometer as a temperature change of 0 0002° On similar grounds, the thermometer must be immersed always to the same depth in solvent and solutions It should be mentioned here that platinum resistance thermometers have been used in accurate cryoscopic work instead of the Beckmann instruments (see Chrustchoff, Compt rend 1900, 131, 883, 1901, 133, 955, Bedford, Proc Roy. Soc. A, 1910, 83, 454) The difference between the freezing points of solvent and solution has also been determined thermoelectrically (Haus-Tath, Ann Physik. 1902, [iv] 9, 522; Jahn Zeitsch physikal Chem. 1907, 59, 31, Flugel, *ibid.* 1912, 79, 577; Adams, J. Amer. Chem Soc. 1915, 37, 481).

The temperature of the cooling bath is a matter which has to be carefully considered, if the freezing point depression for a dilute solution is to be correctly determined. Suppose that in an experiment with the ordinary Beckmann apparatus the aqueous solution in the inner tube cools without freezing, it is obvious that the lowest temperature to which the solution can fall must be higher than that of the cooling bath, because of the heat conducted from the air to the solution through the thermometer. stirrer, and tube, and because of the heat generated by the stirring This lowest temperature, which the contents of the freezing tube tend to assume when no freezing takes place, is known as the convergence temperature difference between the convergence temperature and the temperature of the cooling bath varies, of course, with each apparatus, it decreases as the facility for heat exchange between the solution and the external air is lessened, and as the rate of stirring is diminished Suppose now that the solution under examination has become supercooled, and that it has reached the convergence temperature. The introduction of a crystal of the solid solvent at this stage initiates the freezing process; heat is liberated and the temperature of the solution rises. Inasmuch, however, as the solution is no longer at the convergence temperature, there is an influence at work tending to lower the temperature of the solution, so that the latter never reaches its true freezing point the maximum position reached by the mercury is only what may be called the apparent freezing point of the solution. Similarly, when the freezing point of the solution lies below the convergence temperature, an apparent freezing point is observed which is somewhat higher than the true freezing point. In both cases, the apparent freezing point lies between the true freezing point and the convergence temperature. In view of these considerations, it is necessary, in cryoscopic work

of the most accurate kind, either to adjust the cooling bath so that the convergence temperature and the freezing point are practically the same, or to apply a correction to the apparent freezing point (see Raoult, lc; Nernst and Abegg Lc)

Abegg, lc)

The freezing point of a solution is the temperature at which the solution and the solid solvent are in equilibrium, and in order that this equilibrium, and therefore the freezing point, may be well defined, it is essential that a considerable quantity of solid should be in contact with the solution. In the case of aqueous solutions, this has generally been effected by supercooling to the extent of 05° or 10°, and then introducing a crystal of ice If this method is adopted, then a correction must be made for the charge of concentration resulting from the separation of ice Some workers, however, determine the freezing point by adding the cooled solution to a fairly large quantity of finely divided ice, and then observing the steady temperature shown by a thermometer immersed in the mixture (see Walker and Robertson, Proc Roy Soc Edin 1903, 24, 363, Richards, J Amer Chem Soc 1903, 25, 291, Jahn, Zeitsch. physikal Chem 1904, 50, 129; Roth, *ibid*. 1912, 79, 601, Adams, J Amer Chem. Soc 1915, 37, 481, compare also Prytz, Ann Physik 1902, [iv] 7, 882) In this method of procedure, equilibrium between the two phases is very rapidly established and the concentration of the liquid is ascertained by an analysis made subsequently to the determination of the freezing point

It has already been pointed out that the freezing point depression is proportional to the number of dissolved units. The cryoscopic number of dissolved units. The cryoscopic method may therefore be employed, not only in the determination of the molecular weights of dissolved substances, but also in the study of the question whether in a particular case a change in the number of dissolved units takes place. It is found, for instance, that the freezing points of potassium iodide solutions are not appreciably affected by the addition of iodine, which shows that the iodine must combine with the units already present in the solution (see Le Blanc and Noves, Zeitsch physikal Chem 1890, 6, 385, Paterno and Peratoner, Gazz chim ital 1890, The cryoscopic method may similarly be employed in following the course of a reaction between dissolved substances which involves a change in the number of units, as for instance, the inversion of sucrose (see Kahlenberg, Davis, and Fowler, J Amer Chem Soc 1899, 21, 1). CRYSTALLISATION. Crystals are often produced during the concentration of liquors in evaporating pans. Hand or mechanical scrapers are used for removing these crystals continuously. Such crystals are generally too

impure for sale and are redissolved in sufficient hot water to produce a solution, which, after clarification by subsidence or filtration, will yield, in the crystallising pan, bright and marketable crystals. The temperature and concentration of the solution, to yield the best result, have to be determined for every substance mother liquor is run off and the crystals transferred to drainers or centrifugal machines to be dried before packing In some instances, several repetitions of this treatment are made, and the crystals are washed with water or liquor after each treatment. The crystallising pans are made of materials which give the best economic result, either they resist the mother liquors or, if attacked, do not spoil the product by discolouration or too much impurity iron tanks about 2 feet deep with bottoms sloping to the outlet and rounded corners, are Wooden tanks unlined or lined with common sheet lead, zinc, tin, or other metal, are used Some manufacturers suspend roughened strips of metal in the pans, to which the crystals adhere For rapid production, crystallisation by repose is now giving place in many industries to crystallisation in motion crystallising vessels are provided with circulating blades or with compressed air jets, so that the crystals as they form are prevented from adhering to the sides of the vessel, but remain suspended in the liquor, which, on complete cooling, flows directly to the centrifugal machines for the separation of the mother liquor These crystals are purer and more convenient to handle than those obtained by repose methods In the case of deliquescent substances and also in those instances where the mother liquor is sufficiently pure to make it unnecessary to purify by crystallisation, the liquor is concentrated in film evaporators so that only sufficient water remains in it to form the crystal hauor produced is run into drums, and forms on cooling, a solid block of crystals In some works, the liquor is run into a jacketed worm conveyor so that the crystals which form, leave the apparatus in a loose state

The capacity of crystallising plant can be determined from a knowledge of the physical data involved When crystallising by repose methods the rate of evaporation of the solution is given very closely by the utility formula:

$$\mathbf{W} = \left(\frac{p_{e} - p_{d}}{50}\right)^{1.2}$$

where W is the weight of water in kilograms evaporated per hour per square metre of surface of the liquid,  $p_e$  is the vapour pressure of the solution in mm of mercury at the temperature under consideration, and  $p_d$  is the pressure of the aqueous vapour in the atmosphere of the factory. If a draught with a velocity exceeding (say) 1 metre per second is produced in the crystallising room, the figure given by the above formula will be low, and should be multiplied by a factor which is approximately the square root of the velocity in metres per second

If the mother liquor is run into the crystallising vessels hot, then the time of cooling and evaporation can be determined by a graphical integration of the rates of cooling from the surface of the vessel and cooling from evapora-

tion from the surface of the liquid at a series of temperatures.

Many solutions will not produce bright crystals at temperatures above 20°C.; in such cases, propeller fans are most useful in keeping down the temperature and increasing the output.

Substances which form hard comented masses on the cool surfaces of the crystallising vessels may be most satisfactorily treated in vacuum evaporators, where the crystals form on the surface and then drop to the bottom of the vessel, unless a surrer be provided to keep them in suspension. This method is most useful when crystallising from volatile solvents

Crystals of uniform size are also most efficiently produced in this way, since the rate of evaporation and the temperature can be perfectly regulated. A mother liquor of suitable strength is produced in the pan and allowed to cool to saturation temperature. The solution is then 'sown' with a suitable quantity of finely powdered substance, and the heating coils and vacuum pump set to work at such a rate as to maintain the temperature and produce the required amount of evaporation, the liquid being stirred continuously. As soon as the crystals are known to have reached the required size, the mass is discharged through strainers and the mother liquor returned to form a portion of the next charge.

CUMENES. Cumols. The name cumene, originally applied to isopropylbenzene

 $C_0H_0\cdot CH(CH_3)_2$ 

to indicate its connection with cumic acid, from which it was obtained by distillation with lime, is frequently employed as a generic term to denote any of the isomeric benzene hydrocarbons of the formula C<sub>9</sub>H<sub>12</sub>. Theory predicts

CUMENES. 433

the existence of eight of these, all of which have been found in coal-tar oil.

Propylbenzenes.

1. Normal propylbenzene (n. cumene)

C<sub>6</sub>H<sub>5</sub>·CH<sub>2</sub>·CH<sub>2</sub>·CH<sub>3</sub>

Present in coal tar oil in fraction boiling at 153°-157° (Schultz and Perl, Ber 1909, 3602) By the action of sodium on a mixture of bromobenzene and propyl bromide in ethereal solution (Fittig, Schaffer and Konig, Annalen, 149, 324) By the action of aluminium chloride on trimethylene bromide, propylbenzene and diphenylpropane (sym) are formed, the latter of which, on further treatment, yields propylbenzene and cumene (Bodroux, Compt rend 132, 155). From benzene, aluminium chloride and propyl bromide, when kept at 0° (Heise, Ber 1891, 768; Genvresse, Bull Soc chim 9, [3] 219). From benzyl chloride, C<sub>6</sub>H<sub>5</sub> CH<sub>2</sub>Cl and zinc-ethyl (Paternò and Spiza, Ber 10, 294). Liquid boiling at 159° (corr.), sp. gr. 0.867 at 15°[15° (Perkin, Chem. Soc Trans. 1900, 274) Yields benzoic acid on oxidation with chromic acid.

Cumene, together with toluene, may be obtained from cymene by demethylation by the action of aluminium chloride in presence of benzene.

 $\mathrm{C_3H_7\,C_6H_4\,CH_3}{+}\mathrm{C_6H_6}$ 

 $^{6} = C_{6}H_{5} CH_{3} + C_{3}H_{7} C_{6}H_{5}$ 

(Bædlker and Halse, Bull Soc. chim. 1916, 19, 444)

2 İsopropylbenzene (Cumene)

 $C_6H_5\cdot CH(CH_3)_2$ 

Present in American petroleum (Maberry and Dunn, Amer Chem J 18, 215) By distilling cumic acid  $C_6H_4[\mathrm{CH}_{(2H_3)_2}]\mathrm{CO}_2H(1,4)$  with lime or baryta (Gerhardt and Cahours, Ann. Chim Phys [3] 1, 87) From benzal chloride  $C_6H_5$  CHCl, and zinc-methyl (Liebermann, Ber 13, 46) Phenyl magnesium bromide reacts with acetone to give methylethenylbenzene, which, on hydrogenation, yields cumene (Tiffeneau, Compt rend 134, 845) From benzance and either isopropyl bromide or normal propyl bromide in presence of aluminium bromide (Gustavson, Ber 11, 1251) Liquid boiling at 152 5°–153° (cort.), sp. gi. 0.8727, 79°/4° (Perkin, Chem Soc Trans 1900, 275) Yields benzoic acid on oxidation with chromic acid

Methylethylbenzenes (Ethyltoluenes) The three methylethylbenzenes are obtained by the action of sodium on a mixture of ethyl bromide or iodide with the corresponding bromotoluenes (ortho-, meta-, or para-)

1. o-Methylethylbenzene

 $C_6H_4(CH_3)(C_2H_5)(1, 2)$ 

Liquid boiling at  $158^{\circ}$ – $159^{\circ}$ , sp gr 0.8731 at  $16^{\circ}$ . Dilute intric acid oxidises it to o-toluic acid  $C_8H_4(CH_3)CO_2H(1,2)$ 

2. m-Methylethylbenzene

 $C_6H_4(CH_3)(C_2H_5)(1, 3)$ 

Liquid boiling at  $158^{\circ}-159^{\circ}$ ; sp gr. 0.869 at  $20^{\circ}$ . Chromic acid oxidises it to isophthalic acid  $C_6H_4(CO_2H)_3(1,3)$ .

3. p-Methylethylbenzene

 $C_6H_4(CH_8)(C_9H_8)(1, 4)$ 

Liquid boiling at 161° 162°; sp.gr. at 0.8652 at C. H<sub>3</sub>(CH<sub>3</sub>)<sub>2</sub>CO<sub>2</sub>H—xylic acid and p-xylic acid. Vol. II.—T.

21°. Yields on oxidation p-toluic and terephthalic acids.

Trimethylbenzenes.

1. Consecutive trimethylbenzene (Hemillitine, Hemimellithene)  $C_0H_3(CH_3)_3(1,\,2,\,3)$  By heating the calcium salt of a-isoduric acid

with lime Liquid boiling at 175° (Jacobsen, Ber 15, 1857, 19, 2517)

2. Unsymmetrical trimethylbenzene (pseudocumene) C<sub>6</sub>H<sub>3</sub>(CH<sub>3</sub>)<sub>3</sub>(1, 2, 4), occurs together with mesitylene in coal-tar (Beilstein and Koglei, Annalen, 137, 317), and is present in many petroleums (Poni, Chem Zentr 1906, 1 459) By the action of sodium on a mixture of either bromo-paraxylene or bromometaxylene with methyl lodide. In order to isolate it from coal tar, Aimstrong recommends (Chem News, 38, 5; Ber. 11, 1697) that the mixture of pseudocumene and mesitylene (v infia) boiling between 160° and 170°, obtained from coal tar by fractional distillation, should be converted by treatment with an equal volume of concen trated sulphuric acid into sulphonic acids. The mixture of sulphonic acids, which separates as an oily layer on carefully adding water to the sulphuric acid solution, is heated with concentrated hydrochloric acid in a sealed tube for 1 hour at 100°. In this way, the mesitylene sulphonic acid is decomposed, regenerating mesitylene, whilst the pseudocumenesulphonic acid is not attacked After separating the mesitylene the pseudocumenesulphonic acid is precipitated from the hydrochloric acid solution by sulphuric acid, purified by recrystallisation from dilute sulphuric acid and finally decomposed by heating with hydrochloric acid at 140°-150°, when it breaks up into pseudocumene and sulphune acid Jacobsen (Ber 9, 256) treats the mixture of sulphonic acids with barium or calcium carbonate, which removes the excess of sulphuric acid and converts the sulphonic acids into barium or calcium salts, transforms these by double decomposition with sodium carbonate into sodium salts, heats the latter with phosphorus pentachloride, with which they yield the sulphonic chlorides C<sub>2</sub>H<sub>11</sub> SO<sub>2</sub>Cl, converts the chlorides into the sulphonamides

by the action of ammonia, and separates the two isomeric sulphonamides by recrystallisation from alcohol, in which mesitylene sulphonamide is readily, pseudocumene sulphonamide only sparingly, soluble. The sulphonamides are then hydrolysed by heating with concentrated hydrochloric acid at 175°.

Another method proposed by Jacobsen (Annalen, 184, 199) is to separate the two sulphonic acids by fractional crystallisation; pseudocumensulphonic acid is soluble with difficulty in sulphuric acid and crystallises out. On heating to its melting-point (110°) and passing in steam at a temperature of 250°, pure pseudocumene is obtained (see also Schultz and Herzfeld, Ber 1909, 3602). Pseudocumene boils at 168 2°, and has sp.gr. 0 877 at 18° (Schultz and Herzfeld, lc) On oxidation with intric acid, it yields two isomeric acids of the formula  $C_6H_3(CH_3)_2CO_2H$ —xylic acid and p-xylic acid

434 CUMENES

-and a small quantity of the isomeric methylisophthalic and methylterephthalic acids

$$C_6H_3(CH_3)(CO_2H)_2$$

(Bentley and Perkin, Chem Soc Trans. 1897,

3. Symmetrical trimethylbenzene (Misityline) C<sub>6</sub>H<sub>3</sub>(CH<sub>3</sub>)<sub>3</sub>(1, 3, 5) In coal-tar oil, in fraction boiling at 157°-162° (Fittig and Wackenroder, Annalen, 151, 292, Schultz and Perl, Ber 1909, 3602), and in American petroleum (Maberry and Dunn, Amer Chem J. 18, 215). By distilling acetone with sulphuric acid

$$3CO(CH_3)_2 = C_6H_3(CH_3)_3 + 3H_2O$$

(Kuster and Stollberg, Annalen, 278, 207, Meyer and Molz, Ber 1896, 2831), or by dissolving allylene CH<sub>3</sub>C CH in sulphuric acid and distilling with water 3CH<sub>3</sub>C CH=C<sub>6</sub>H<sub>3</sub>(CH<sub>3</sub>)<sub>3</sub> (Fittig and Schrohe, Ber 8, 17) (On the isolation of mesitylene from coal tai and the method of separating it from pseudocumene, v preceding paragraph.) Liquid boiling at 164 5°; sp gi 0 8768 at 4°/4° (Perkin, Chem Soc. Trans. 1896, 1193) Dilute nitric acid oxidises it to mesityleme acid C<sub>6</sub>H<sub>3</sub>(CH<sub>3</sub>)<sub>2</sub>CO<sub>2</sub>H and uvitic acid  $\mathrm{C}_{6}\mathrm{H}_{3}(\mathrm{CH}_{3})(\mathrm{CO}_{2}\hat{\mathrm{H}})_{2}$ ; with potassium permanganate it yields uvitic acid and trimesic acid  $C_6H_3(CO_1H)_{13}(1,3,5)$  CUMIDINES  $C_9H_{13}N$  Of the sixteen iso-

meric cumidines which have hitherto been obtained, pseudo- or  $\psi$ -cumidine and mesidine are perhaps the most important. These bases are derivatives of pseudocumene and mesitylene respectively, the first of which is theoretically capable of yielding three isometic \( \psi\)-cumidines, and the latter one cumidine only

Pseudocumidine, sym - \psi - cumidine

 $(CH_3)_3C_6H_2$   $NH_2[CH_3$   $CH_3$   $CH_3$   $NH_2=1$  2 4 5] can be obtained by nitrating pseudocumene with fuming nitric acid in the cold, and reducing the nitro- compound (m p 71°) with tin and hydro-chloric acid (Schaper, Zeitsch chem [2] 23, 1) The base is prepared technically by digesting xylidine hydrochloride with methyl alcohol in an autoclave at 280°-300°, converting the crude product into the nitrate, separating the spaningly soluble nitrates by means of a centrifugal machine, washing the product with water and The mixture of finally treating with an alkali bases consisting of cumidines and xylidines is then fractionated, and the portion distilling between 225°-245° is allowed to crystallise, and finally freed from non-crystallisable bases by pressure (Aktiengesellschaft fur Anilin-fabrikation, D. R. P. 22265). The cumidine so The cumidine so obtained contains mesidine and other impurities (Hofmann, Ber 17, 1912; Engel, ibid 18, 2229), but consists chiefly of Schaper's pseudocumidine (cf Hotmann, ibid. 15, 2895) which can be prepared in the pure state by digesting o-4-xylidine [NH<sub>2</sub>.CH<sub>3</sub>.CH<sub>3</sub>=1 3 4] or paraxylidine with methyl alcohol under similar conditions (Nolting and Forel, ibid. 18, 2680)

Properties — Pseudocumidine crystallises in large, lustrous prisms, melts at 63° (Hofmann), at 68° (Auwers, Ber. 18, 2661), and boils at 234°. It is insoluble in water, but readily soluble in alcohol. The nitrate is characterised by being very sparingly soluble in water. Its acetyl derivative crystallises in compact white needles, melts at 161° (Edler, ibid. 18, 629; Nölting and Baumann), at 164° (Auwers) and boils above Pseudocumidine is used as a source of azo- dyes (D. R. PP 3229, 1878; 22265, 1882) as-ψ-cumidine [CH<sub>3</sub> CH<sub>3</sub> CH<sub>3</sub> NH<sub>2</sub>=1.2.4:6] has been prepared by Edler (l.c.). It melts

at 36°.

 $\psi$ -cumidine [CH<sub>3</sub> CH<sub>3</sub>.CH<sub>3</sub>:NH<sub>2</sub>=1.2:4.3] is obtained by digesting 0-3-xylidine hydro-chloride [NH<sub>2</sub> CH<sub>3</sub> CH<sub>3</sub>=123] with methyl alcohol in an autoclave at 300° (Nolting and Forel; cf Mayer, Ber 20, 972) It boils at 240° (Nolting and Forel), 236° and does not solidify at -15° (Mayer). Its acetyl derivative melts at 186°.

Mesidine  $[CH_3 CH_3 CH_3 NH_2=1.3.5 2]$  is obtained by treating mesitylene with nitric acid (sp gr 138) and reducing the nitro-derivative with tin and hydrochloric acid (Fittig and Storer, Annalen, 147, 3) It can also be prepared by digesting  $\alpha$ -metaxylidine [NH<sub>2</sub> CH<sub>3</sub> CH<sub>3</sub>=1 2 4] (Hofmann, Ber 5, 715, 8, 61) or  $\beta$ -metaxylidine [NH<sub>2</sub> CH<sub>3</sub> CH<sub>3</sub>=1 2 6] hydrochloride (Nolting and Forel) with methyl alcohol at 300°

Properties—Mesidine is a colourless liquid, which boils at 229°, and has a sp gr 0 9663. The acetyl derivative melts at 216° and crystal-

lises in prisms

Isocumidine [CH<sub>3</sub> CH<sub>3</sub> CH<sub>3</sub> NH<sub>2</sub>=1 2 3 5], prepared by digesting the hydrochloride of γ-metaxylidine

$$[NH_3.CH_3.CH_3=1.3.5]$$

with methyl alcohol, at  $300^\circ$  (Nolting and Forel; Limpach, Ber 1888, 644), melts at  $67^\circ$ – $68^\circ$ , boils at  $245^\circ$ , and yields an acetyl derivative melting at  $163^\circ$ – $164^\circ$ 

Para-aminopropylbenzene, formed by heating aniline, propyl alcohol, and zinc chloride at 280° for 8 hours (Louis, Ber. 16, 105, Francksen, ibid. 17, 1221), boils at  $224^{\circ}-226^{\circ}$ . The acetyl derivative melts at  $87^{\circ}$ .

Orthoaminoisopropylbenzene, - o - cumidine, formed by heating aminocumic acid with baryta (Filetti, Gazz chim. ital. 13, 379; cf Constam and Goldschmidt, Ber 1888, 1158), boils at 213 5°-214 5° at 732 mm The acetyl derivative melts at  $72^{\circ}$ 

Para-aminousopropylbenzene, cumidine, formed by heating isopropyl alcohol, aniline, and zine chloride at 260°-280° (Louis, Ber 16, 111, cf. Nicholson, Annalen, 65, 58), boils at 216°-218°. The acetyl derivative melts at 102°-102 5°. By oxidation with sodium chlorate and potassium ferrocyanide in hydrochloric acid solution, cumidine yields a dyestuff of the aniline black series (Kirptischnikow, Chem. Zentr 1906, 1. By treatment with cyanogen chloride in pyridine solution, condensation is effected and a dyestuff is produced (Konig, D R. P. 155782; Chem Zentr 1904, n 1557).

Ethylorthotoluidine, prepared by treating orthotoluidine in ethyl alcohol with zinc chloride at 270° (Benz, Ber 15, 1650), boils at 229°-230°. The acetyl derivative melts at 105°-105 5°, and boils at 313°-315°.

CUMIDINE RED v. AZO- COLOURING MAT-TERS

CUMIN, OIL OF, v. Cils, Essential. CUPFERRON v. HYDROXYLAMINE. CUPRATION. Copper albuminate.
CUPREINE v. CINCHONA ALKALOIDS.
CUPRENE (C<sub>7</sub>H<sub>6</sub>)<sub>2</sub>. A yellow substance CURARA 435

obtained by passing acetylene over reduced copper heated above 180°, and treating the brown solid so formed repeatedly with acetylene until no further change occurs.

CUPRI-ADEPTOL. Copper m-phenol sulphonate.

CUPRISIN. Trade name for a preparation of cupric cyanide and potassium cyanide, used for the treatment of trachoma.

CUPRITE. Native cuprous oxide, Cu2O, crystallising in the cubic system Brilliant, transparent crystals of a ruby-red colour (hence the name ruby-copper-ore) are not uncommon; spgr 6.0 In the variety called chilcotrichite, the crystals are capillary in form, being enormously elongated in the direction of one of the cubic edges, and are loosely matted together in plush-like masses. Another variety, known as tile-ore (Ger Ziegelerz), is earthy or compact and of a brick-red or brownish colour, it consists of an intimate mixture of cuprite and limonite, and has resulted from the alteration of copper-pyrites Cuprite is sometimes of importance as an ore in the upper oxidised portions of copper veins

CUPROCITROL. Trade name for copper citrate

CUPROL. A compound of nucleinic acid and copper

CUPRONICKEL v NICKEL.

CUPROSILICON, Cuprous silicide (v. Copper) CURARA. Curare, Urari, Woorani, Woorah,

Curara is the airow poison of those tribes of South American Indians which inhabit the districts lying between the Amazon and the It was first brought to Europe by Sir Walter Raleigh, in 1595, and from that time to this its origin and preparation have been much discussed by travellers and botanists. A summary of the earlier observations of La Condamine, A v Humboldt and Bonpland, Waterton, Schomburgk, Castelnau, Weddell, Thirion, Jobert, Crévaux, and others is given by Planchon (Pharm J [3] 11, 469, 491, 529, 589, 693, and It is shown that curara is an aqueous extract of a mixture of many plants, one of which is always a species of Strychnos, and gives to it the chief toxic power, whilst the remainder contribute those other qualities which render the extract suitable for the tipping of airow The method of preparation adopted by one tribe of Indians is described by Schomburgk The product differs some-(*ibid* [3] 10, 646) what with the locality in which it is prepared. distinguishes four varieties. curara of the Orinoco, of the Upper Amazon, of French Guiana, and of British Guiana chief active ingredient in the preparation of the first is a Strychnos plant, closely allied to Schomburgk's S toxifera (J Pharm Chim [5] 5, 20), of the second, S Castelner (Weddell), of the third, S Crevauxiana (Baill.), and of the fourth, S. toxifera (Schomb).

As seen in Europe, curara is a brown to black, nearly solid, or even brittle, extract. It has a bitter taste, and in its poisonous action it is related, though opposed, to strychnine. In medicine, it has been occasionally employed in the treatment of tetanus and hydrophobia, but it is not included in any pharmacopœia. Great care is necessary in its administration, and the solution should first be tested on animals.

For the earlier chemical investigations of curara, see Fluckiger (Arch Pharm 1890, 228, 78). Our present knowledge is mainly due to Boehm (Chem Zentr 1895, u. 1084, 1897, u. 1078; Arch. Pharm 1898, 235, 660), who showed that the alkaloids of curara can be divided into two classes: (1) compounds similar to curine, partly crystalline and partly amorphous, soluble in water with difficulty and precipitated from solution by ammonia, in which the characteristic toxic effect of curara is shown very slightly or not at all, (2) amorphous yellowish-red substances easily soluble in water as curarine, not precipitated by ammonia, and showing the most marked toxic action. Of most specimens of curara, about 70-90 p.c. is soluble in tepid water; sometimes, however, scarcely more than half is soluble Para curara, which is imported in bamboo tubes and is the variety now usually met with in commerce, contains about 11-14 pc water, 12 pc ash, 12-15 pc. curine  $C_{18}H_{19}O_3N$ , which is isolated by extracting the raw material with water, precipitating by aqueous ammonia and expectations. tracting with alcohol. It melts at 212°, and is obtained in crystals from benzene or alcohol with one molecule of the solvent or from methyl alcohol without alcohol of crystallisation Tubocurarine (paracurarine) C19H21O4N was obtained as a reddish-yellow substance which forms about 9-11 pc of raw curara. It is not identical with the previously known curarine, isolated from calabash curara The latter kind, which was sent over from the Orinoco via Venezuela in small gourds, used to be the common variety, but is now seldom met with, it is much superior to tube curare, and seems to be derived from Strychnos toxifera Earlier investigations, as a rule, refer to this The active principle, curarine C<sub>19</sub>H<sub>26</sub>ON<sub>2</sub> (?), consists of haid glistening garnet-red laminæ, decomposing and giving off a smell of trimethylamine when heated to 150°. A minute quantity of a second alkaloid was found to be present

A third variety of curara, from the Upper Amazon, occurs in the market in small jars of unburnt clay. This differs widely in respect to active principles from the other varieties. The following substances have been extracted from 1t protocurine C<sub>20</sub>H<sub>23</sub>O<sub>3</sub>N, colourless needles, which turn brown at 160° and melt, with decomposition, at 306°, protocuridine C<sub>19</sub>H<sub>21</sub>O<sub>3</sub>N, colourless prismatic crystals, m p 274°-276°; and protocurarine C<sub>19</sub>H<sub>23</sub>O<sub>2</sub>N (?), an amorphous red powder, more poisonous than the other curarines.

The mert, or slightly active, curines appear to be tertiary bases, the curarines are quaternary ammonium bases, and in this connection it is noteworthy that, according to Crum Brown and Fraser (Proc Roy Soc Edinburgh, 1869, 560), nearly all ammonium bases paralyse motor nerve endings and have a curare-like effect. In the case of curine and tubo-curarine, at least, there seems to be a close chemical relationship: both appear to be derivatives of methoxylated quinoline Curine methiodide produces the typical curare effect and resembles tubocurarine. The colour reactions of curarine indicate a relationship to strychnine. Pure curarine is extremely active; 100-100 mg. injected will paralyse a frog; given by the 436 CURARA.

mouth it is mactive. It paralyses the motor nerve endings, but, even in large doses, leaves other tissues unaffected. Hence it is much employed in physiological research (cf. e.g. Edmunds and Roth, Amer J. Physiol. 1908, 23, 28, 46).

cURCAS OIL, purging nut oil, physic nut oil (Oleum internal), is obtained from the seeds of Jatropha curcus (Linn), (purging nut'), by hot expression. The seeds consist of 66 p.c. of kernels and 34 p.c. of husks. From the former there is obtained by extraction with ether 52 p.c. of oil of a pale colour, becoming yellow, with a reddish tint, on exposure to the an Characteristic of the oil is its unpleasant odour, which assists in distinguishing curcas oil from other oils. Most prominent are the strong purgative properties of the oil, which are much more pronounced than those of castor oil. It may be distinguished from castor oil by its sparing solubility in alcohol, and ready solubility in petroleum spirit. The oil belongs to the semi-drying oils, its liquid fatty acids consist of about equal proportions of class and broken.

bark contains about four alkaloids, a little ethereal oil, a bitter principle, and a glucoside. Of total alkaloids there is 1 8 p c free and 0 6 p.c. in a combined state. By far the most abundant alkaloids are cusparine and galipine, discovered by Korner and Bohringer (Gazz chim. ital. 1883, 13, 363). They are removed from the ethereal percolate of the bark by shaking with 20 p c acetic acid, which leaves small quantities of other bases behind. The separation of cusparine from galipine is effected by fractional crystallisation of the free bases, from ligion, but principally by conversion into the oxalates, cuspaine oxalate is very little soluble in water, while galipine oxalate remains in solution (Troger and Kroseberg, Arch. Pharm. 1912, 250, 494).

Galipine  $C_{20}H_{21}O_3N$  forms colourless needles, mp 115°, when pure the salts are colourless. Oxidation with permanganate yields veratife and methoxyquinoline carboxylic acids, whence Troger and Kroseberg have suggested the following constitution:

Angostura Bitters. It is believed that Angostura Bark does not form a constituent. See article on Liqueuis and Cordials in Vol.  $\beta$

CUSPARIA BARK. Angostura bark, Carony bark. (Ecoice d'Angusture, Fr., Angostura-Rinde, Ger) The baik of the Cuspana febrifuga (Hiemb) or Galipea cuspana (St Illaire), a tree inhabiting the mountain districts drained by the Orinoco (cf Bentl a Trim Confusion has sometimes occurred between cusparia and nux vomica bark. The two barks may, however, be readily distinguished by treatment with a drop of nitric acid, which either deepens the colour of the cusparia or gives it a bluish shade, while nux vomica, similarly treated, exhibits a blood-ied colour Several other barks have, from time to time, been substituted for true angostura (For these, and the mode of detecting them, v Pereira (Mat Med 3rd ed 2, 1915); Maisch (Amer. J Pharm 1874, 50), Cazeneuve (Rép de Pharm 1874, 261); Oberlin and Schlagdenhauffen (Pharm Zeit 1878, 853)) For the bark of Esenbeckia febrifuga, which enters commerce under the name of angostura bark, see Hartwich and Gamper (Arch. Pharm. 238, 568). Cusparia

red, Frohde's reagent a deep-blue, colouration On melting its salts with organic acids, it pyrocusparine C18H15O3N, mp. changes to 255°, which base gives well-crystallised salts Like galipine, cuspărine seems to be a quinoline derivative (Troger and Beck) It is a tertiary base, and contains one methoxyl group. As protocatechnic acid is obtained by potash fusion, it is conceivable that it contains a methylenedioxy group instead of the two methoxy groups of galipine, which would be in accordance with the empirical formula Cuspareine C18H19O2N, according to Troger and Runne (Arch Pharm 1911, 249, 174), is extracted by light petroleum from the amorphous bases left after crystallisation of cusparine and galipine It melts at 56°, distils almost without decomposition, contains two methoxy groups, and yields quinoline on zinc-dust distillation Troger and Runne also describe galipoidine C<sub>19</sub>H<sub>15</sub>O<sub>4</sub>N, m.p 233°, and Troger and Beck (1c) yet another alkaloid C<sub>16</sub>H<sub>13</sub>O<sub>2</sub>M (?), m p 186°. Cusparidine and galipidine of Beckurts and Nehring are, according to Troger and Kroseberg, merely mixtures of cusparine and galipine. Other papers on angostura alkaloids are by Troger and Muller (Arch Pharm. 1910, 248, 1, 1914, 252, 459), by Beckurts and Nehring (Arch Pharm. 1891, 229, 591), and by Beckurts and Frenchs (Arch. Pharm 1905, 243, 470).

The essential oil (from Cusparia trifoliata, Engl.) is described in Schimmel and Co.'s Semi-Annual Report, April, 1913. The yield was 1.03 p.c. of the bark;  $D_{5}^{15}$  0.9285;  $\alpha_{p}^{20}$  -7.32°;

 $n_{\rm p}^{20}$  1 50744; colour, pale brown; acid number, 18; ester number, 5.5; acetyl number, 357, the oil is not completely soluble even in 9 volumes of 90 pc alcohol.

Angosturin C<sub>9</sub>H<sub>12</sub>O<sub>5</sub>, m p 58°, is a crystal-line bitter principle, readily soluble in water and in alcohol, but not in ether (Beckurts and

Nehring)

Angostura bark is a constituent of 'Angostura bitters,' and is used in medicine as a tonic in derangements of the alimentary canal, but it is not included in the BP nor in the USP

CUSSO, KOUSSO, v Kosin, art. Resins. CUSYLOL. Trade name for soluble copper citrate

CUTCH. Considerable quantities of cutch are now prepared in Burma. It is obtained from the Acacia Catechu, the trees being felled while green, the bark taken off, and the timber chopped up and boiled in large cauldrons. The resultant liquid is drained off, and solidifies In the better qualities of cutch as it cools only the heart-wood of the tree is utilised is brought to the market in several forms, the three principal ones being · (1) tablets—small rectangular blocks weighing from 1 to 2 lbs; (2) blocks-more or less square blocks weighing from 28 to 56 lbs; (3) baskets—a soft cutch of a thick consistency. Tablet cutch is the best quality, and basket cutch the lowest and basket cutch usually contain more impurities than tablet cutch On arrival in Rangoon the cutch is packed in wooden cases (usually containing 1 ewt net), and is then ready for export

Cutch trees are found throughout the whole of Burma, but the principal producing districts are Prome, Thayetmo, Myingyan, Minbu, Pegu,

Yamethin, and Pyinmana

Cutch is used largely as a dye, and for tanning, and as a preservative, especially for preserving fishing nets and sails See also CATECHU

CYANACETIC ACID v Malonic acid

CYANELLAGIC ACID Cyanellagic acid  $\rm C_{14}H_6O_{10}$  is prepared by heating cliagic or flavellagic acid with 100 p c sulphuric acid at  $185^{\circ}-230^{\circ}$  (Perkin, Chem. Soc. Proc. 22, 114), or with arsenic and sulphuric acids at 130° crystallises from pyridine in small yellow prismatic needles, and is soluble in strong alkaline solutions with a green-yellow tint, changing to deep blue on dilution. The hexa-acetyl derivative  $C_{14}O_{10}(C_2H_3O_6)$ , forms colourless needles, melts at 330°–332°, and the hexabenzoyl compound, colourless needles, m p 343°-345° Cyanellagic acid is most probably dihydroxyellagic acid, and in this case possesses the following constitution .

It dyes mordanted fabrics more readily than ellagic acid A Ğ. P.

CYANIDES. Compounds of the radical cyanogen UN The history of the cyanid

industry begins with the discovery of Prussian blue by Diesbach in 1704 (H. Kopp, Geschichte der Chemie, 4, 369) While attempting to make Florentine lake by precipitating a mixture of cochineal infusion, alum, and ferrous sulphate with an alkali, he obtained a blue colour The alkali used was potash, over which Dippel had distilled his animal oil, and Dippel recognised in this the source of the blue colouring matter. The new blue very quickly came into use in place of ultramarine, and in 1710 it was sold at one-tenth the price of the latter. The method of manufacture was a secret until 1724, when Woodward showed that the blue could be prepared by calcining blood with potassium carbonate and then treating the aqueous extract 1 with ferrous sulphate and alum, the greenish precipitate so obtained yielding Prussian blue when treated with hydrochloric acid.

This, in its essential features, was the method of manufacture which supplied the world's requirements of cyanogen compounds

for nearly 150 years

Macquer, in 1752, showed that alum is not required, and that Prussian blue, when boiled with an alkali, yields ferric hydroxide and a soluble salt from which the blue can be re-generated. This salt, potassium ferrocyanide, was first obtained in the crystalline form by Sage in 1772

The brilliant researches of Scheele, 1782-3 (Chemical Essays, London, 1786), Berthollet, 1790 (Ann Chim Phys 1790, 1, 30), and of Gay Lussac, 1815 (*ibid* 1815, 95, 156), in the course of which the relationships of the ferrocyanides, hydrocyanic acid, cyanogen, and many of their derivatives were discovered, laid a firm scientific foundation for the industry

Prussian blue was manufactured in Great Britain in 1770 by Bramwell & Co of Newcastle, it sold then at 2 guineas per lb; the price had fallen in 1815 to 10s 6d, in 1820 to 2s 6d, and in 1850 to 1s 9d Crystallised potassium ferrocyanide was first known in commerce about 1825, the price being 5, per lb, although a solution had been sold previously (Graham, Reports of Juries, Exhib of 1851, 1, 95)

The conversion of potassium ferrocyanide into potassium cyanide by fusion with potassium carbonate, was first described by F and E. Rodgers in 1834 (Phil Mag. 1834 [3] 4, 91), but the simple cyanides were not used in any considerable quantity until the process of electro-plating with gold and silver, from a cyanide solution, was discovered by J. R. and H. Elking-

ton in 1840 (Eng Pat 8447, of 1840)

An interesting application of potassium ferricyanide was discovered by Sir J Herschel in 1842 (Phil Trans. 1842) Paper, treated with a solution containing ferric ammonium citrate and potassium ferricyanide, becomes blue when exposed to light, owing to the reduction of the ferric salt and consequent formation of Prussian blue Paper sensitised in this way is used for the reproduction of engineering drawings.

A very remarkable attempt was made by Possoz and Boissière in the year 1843, to manufacture cyanides from atmospheric nitrogen;

1 Liximum sangumis or blood-lye, whence the German name of potassium ferrocyanide, blutlaugen-

this is described under the heading Potassium inch.

The year 1860 witnessed three important developments in the cyanide industry. Gautier-Bouchard (A W Hofmann, Reports by the Juries, Inter Exhib of 1862, 59-63) began to produce prussiate from the spent oxide of the Paris gas works A Gélis (Eng Pat 1816, of 1860) synthesised it from carbon disulphide and ammonia; and Margueritte and de Sourdeval (Eng Pat 1171, of 1860) attacked the problem of the fixation of atmospheric nitrogen by means of baruim oxide and carbon.

The existence of cyanogen compounds in coal gas was known in 1843, and possibly still earlier. E Jacquemyns (Annalen, 1843, 46, 236), whose attention was drawn to them by H. Rose, says that he found none in gas lime, but obtained 0.75 gram of Prussian blue per litre from ammonia liquor The purification of coal gas by means of iron oxide was introduced in 1847. Owing to the repeated use of the same quantity of oxide, the cyanogen compounds accumulate in it in a relatively concentrated form, and it was therefore naturally the first gas works product to be used in their manufacture Prussian blue, made from spent oxide, was exhibited by Gauthier-Bouchard at the London Exhibition of 1862

Both the process of Gélis and that of Margueritte and de Sourdeval were soon abandoned by their inventors, the recovery of cyanides from spent oxide, on the other hand, developed fairly rapidly, and, according to Dupré (Journ fur Gasbeleuchtung, 1884, 885), there were, in 1884, 10 works making prussiate by this means.

The competition of the gas works ferrocyamide, the increasing cost of nitrogenous organic matters (which were being more and more used as fertilisers), and the diminished use of Prussian blue due to the competition of blue colouring matters derived from coal tar, led to the disappearance of the old process in Europe about this time

In the United States of America, it appears to have held its own somewhat longer, the returns of the U.S. Census for 1900 (Bulletin No. 210, 31, 1902) show 18 works engaged in the manufacture of cyanides with a joint annual production of 2752 tons of yellow prussiate, almost entirely made from hoofs, horns, and scrap leather, only 1200 tons of spent oxide having been used

Between 1875 and 1885, the sulphocyanides, especially the tin and aluminium salts, appear to have been used in calico printing instead of the acctates (Bertelsmann, Die Technologie der Cyanverbindungen, 303), and Gélis' synthesis was taken up and improved by Gunzburg and Teherinae (Eng. Pat. 1148, of 1878, 1359, of 1879, 1261, of 1881), but without financial success.

In 1887, J S MacArthur, R. W and W Forrest (Eng Pat 14174, Oct 19, 1887; 10223, of 1888) patented their process for the extraction of gold and silver from their ores by means of a dilute solution of a cyanide. The process was carried out by allowing a solution containing 0.25 p c or less of potassium cyanide to percolate through the ore, which was usually ground to pass a sieve with 40 or 60 holes to the linear

inch. The gold is dissolved in the form of potassium aurocyanide, and is recovered from the solution by passing it through a mass of zinc shavings. The process was first put into practice at Karangahake, New Zealand, in 1889, and near Johannesburg, Transvaal, in 1890. The success of these installations led to a very rapid adoption of the process in all the gold-producing countries of the world.

Prior to the introduction of this process, the cyanide industry was quite a small one. The world's consumption of potassium cyanide (produced exclusively from ferrocyanide by the Rodgers process) (F. Roessler, V. Internationaler Kongress für Angewandte (Themie, Berlin, 1903, 1, 638) did not exceed 50–70 tons per annum (G. Beilby, J. Soc. Chem. Ind. 1898, 134) and that of yellow prussiate was probably under rather than over 5000 tons (worth together about 325,000l).

Ten years later, just before the Transvaal War, the European production of potassium eyanide was estimated by Beilby (V Inter Kongiess Angew Chem Berlin, 1903, I, 630) as 5500 tons, adding the American production of about 1000 tons (U S Census Bulletin, No 210, 31, 1902), we arrive at a total production of 6500 tons

The increased quantities of potassium cyanide required by the gold-mines were at first supplied by fusing potassium ferrocyanide with potassium carbonate, and very soon afterwards by E. Erlenmeyer's process (Ber. 1876, 1840), in which dry prussiate and metallic sodium are used: K<sub>4</sub>Fe(CN)<sub>6</sub>+2Na=2Na(N+4KCN+Fe Synthetic processes producing cyanide direct without the intervention of prussiate, were also proposed in great numbers. The approximate numbers of patents connected with cyanide manufacture applied for were 1889–1898, 104, 1899–1908, 129, 1909–1917, 106. The principal processes which have been worked with some measure of success, are—

Process	Where worked	Began pro-
Siepermann	Stassfurt, Germany.	1892
Beilby.	Glasgow, Scotland	1892
British Cyanides	Oldbury, England	1895
Raschen.	Runcorn, England.	1898
Readman.	Leven, Scotland.	1899
Castner.	Germany, Scotland, USA	1899-1900
Bueb ('Schlempe').	Dessau, Germany.	1902

These, and others, are described fully below

The recovery of cyanides from the products of distillation of coal was also improved by the introduction of special cyanide scrubbers during the decade 1890-1900, whereas the iron oxide purifiers had yielded but little more than one-half of the cyanogen in a useful form, the newer processes give an almost quantitative recovery.

About the year 1900 the fruit trees of California and the Southern States of America were threatened with extermination by a parasitic scale. The investigations of the Experiment Stations of the US Department of Agriculture showed that this could be killed without injury to the trees by fumigation with hydrocyanic acid. The method, which was introduced

about 1903, is now very widely used, both in the United States of America and in other countries. It has also been extended in other directions, such as killing insects in hot-houses, and freeing railway carriages and houses from vermin (in South Africa). Details will be found under the heading Hydrocyanic acid Statistics collected by George P. Gray show that the consumption of sodium cyanide for fumigating citrus trees during 1916 in the State of California alone exceeded 1300 tons (J Ind. Eng Chem. 10, 301, 1918).

Another application which may be mentioned is in case-hardening iron; immersion in fused cyanide produces a very hard skin on mild steel, and both cyanides and ferrocyanides have long been used for this purpose in ordinary workshop practice. According to J E Bucher (J Ind Eng Chem 9, 236, 1917), the reversible reaction  $2\text{NaCN} \rightleftharpoons 2\text{Na} + 2\text{C} + \text{N}_2$  takes place in presence of iron; if pure iron is heated with sodium cyanide the latter is decomposed and the carbon combines with the iron, if, on the other hand, carbonised iron is heated with sodium and introgen, the carbon is removed from it, and cyanide formed.

Potassium cyanide, as used in electro-plating, was a material having the appearance of unglazed porcelain, and containing from 30 to 70 p c. of KCN, together with large quantities of carbonate and cyanate The material supplied to the gold-mines in the early days of the gold-extracting process was a black mass containing some 75 p c of KCN, and all the iron and carbon liberated by the decomposition of the ferrocyanide This was replaced by the pure white crystalline product of the Erlenmeyer process, which contained about 2 molecules of KCN to 1 molecule of NaCN, the cyanogen content being about 40 pc, equivalent to 98-100 pc of KCN. The earlier produce of the Beilby process was in the form of cakes, which were coloured black by a small percentage of charcoal Later, by filtration of the molten cyanide, the charcoal was removed, and the product was white or pale grey, and free from insoluble imputities Shortly after the introduction of the Castner process, in 1900, solid cakes of pure white crystalline sodium cyanide, containing 97 p c. to 98 p c of NaCN (equivalent to 129-130 p c of KCN), became an article of commerce, and this is at present the form in which the greater part of the cyanide employed in gold-extracting is used Sodium cyanide, obtained by the evaporation of aqueous solutions, as in the Readman and 'Schlempe' processes, is compressed into briquettes, which contain about 90 pc of NaCN.

Potassium ferrocyanide has also been replaced to a very large extent by the sodium salt which is quite easily prepared by the more recent methods of extracting the hydrocyanic acid from coal gas by special cyanogenwashers

The rapid rate of increase in the world's consumption of cyanide which followed the introduction of the gold-extracting process has not been maintained. Since 1909 the annual value of the world's gold output has been almost stationary at a little more than 90,000,000, and improvements in the process of extraction have everywhere tended to diminish the quantity

of cyanide needed to produce this. On the Rand, where this tendency seems to have almost reached a limit, the average consumption of cyanide is 0 4 lb. KCN per ton of ore treated (H A. White, J. Chem Met and Min Soc S Africa, 1915, 16, 24). Increased use in the treatment of silver ores (much delayed, however, by political troubles in Mexico) and in agriculture have kept the world's consumption from 1910 to 1920 approximately constant at, in round figures, 20,000 tons per annum. In 1912 and 1913 Germany exported 6700 tons per annum (The Mineral Industry, 1917, 25, 882) The deficit caused by the cessation of these exports on the outbreak of war in 1914 has been covered by increased production in Great Britain; a temporary shortage in the United States was soon overtaken by the American makers

Manufacture of Potassium and Sodium Ferrocyanides—(1) From nitrogenous organic

matter

The method of manufacture from nitrogenous organic matter is now only of historical interest

The sources of nitrogen were horn, dried blood, hair, waste wool, and feathers (15–17 p.c. N), woollen rags (10–16 p c N), pigs' bristles (9–10 p c N), and old leather (45–7 p c N). These materials were sometimes charred before use, about 80 p c. of the nitrogen being driven off in the form of ammonia, hydrocyanic acid, and a complicated mixture of nitriles and organic bases

The process was carried out at first in pearshaped, cast-iron muffles, which were replaced later by reverberatory furnaces, the beds of which were formed of cast-iron pans, 5 feet long, 3 feet wide, 4 inches deep, and about 2 inches A charge of 2 cwt of potash (usually made up of 2 parts of the 'blue salt' recovered in a later stage of the process, and 1 part of fresh potash) was put into the pan and fused with 18-20 lbs of non turnings; 2 cwt of the dry nitrogenous materials were then stiried in gradually (25 to 3 cwt of charred material could be added without making the mass too The temperature was then raised in order to complete the reaction, and the melt ladled out into iron moulds After solidification, it was broken up and digested for 24 hours with water at 50°-60°, and finally extracted completely with boiling water The solution obtained contained potassium ferrocyanide, sulphocyanide, carbonate and sulphide 1t was evaporated to sp gr 1 28, and allowed to crystallise Further evaporation yielded a second crop of impure crystals, the mother liquor of which was evaporated to dryness. leaving a mixture of potassium carbonate and sulphide, known as 'blue salt' which was returned to the fusion pan

The black insoluble residue left from the extraction of the 'metal,' as the product of the fusion was called, contained considerable quantities of potassium, mainly in the form of potassium ferrous sulphide and of double potassium, calcium, and aluminium silicates.

potassium, calcium, and aluminium silicates.

The quantity of 'metal' produced was very little greater than the weight of potash used, and 4 charges were put through in 24 hours, but practice varied considerably: C Karmrodt (Wagner's Jahresber. 1857, 3, 139) speaks of

6 charges of 500 lbs, each as the normal output of a pan in 24 hours

The yield of ferrocyanide was seldom more than 20 pc of the quantity theoretically obtainable from the introgen in the materials used when they were not previously charred. Using charred materials, as much as 57 pc of the remaining nitrogen was converted into ferrocyanide, corresponding with a yield of about 12 pc on the nitrogen originally present. The quantity and composition of the black

residues varied greatly with the kind of organic matter used The main constituents were carbon (4-9 pc), ferrous sulphide, iron, and inorganic substances derived from the ash of the animal matters and adhering dirt, the principal being silica, lime, alumina, and phosphoric acid The quantity of potassium combined with these substances in an insoluble form was considerable According to Karmrodt (Wagner's Jahresber Recording to Karmiott (wagners salresser 1857, 3, 139), 100 parts of 'metal' made (1) from horn gave 18 7 pc of dry residue, containing 12 2 pc of  $K_2O$ , (2) from rags, 28 3 pc of residues, with 16 7 pc  $K_2O$ ; (3) from leather, 35.1 p c of residue, with 10.2 p c K<sub>2</sub>O quantities represent about  $4\frac{1}{2}$ , 9, and 7 pc. of the potassium contained in the original charge, and since only some 10 pc of this is converted into ferrocyanide at each operation (R Brunquell, Wagner's Jahresber 2, 102, 1856), the loss of potash in the residues appears to have been from 45 to 90 p c of that usefully employed Potash was also carried away with The iron pans survived several the flue gases hundred operations

The theory of the process was first given by Liebig (Annalen, 1841, 38, 20). Scheele (Chemical Essays, London, 1786, reprinted 1901) had already shown that lixivium sanguinis is essentially a solution of potassium cyanide and that the addition of a ferrous compound is necessary to convert it into prussiate Liebig confirmed this by extracting the 'metal' with alcohol, which dissolves out potassium cyanide, leaving a residue from which no ferrocyanide can be obtained. He attributed the formation of the evanide partly to the action of ammonia (formed by destructive distillation of the organic matter) on carbon, C+NH<sub>3</sub>=HCN+H<sub>2</sub>, and partly to the action of potassium on the nitrogenous residue of carbon It may be remarked that the temperature of the fusion could not have exceeded 1000°, since cast iron melts about 1100°, and the pans withstood some hundreds of The temperature, too, was lowered by the addition of the organic matter, occasionally sufficiently to cause the charge to solidify, so that the reaction between ammonia and carbon, which requires a temperature of about 1000°, could not have occurred to any great extent. The direct action of ammonia on potassium carbonate would, however, take place, although, the ammonia being evolved on the surface of the mass, the conditions were not favour-As to the second of Liebig's able to it reactions, the writer has found that potassium is not formed in appreciable quantity from a mixture of charcoal and potassium-carbonate below about 1200°, certainly not at 1000°, so that the greater part of the cyanide must have been formed by the action of potassium carbonate itself on the unknown carbon-nitrogen com-

pounds contained in the charred organic matter. That cyanide may be formed in this way is indicated by the fact that carbazol, when heated to redness with caustic potash, yields considerable quantities of it (G Kraemer, Eng Pat. 16529, of 1894). The rôle of sulphur in the process was explained by Liebig thus: potassium sulphate, which is always present in the potash, is reduced by carbon to sulphide, carbonate, and polysulphide The latter dissolves iron, forming a double sulphide of iron and potassium which, when the product is lixiviated, dissolves in the potassium cyanide solution thus:

If insufficient iron is present in the fusion, the polysulphide is not entirely decomposed, and potassium sulphocyanide is also formed R Hoffmann (Annalen, 1860, 113, 81) investigated the behaviour of the sulphur compounds in the process in some detail, and found that the sulphur of potassium sulphide is rapidly and completely removed by iron alone in the fusion process, and that the same is true of potassium sulphiate in presence of carbon. When organic matters are added to the sulphurfree melt, however, sulphocyanide is produced in proportion to the quantity added Hoffmann, therefore, attributes its formation to the organic sulphur

The behaviour of potassium sulphocyanide in the fusion is not clearly understood. Hoffmann found that it is completely decomposed by fusion with excess of potassium carbonate, yielding cyanate and sulphide, 1 but if the mixture is again heated with carbon, the sulphocyanide is regenerated. It appears, therefore, that, under the conditions of the process, sulphocyanide is not decomposed. The reaction between iron and sulphocyanide is described below.

A part of the sulphide of iron formed is present in the form of a potassium ferrous sulphide, FeS xK $_2$ S, which dissolves in hot water to a dark-green, colloidal solution which is coagulated by cooling or by adding excess of potassium carbonate. Another part is probably present in the form of the crystalline potassium ferric sulphide K $_2$ S Fe $_2$ S $_3$ , obtained by K. Preis (J. pr. Chem. 1869, 107, 10), by fusing together finely divided iron, potassium carbonate, and sulphur. He found that the crystalline sulphide was formed at very high temperatures, and the amorphous one, yielding the green solution, at lower temperatures.

The reaction between potassium cyanide and ferric sulphide

13KCN + Fe<sub>2</sub>S<sub>3</sub> = 2K<sub>4</sub>Fe(CN)<sub>6</sub> + KSCN + 2K<sub>2</sub>S

would give a ratio of cyanogen in the form of sulphocyanide to cyanogen in the form of ferrocyanide of  $1\cdot 12$ , whilst Hoffmann, in 10 experiments, found ratios varying from  $1\cdot 5$  to  $1\cdot 18$ 

The improvements in the process which were proposed aimed at saving the ammonia evolved in the early stages by distilling the organic matters separately and passing the ammonia

 $^{\circ}$  I can confirm the accuracy of this observation Equal molecules of potassum carbonate and sulphocyanide were fused together in a closed aluminium crucible at 500°-580° for  $1_{1}^{\downarrow}$  hours, a little more than half of the materials had reacted in accordance with the equation KSCN+K<sub>2</sub>CO<sub>3</sub>=KCNO+K<sub>2</sub>S+CO<sub>2</sub>.—T E.

through a red-hot mixture of potash and charcoal (Brunquell, Wagner's Jahresber 1856, 2, 102), or a similar mixture with iron added (Karmrodt, ibid 1857, 3, 139), or over red-hot charcoal forming hydrocyanic acid which was to be absorbed, together with the unchanged ammonia, in a solution of ferrous sulphate (Brunquell) These proposals, unfruitful at the time, are interesting as foreshadowing processes which came into successful operation nearly half a century later

The belief, which prevailed until about the end of the nineteenth century, that cyanogen compounds are more easily produced from potash than from soda, is not entirely in accordance with the older experimental evidence The truth appears to be that equally good results can be obtained with sodium carbonate under suitable conditions, but the conditions are not so easily

L Possoz (Compt rend 1858, 47, 209) obtained, under manufacturing conditions, 5 parts of sodium prussiate, instead of 25 parts of the potassium salt, from 100 parts of horn Hoffmann (Annalen, 1860, 113, 81), using a very high temperature and sodium carbonate, got the equivalent of 11 parts of potassium ferrocyanide from 100 parts of woollen rags, against 10 to 14 parts with potash, and S Tanatar (Dingl poly J 1880, 237, 234) obtained the results tabulated below, as the means of 3 to 5 experiments:-

Manufacture of Potassium and Sodium Ferrocyanides -(2) From the products of distillation of coal The coal used in the manufacture of illuminating gas may be taken to contain from 1 to 19 pc of nitrogen (Drehschmidt, Journ fur Gasbeleuchtung, 1904, 677; McLeod, J Soc Chem Ind 1907, 26, 137) When the coal is distilled, a part of this nitrogen passes into the gas in the form of ammonia, hydrocyanic acid and free nitrogen, a small part is found in the tar, and the remainder in the coke The distribution of the nitrogen between these products varies considerably, being influenced by the nature of the coal, the amount of moisture in it, the temperature of distillation, and the kind of retort used The following table indicates the magnitude of the quantities involved when the coal is distilled dry:

Ne	Wind of soil	P c of the total N of the coal in

Report, 1906, 58

4. J McLeod, J. Soc Chem Ind 1907, 26, 137; and Alkalı Works, 44th Report, 1907, 215

The effect of temperature on the distribution of the nitrogen has been investigated by O Simmersbach (J. Soc Chem Ind 1915, 34, 895), using a Silesian coal containing 1 396 p c of N The following table contains some of his results

Temp		P c of	the tota	ıl nıtrogen

Even the ammonia liquor from low temperature carbonisation retorts working at 427°-455° contains traces of cyanogen compounds (Alkali Works, 45th Report, 1908, 52)

Hydrocyanic acid is converted into ammonia by water vapour at the temperature of distillation used in gas works and coke ovens

$$HCN + H_2O = NH_3 + CO$$

(Carpenter and Linder, J Soc Chem Ind 1905, 24, 63) The gas from coke ovens distilling coal with some 12 p c of moisture therefore contains about two-thirds of the quantity of hydrocyanic acid found in the gas made from almost dry coal in gas works

The gas leaving the retorts contains the whole of its cyanogen in the form of hydrocyanic acid (Alkali Works, 43id Rep. 1906, 33), the fate of this depends on the process of purification adopted In common practice about one-third of it is condensed along with the ammonia in the virgin liquor and ammonia scrubbers in English works (Alkalı Works, 43rd Rep 1906, 61), but less in many German works, where less water is used in the scrubbers (Bertelsmann, Technologie der Cyanverbin-dungen, 171) Thegreater part of this is converted into sulphocyanide, and escapes finally in the effluent from the ammonia stills From 50 to 70 p c is caught in the iron oxide purifiers, the remainder passing away with the gas, where it is a source of damage to meters and gas-holders A more complete recovery is obtainable when one of the cyanide washers described below is placed before the ammonia scrubbers Up to 1908 attempts to recover cyanogen compounds from coke-oven gases had been unsuccessful (Alkalı Works, 44th Rep 1907, 40)

The total quantity of cyanogen compounds formed during the destructive distillation of coal is very considerable. In 1912 the world's production of ammonium sulphate was 1,144,000 tons. In Great Britain over 70 p c of the production came from gas works and coke ovens in which roughly one molecule of hydrocyanic acid accompanies ten molecules of ammonia Assuming the same conditions in other countries, it appears probable that hydrocyanic acid equivalent to 80,000 tons of KCN is formed annually; only a small part of this is actually

Formation of HCN from Ammonia and Carbon.

-The earliest synthesis of hydrocyanic acid was effected by Clouet (Ann. de Chim. 1791, 11, 30), by passing dry ammonia over wood charcoal heated to bright redness in a porcelain tube. This reaction has been studied quantitatively by E Bergmann (Journ. fur Gasbel 1896, 39, 117), D Lance (Compt rend 1897, 124, 819), G A. Voerkelius (Dissertation, Hannover, 1909), and Carpenter and Linder (Alkalı Works, 45th Rep. 1908, 26; 46th Rep. 1909, 21) The formation of hydrocyanic acid begins at about 700°, and the best yields, calculated on the ammonia used, are obtained at temperatures between 1000° and 1100° The reaction NH<sub>3</sub>+C  $\rightleftharpoons$  HCN+H<sub>2</sub> is reversible, and should lead to an equilibrium between ammonia, hydrocyanic acid, and hydrogen, the equilibrium, however, cannot be realised, because both ammonia and hydrocyanic acid are unstable at the temperatures required The final result depends, therefore, on the rates of decomposition of ammonia and hydrocyanic acid and on the rate of reaction between ammonia and charcoal Even at 1000°, the rate of decomposition of hydrocyanic acid in presence of charcoal is small, but in presence of other substances it may be large Voerkelius, for example, passed a mixture of hydrocyanic acid and hydrogen through an unglazed porcelain tube at 1000°, and found that over 70 p.c of it was decomposed, but after a layer of carbon had been deposited on the tube the decomposi-tion fell to 19 p c. The rate of decomposition of the ammonia is even more variable; for example, at 720°, 28 pc of the ammonia survived 6 minutes' contact with fresh finely ground wood charcoal, whilst 82 pc unchanged when the charcoal was in the form of lumps which had been already used rate of decomposition of the ammonia is diminished by diluting it with an indifferent gas

In the 66 experiments recorded by Voerkelius, the ammonia (diluted with hydrogen) was in contact with the charcoal for from 16 to 360 seconds, within these limits, the ratio between the numbers of molecules of ammonia and of hydrocyanic acid in the product is roughly independent of the time of reaction, but the quantity of ammonia decomposed into its elements increases with the time of contact The following table is calculated from the figures The figures show the given by Voerkelius influence of the quality of the charcoal on the

result :-

		Mols NH <sub>3</sub>

Nernst's thermodynamic theorem (Applications of Thermodynamics to Chemistry, London) 1907, and Theoretische Chemie, 5th and 6th ed has been applied to this reaction by v. Wartenberg (Zeitsch anorg. Chem 1907, 52, 299). Since the reaction NH<sub>3</sub>+C=HCN+H<sub>2</sub> absorbs 39,500 cals per molecule, the equilibrium must

lead to the formation of more hydrocyanic aci at higher temperatures, the calculation indicate that the ratio of the partial pressures (in atmo spheres) of the gases in equilibrium should hav the following values -

	$p_{ m NH_3}$
Temperature	$\overline{p_{ ext{HCN}}  imes p_{ ext{Ho}}}$
500°	632
800°	0 27
1100°	0 003
1400°	0 0002

In the experiments tabulated above, the fine mixture of gases usually contained nearly 95 p of hydrogen, the partial pressure of which we therefore almost 1 atmosphere The molecule ratio of ammonia to hydrocyanic acid is, there fore, almost the same as the ratio of the partie pressures. A comparison of the experiments values with those calculated shows that equil brium is never even approximately attained They agree in indicating 700° as the lower temperature at which appreciable quantities c hydrocyanic acid can be formed

Carpenter and Linder's independent invest gation yielded results in close agreement wit those obtained by Voerkelius It seems fairl certain that the greater part of the hydrocyani acid found in the products of destructive dis tillation of coal is formed by the reaction which has just been discussed. The presence of sma quantities of HCN in the products formed a temperatures below 600° indicates, however that it may be, in part, a primary product c

the decomposition Spent oxide. The hydrated oxide of iro first used in gas purification was made by mixin ferrous sulphate and slaked lime, sawdust bein added to increase the porosity (Laming, Eng Pat 11944, of 1847), natural iron ores were intro duced by Howitz in 1870 Sulphuretted hydro gen is absorbed, yielding a mixture of ferrou and ferric sulphides which is regenerated b exposure to air and moisture, free sulphur an ferrous and ferric hydroxide being produced Ferrocyanide is formed from the ferrou hydroxide and ammonium cyanide, and the converted into Prussian blue by interaction wit the ferric iron Sulphocyanides are also forme in very variable amount, doubtless by the inter action of hydrocyanic acid and ammoniui polysulphide. Since ammonia, sulphurette hydrogen, and free sulphur are always preser in the purifiers, it is obvious that polysulphide of ammonium can always be formed; it appear to be generally allowed, however, that sulphe cyanide is only produced in large amount whe the mixture becomes warm, as, for example when the regeneration proceeds rapidly in large mass of material The spent oxide finall contains 30 to 40 pc of sulphur (or more soluble ammonium salts and Prussian blue, i addition to tar and iron oxides Good matern contains 11 to 12 p c of Prussian blue, calculate on the air-dried substance, whilst ammonium

As already mentioned, prussiates were fire produced from spent oxide by Gautier-Bouchar about 1860 Ammonium salts were first re moved by washing with water; the residue wa then mixed intimately with sufficient lime t

sulphocyanide varies from traces to 10 p c.

convert the Prussian blue into calcium ferrocyanide and the mixture submitted to systematic lixiviation with cold water. This operation must be done in the cold, because otherwise calcium polysulphide is produced from the lime and free sulphur, and this converts the ferrocyanide into sulphocyanide. The calcium ferrocyanide was converted into the potassium salt by means of potassium carbonate, and the sulphur in the extracted residue burned to sulphur dioxide and converted into sulphuric acid (A. W. Hofmann, Reports by the Juries, Inter Exhib. of 1862, 59-63). This process contains the essential features of all those which have since been worked successfully

T. L G. Bell (Eng. Pat 257, of 1868) proposed to extract the sulphur with carbon disulphide, and, after removing soluble ammonium salts with water, to boil the residue with lime In order to obtain a pure product, the solution was then acidified and precipitated by the addition of ferric chloride, the Prussian blue being then converted into potassium ferro-The preliminary extraction of the cyanide sulphur has occasionally been carried out, but it is difficult to separate the sulphur from the tar which is extracted along with it. In spite of the great difficulty of filtering and washing Prussian blue, this method of purification appears to have been fairly generally used up to the year 1883, when Kunheim and Zimmer-mann (Eng Pat. 3342, of 1883) described two new methods.

In the first, the ammonia is only partially removed from the spent oxide by the preliminary washing, enough being left behind to produce the double salt Ca(NH<sub>4</sub>)<sub>2</sub>Fe(CN)<sub>6</sub>. The extraction with line then yields an ammoniacal solution of calcium ferrocyanide, which, when neutralised with hydrochloric acid and heated to 80°, deposits the very sparingly soluble calcium ammonium ferrocyanide, which is comparatively easily filtered and washed

By the second method, the solution of calcium ferrocyanide, obtained by following Gautier-Bouchard's original procedure, is treated with a solution of potassium chloride which precipitates the double salt  $\text{CaK}_*\text{Fe}(\text{CN})_6$  in minute crystals, which are very readily washed and are then converted into potassium ferrocyanide by boiling with potassium carbonate By this means one-half of the potassium carbonate is replaced by the cheaper chloride, and a very pure product is obtained (Franz Bossner, Die Verwerthung der Ausgebrauchten Gasreinigungsmassen, 1902). From the calcium ammonium salt, sodium ferrocyanide is readily obtained.

During the decade 1885 to 1895, the spent oxide of the gas works was the principal source of prussiates; its importance, however, has been diminished by the introduction of the more efficient wet methods of recovering the hydrocyanic acid.

Cyanide Washers —The first practicable proposal of this kind was made by O Knublauch (Eng Pat. 15164, of 1887). Coal gas was to be scrubbed with a solution of the oxide, hydroxide, carbonate, or sulphide of ammonium, or of an alkali or alkaline-earth metal containing the hydroxide or carbonate of iron, zinc, or manganese in suspension. The process did not succeed

at the time, probably for commercial reasons. The very similar process of Foulis (Eng. Pat. 9474, of 1892; Foulis and Holmes, Eng Pat. 15168, of 1895) has since been introduced at several gas works with satisfactory results. In this process, the reagent required is prepared by precipitating a ferrous salt with sodium carbonate The washed precipitate (a partially oxidised mixture of ferrous carbonate and hydroxide) is suspended in a solution of sodium carbonate and the gas passed through it in a rotary scrubber Foulis wished to obtain the whole of the ferrocyanide in the form of a solution of the sodium salt, and therefore placed the cyanogen washer after the ammonia scrubbers because, in presence of ammonia, an insoluble ammonium ferrous ferrocyanide is formed which is only decomposed by sodium hydroxide, but not by the carbonate At the Hague gas works, however, this order was reversed in order to catch the hydrocyanic acid which is otherwise condensed along with the ammonia (Rutten, Journ of Gas Lighting, 1902, 80, 879, Johnsen and Rutten, Journ für Gasbeleuchtung, 1903, 716) The saturated liquor from the cyanide washer contains Prussian blue and potassium and ammonium ferrous ferrocyanides in suspension and potassium ferrocyanide and ammonia in solution (potassium carbonate is used instead of the sodium salt) This mixture is filter-pressed and the solution distilled to separate the ammonia and then evaporated in vacuo and crystallised. The press cake is boiled with caustic potash and the ammonia collected, the residual iron oxide returning to the cyanide washer, and the solution of ferroeyanide going to the evaporating plant

In another set of proposals, the use of an alkalı other than the ammonia of the gas is dispensed with, the crude coal gas being simply washed with a solution of ferrous sulphate Since ammonia and sulphuretted hydrogen are present in much larger quantities than hydrocyanic acid, the ferrous sulphate is soon converted into a suspension of ferrous sulphide in a solution of ammonium sulphate, and the subsequent changes may be regarded as due to the action of a solution of ammonium cyanide on ferrous sulphide If a large excess of the latter is present, the main product is ferrous ferrocyanide Fe<sub>2</sub>[Fe(('N)<sub>6</sub>]; as the ferrous sulphide is used up, ammonium ferrous ferrocyanide (NH<sub>4</sub>)<sub>2</sub>Fe[Fe(CN)<sub>6</sub>] is formed in increasing quantities, and finally, when but little FeS remains, ammonium ferrocyanide is found in solution (Feld, Journ. fur Gasbeleuchtung, 1904,

The earlier patentees of processes based on these reactions attempted to obtain the ferrocyanide in a soluble form by using a dilute solution of a ferrous salt, and so having a large excess of ammonia present (Rowland, Eng. Pat. 22347, of 1891; Lewis and Cripps, Eng. Pat. 20883, of 1896; Schroder, Eng. Pat. 19849, of 1898, Teichmann, Eng. Pat. 12485, of 1899), but since insoluble compounds are always formed to some extent, it appears to be easier to obtain all the fefrocyanide (or the greater part of it) in the insoluble form by using a saturated solution of ferrous sulphate, and so having a large excess of iron present as first proposed by Bueb (Eng. Pat. 9075, of 1898). Bueb's process

has been adopted by a considerable number of gas works It is said to absorb 98 pc. of the hydrocyanic acid in the gas, yielding a mud containing 6-7 pc of ammonia and cyanogen compounds, equivalent to 18-20 pc of yellow prussiate of potash. A small part of the ferrocyanide is in solution. This is precipitated by boiling the mixture with ferrous sulphate, the precipitate is then filtered off and treated with lime, the calcium ferrocyanide solution obtained being worked up in the way already described when dealing with spent oxide

As already mentioned, part of the hydrocyanic acid in coal gas is always converted into sulphocyanide owing to liberation of free sulphur by the action of atmospheric oxygen on sulphuretted hydrogen. By suitable means the whole of the hydrocyanic acid may be fixed in the form of sulphocyanide, which is then converted into ferrocyanide by one of the processes

described in the next section

In 1877 W Marriott (Eng. Pat. 3311, of 1877) proposed to scrub gas with a solution of sodium polysulphides, and in 1888 Campbell and Boyd (Eng. Pat. 10186, of 1888) proposed the use of manganese dioxide suspended in water This liberates sulphur from a part of the sulphuretted hydrogen in the gas, and this free sulphur combines with ammonium sulphide to form polysulphid, which converts the cyanide into sulphocyanide The final step, which led to a successful and economical process, was made by H Wood Smith (H. Wood Smith, Gidden, Salamon, and Albright, Eng Pat 13658, of 1901) by simply scrubbing the gas through a suspension of sulphur, whereby the hydrocyanic acid is removed quantitatively, and a solution containing as much as 200 grams of ammonium sulphocyanide per litre may be obtained. This process is in use at several gas works, and yields practically the whole of the sulphocyanides made at present

Manufacture of Sodium and Potassium Ferrocyanides—(3) From Sulphocyanides A Gélis (Eng Pat 1816, of 1860) was the first to manufacture potassium ferrocyanide by heating dry potassium sulphocyanide with iron, made by reducing the oxide, at a dull-red heat, in a closed vessel He states that too high a temperature leads to considerable loss fusion process yields a mixture of potassium cyanide and ferrous sulphide which gives potassium ferrocyanide, when treated water in the same way as the 'metal' of the old process (A W Hofmann, Reports by the Junes, Inter Exhib of 1862, 59-63) Sir G Beilby has informed the writer that he made considerable quantities of potassium ferrocyanide by this process in the years 1873-1876 Potassium sulphocyanide was heated with iron turnings in air-tight iron retorts and, after cooling sufficiently, the product was extracted with water in the retort itself, without coming in contact with In this way the only serious difficulty of the process, which is due to the extreme proneness to oxidation of the fusion product, is avoided and satisfactory yields obtained.

The process was taken up again in 1878 by Gunzburg and Tchermac (Eng. Pat 1148, of 1878, 1359, of 1879, 1261, of 1881) They dried the sulphocyanide by fusing it at 300°, and then mixed it intimately with the oxide-free

iron by grinding them together. The mixture was heated in iron boxes with closely fitting covers at 445°, the vapour of boiling sulphur being used to obtain a constant temperature. After working for two or three years, the process was given up, but it was revived for the third time in 1894 by the United Alkali Co, Ltd. (Hetherington and Muspratt, Eng Pat. 5830, of 1894), and by the British Cyanides Co, Ltd. (Crowther, Rossiter, Hood and Albright, Eng. Pat 8305, of 1894) The patent specifications of Hetherington and of Crowther add but little to the information given above In both cases, some 20 to 30 p c excess of iron is used, and the temperature is almost the same as that recommended by Gunzburg and Tchermac Crowther says that mere fusion is insufficient to dry the sulphocyanide; a current of an indifferent gas must be passed through it for some time Conroy (J Soc Chem. Ind 1896, 15, 12) was able, in a small scale experiment, to convert 76.8 p.c of the sulphocyanide used into ferrocyanide (leaving 18.2 p.c unchanged) by means of Hetherington's method The process has been worked by the British Cyanides Co at Oldbury since 1894 (Brussels Exhib 1910. Catalogue of British Chem Section, 155)

The conversion of sulphocyanides into ferrocyanides is also possible in aqueous solution Sternberg (D R P 32892, of 1882), found that by heating a solution of potassium sulphocyanide with double the theoretical quantities of iron filings and ferrous hydroxide under pressure at 110°–120°, about 80 pc of the material could be converted into ferrocyanide

in accordance with the equation

 $6KCNS + 6Fe + Fe(OH)_2 = 6FeS + K_4Fe(CN)_6 + 2KOH$ G R Bower (Eng Pat 361, of 1896) succeeded in removing the sulphur from ferrous sulphocyanide by means of copper in a similar way Fe(CNS)<sub>2</sub>+2Cu=2CuS + Fe(CN)<sub>2</sub> Conroy (Conroy, Hurter, and Brock, Eng Pat 3867, of 1896, J T Conroy, J. Soc Chem Ind 1898, 17, 98) then found that a mixture of a soluble sulphocyanide and a ferric or ferrous salt would do as well as pure ferrous sulphocyanide, and also that the sulphur is more rapidly removed by finely divided iron than it is by copper Using very finely divided iron, the reaction takes place quantitatively in 5 to 6 hours at a temperature of 135°-140° and a pressure of 50 to 60 lbs per square inch, in accordance with the empirical equation  $Fe(CNS)_2 + 2Fe = Fe(CN)_2 + 2FeS$  (Sodium or potassium sulphocyanide is acted on by iron under similar conditions very slowly and incompletely) The black mud produced is either boiled with caustic alkali to decompose the ferrous ferrocyanide, or the ferrous sulphide is first dissolved in hydrochloric acid. latter course is to be preferred, owing to the fact that ferrous sulphide combines with the alkalis, each 3 or 4 equivalents of it rendering 1 equivalent of either caustic soda or potash insoluble, a difficulty with which the manufacturers of ferrocyanide from nitrogenous organic matter had long been familiar

#### PROPERTIES OF THE FERROCYANIDES.

The principal characteristics of those salts which possess some technical interest are described here; further information is to be

found in Cyanogen Compounds, by H E Williams, 1915, or in the text-books of inorganic chemistry.

Ammonium ferrocyanide is readily prepared in aqueous solution from the free acid and ammonia, or from barium ferrocyanide and ammonium sulphate. The solid salt

$$(NH_4)_4$$
Fe $(CN)_6$ ,  $3H_2O$ 

is obtained by evaporating the solution in vacuó, or by precipitation with alcohol. The salt crystallises with difficulty in very pale yellow plates, which are isomorphous with potassium ferrocyanide (Bunsen, Pogg. Ann. 1835, 36, 404). The aqueous solution decomposes when boiled, yielding ammonium cyanide and an insoluble residue, which possibly consists of more or less oxidised ammonium ferrous ferrocyanide.

 $2(NH_4)_4Fe(CN)_6-(NH_4)_2Fe[Fe(CN)_6]+6NH_4(NH_4)_2Fe[Fe(CN)_6]$ 

From solutions containing much ammonium chloride a double salt of the formula

crystallises very readily in well-formed orange-yellow rhombohedra, which were at one time mistaken for the ammonium salt (Bunsen, lc)

Barium ferrocyanide Ba, Fe(CN), 60H<sub>2</sub>O is precipitated when strong solutions of barium chloride and sodium ferrocyanide are mixed, it separates in the form of a light yellow, crystalline powder. Its solubility (grains of anhydrous salt per 100 grains water) is 0.34 at 15.5°, and 1.01 at 100° (Williams). The water of crystallisation is not quite completely driven off even at 160° (Drechsel, J. pr. Chem. 1880, [2]. 21, 77). The dried salt, when heated in vacuo, or in an atmosphere of introgen, carbon, iron, and barium cyanide and cyanamide being formed. When oxygen is completely excluded the product contains about 2 molecules of cyanamide to 1 of cyanide (Ewan and Napier, J. Soc. Chem. Ind. 1913, 32, 467).

## Barium potassium ferrocyanide

 $BaK_2[Fe(CN)_6],3H_2O$ 

is precipitated as a pale yellow, crystalline powder when solutions of barrum chloride and potassium ferroeyanide are mixed in equivalent quantities. Its solubility in water (grams anhydrous salt per 100 grams water) is 2.1 at  $15.5^{\circ}$ , 6.08 at  $100^{\circ}$ .

Calcium ferrocyanide (Ca<sub>2</sub>Fe(CN)<sub>6</sub>,12H<sub>2</sub>O<sub>15</sub> extremely soluble in water, highly concentrated solutions are very viscous and crystallise with difficulty, yielding small yellow trichine crystalls of sp gr 1 68, which effloresce when exposed to the air and lose 11½ molecules of water at 40° H<sub>2</sub> G Colman (Journ of Gas Lighting, 1910, 583) finds that the whole of the water is removed by heating the salt in a current of air. The dry salt begins to decompose (in absence of oxygen) at 500° yielding calcium cyanamide thus

Ca<sub>2</sub>Fe(CN)<sub>6</sub>=2CaCN<sub>2</sub>+Fe+N<sub>2</sub>+4C (unpublished experiments made by the writer).

Calcium ammonium ferrocyanide

Ca(NH<sub>4</sub>)<sub>2</sub>Fe(CN)<sub>6</sub>

is a white, minutely crystalline powder, which becomes coloured on exposure to light; it is anhydrous; 100 grams of water, at 15°-17°, dissolve 0.258 gram of the salt (J. Campbell Brown, Chem. Soc. Trans. 1907, 91, 1826)

Calcium potassium ferrocyanide  $K_2\text{CaFe}(\text{CN})_6$  is a white powder consisting of small quadratic prisms which becomes slightly cream-coloured on exposure to light. It contains no water of crystallisation and, at  $15^\circ-17^\circ$ , 100 grams of water dissolve 0.41 gram of it (J. Campbell Brown, *ibid* 1907, 91, 1826).

According to Williams (lc), the solubities

According to Williams (lc), the solubilities of these salts are rather larger, viz 0 35 at 15°, and 0 39 at 100° for the ammonium salt, and 0 72 at 15°, and 0 80 at 100°, for the potassium salt

Cupric ferrocyanide Cu<sub>2</sub>Fe(CN)<sub>6</sub> 11H<sub>2</sub>O is a red-brown, amorphous substance, obtained by adding a solution of calcium ferrocyanide or hydroferrocyanic acid to excess of cupric chloride solution In general, when solutions of a cupric salt and of a soluble ferrocyanide are mixed, an insoluble substance is produced, in which only a part of the four valencies of the ferrocyanogen ion is saturated by copper, the remainder being occupied by the metal of the ferrocyanide employed A very large number of these substances have been described Colloidal membranes formed of one or other of these copper ferrocyanides have been much used in the study of osmosis. The precipitate formed from potassium ferrocyanide and a cupne salt  $K_4$ Cu<sub>4</sub>[Fe(CN)<sub>6</sub>]<sub>3</sub> was used as a pigment under the name Hatchett's brown. The black, silver deposit in an ordinary photographic 'bromide' print may be converted into a red one, consisting of a copper ferrocyanide, by immersing the print in a solution containing 6 6 grams of copper sulphate crystals, 88 grams of potassium citiate, and 5 8 grams of potassium ferricyanide per litre (Ferguson, Photographic Journ 1900, 133)

Cuprous ferrocyanide Cu<sub>4</sub>Fe(CN)<sub>6</sub> xH<sub>2</sub>O is a white precipitate, which differs from most of the ferrocyanides in evolving the whole of its cyanogen as hydrocyanic acid when boiled with dilute sulphune acid. J. Dewrance and H. E. Williams (Eng. Pat. 28074, 1908) utilise this property in order to obtain complete decomposition of alkali ferrocyanides by distilling them with acid in presence of a small amount of cuprous chloride.

Hydroferrocyanic acid H4Fe(('N)6 is prepared by adding concentrated hydrochloric acid to a saturated solution of potassium ferrocyanide (both should be free from dissolved oxygen) and then enough ether to saturate the solution acid crystallises out in colourless scales which are washed with water saturated with other W Williamson, Annalen, 1846, 57, 225; A Joannis, Ann Chim Phys. 1882, [5] 26, 484), and dried over sulphuric acid. It may be puilfied by dissolving in alcohol and precipitating with ether, it obstinately retains ether, which is removed by heating at 100° in a current of dry hydrogen (Browning, Chem Soc Tians 1900, 1234) A solution of the acid, saturated at 14°, contains 150 grams per little The solution is readily oxidised by atmospheric oxygen, especially at higher temperatures, forming a blue substance which is usually assumed to be Prussian blue. This reaction is utilised in calico printing for the production of blue patterns

Ferrous ammonium ferrocyanide Fe(NH<sub>4</sub>)<sub>2</sub>[Fe(CN)<sub>6</sub>]

is formed when a solution containing ammonium ferrocyanide and excess of an ammonium salt is exactly precipitated by a ferrous salt, oxygen being excluded It is also formed when ammonium ferrocyanide is distilled with an acid in absence of air.

Ferrous cyanide  $Fe(CN)_2$  is formed when a solution of hydroferrocyanic acid is boiled, H<sub>4</sub>Fe(CN)<sub>6</sub>=4HCN+Fe(CN)<sub>2</sub>, or when the dry acid is heated at 300° in an atmosphere of hydrogen (Addie and Browning, Chem Soc Trans 1900, 158; Browning, ibid 1900, 1234)

Ferrous potassium ferrocyanide (Everitt's salt) K<sub>2</sub>Fe[Fe(CN)<sub>6</sub>] is formed in a similar way if potassium salts are present, as, for example, in the preparation of hydrocyanic acid by distilling a mixture of potassium ferrocyamide and dilute sulphuric acid Everitt's salt is a paleyellow crystalline powder which is not identical with the white precipitate obtained by mixing solutions of potassium ferrocyanide and ferrous chloride, although this precipitate has the same composition.

The iron in these ferious salts is displaced by treatment with caustic alkalis, but not by alkalı carbonates.

Ferric ferrocyanides. The blue compounds of iron and eyanogen are all amorphous substances, which yield colloidal solutions in pure water. It is therefore extremely difficult to prepare them in a pure condition Owing to the well-known tendency of colloids to adsorb other substances from solutions, the precipitates require very prolonged washing to free them from adhering salts, and during this process their composition may, and very often does, change, owing to atmospheric oxidation or to hydrolysis On the other hand, the method of determining the composition of a precipitate by mixing known quantities of the reagents and estimating the excess left in the supernatant liquid, is open, in this case, to the objection that the precipitate is not a pure substance because it has adsorbed some of the salts in the solution in contact with This method has been used by E Muller the This method has been used by E. Muller and by P. Woringer (E. Muller and T. Stanisch, J. pr. Chem. 1909, [n.] 79, 81; \*ibid. 1909, [n.] 80, 153, E. Muller, G. Wegelin, F. R. Treadwell, and O. Diefenthaler, \*ibid. 1911, [n.] 84, 353; E. Muller, \*ibid. 1914, [n.] 90, 119, P. Woringer, \*ibid. 1914, [n.] 87, 51.) K. A. Hofmann and his contractor (K. A. Hofmann, O. Hoppe, and F. collaborators (K A Hofmann, O Heine, and F Hochtlen, Annalen, 1904, 337, 1, K A Hofmann and F. Resensheck, *ibid* 1905, 340, 267, 1905, 342, 364; Hofmann, Arnoldi, and Hiendlmaier, ibid 1907, 352, 54), have investigated more especially the composition and properties of the substances which remain after exhaustive purification

The freshly prepared blue precipitates contain indefinite quantities of water, but the whole of it cannot be removed by drying in iacu6 over phosphorus pentoxide until a constant weight is attained (which usually requires from 2 to 5 This residual water must be regarded as constitutional, because when the substances are heated to temperatures a little above 100°, they lose hydrocyanic acid, but not water The formulæ of the dry substanecs given in what follows refer to the very thoroughly washed substances after complete drying over PaOs in the way mentioned above

When cold neutral solutions of one molecule of a ferric salt and one molecule of potassium ferrocyanide are mixed together, a precipitate of ordinary soluble Prussian blue is formed. The dry substance has the composition

 $2[KFe^{III}(Fe^{II}Cy_6)]+3\frac{1}{2}H_2O$ 

The same compound is obtained by mixing equal molecular quantities of a ferrous salt and potassium ferricyande. This was first proved by Skraup (Annalen, 186, 371, 1877).

When a cold solution of potassium ferrocyanide is added gradually to a cold neutral (or ½ p c. hydrochloric acid) solution containing an excess of a ferric or of a ferrous salt, or when soluble Prussian blue is digested with a solution of ferric chloride, precipitates are formed which, after the prolonged exposure to air involved in washing them completely, are identical in com-position and properties. The dry substance is position and properties normal ferric ferrocyanide

 $\text{Fe}_{4}^{\text{III}}(\text{Fe}^{\text{II}}\text{Cy}_{6})_{3} + 10\text{H}_{2}\text{O}$ 

usually referred to as Prussian blue. 'Turnbull's blue, obtained by precipitating a solution of potassium ferricyanide with an excess of a ferrous salt, is, after exhaustive washing with exposure to air, identical with ordinary Prussian blue

The composition of the unwashed precipitates initially formed depends, as Muller has shown, on the relative quantities of reagents employed. Setting out from potassium ferrocyanide and ferric chloride, Prussian blue is precipitated when the ratio mols K4Fe(Cv6)/mols. Fe(13 is less than 0.75, for values between 0.75 and 0.92 the precipitate contains increasing quantities of KFeIII[FeIICy,], and when the ratio exceeds 0.92 the substance

K. FeII FeII Cv.

is also present Setting out from potassium ferrieyanide and ferrous chloride a precipitate of the composition KFeIIFe<sub>5</sub>III[FeIICy<sub>6</sub>]<sub>5</sub> is obtained when the ratio, mols K<sub>3</sub>FeCy<sub>6</sub>/mols FeCl, is less than 0.714 Between 0.714 and 0 75 a substance KFe<sup>II</sup>Fe<sub>3</sub><sup>III</sup>[Fc<sup>II</sup>Cy<sub>6</sub>]<sub>3</sub> is formed, which Muller regards as ordinary Turnbull's blue; from 0.75 to 0.9 increasing quantities of KFeIII[FeIICy,] are present, and finally, when the ratio exceeds 0.9 ordinary Prussian blue appears According to Muller, Turnbull's blue and Prussian blue are interconvertible

 $\begin{array}{c} \operatorname{Fe_4^{III}}[\operatorname{Fe^ICy_6}]_3 + \operatorname{K'} + \operatorname{Fe''} \\ & \stackrel{\textstyle \textstyle \succeq}{\rightleftharpoons} \operatorname{KFe^IFe_3^{III}}[\operatorname{Fe^ICy_6}]_3 + \operatorname{Fe'''}, \end{array}$ 

although a very large excess of ferrous salt is required to convert an appreciable amount of Prussian blue.

It is obvious that the reactions involved in the formation of the blues are not simple double decompositions, mutual oxidations and reductions take place, and adsorption phenomena are superadded, so that, in general, the precipitates first produced are mixtures either of definite insoluble compounds, as Muller supposes, or if insoluble substances with soluble constituents adsorbed from the solutions.

The precipitates obtained from hot acid solutions differ more or less from those formed at ordinary temperatures in their properties, and appear even when washed to be mixtures of different substances.

Both the soluble and insoluble Prussian blue, above described, are ferric ferrocyanides, and not ferrous ferricyanides. This is proved by the fact that they can be made by the action of hydrogen peroxide on a solution containing a ferric salt and potassium ferricyanide in suitable quantities. As Schonbein (J pr. Chem 1866, 98, 65) showed, hydrogen peroxide reduces ferricyanide to ferrocyanide, but has no action on a ferric salt, so that ferrous ferricyanide could not be produced by this reaction

Blue compounds, which are not identical with those described above, are also obtained by the oxidation of ferrous ferrocyanides

(a) By adding a cold neutral solution of 1 molecule of a ferrous salt to a solution of 1 molecule of potassium ferrocyanide, and then oxidising the white precipitate by means of atmospheric oxygen, which is greedily absorbed (or better by hydrogen peroxide), a blue compound of the composition KFe<sup>III</sup>(Fe<sup>II</sup>('y<sub>6</sub>)+H<sub>2</sub>O is obtained. This differs from ordinary soluble blue in being insoluble in oxalic acid solution. It is referred to in the table of properties of the blues as K. A. Hofmann's blue.

(b) By proceeding exactly as in (a), except that the solutions contain 1 p c of sulphuric acid, a white precipitate is obtained, Fe<sup>II</sup>K<sub>2</sub>(Fe<sup>II</sup>Cy<sub>6</sub>), which is rather less readily oxidised to a blue of the same composition as before:

FeIIK(FeIICy,)+H,O

but possessing rather different properties. Like ordinary soluble Prussian blue, it is soluble in water and oxalic acid, but differs from it in being much more stable to ammonia solution. This compound is referred to as 'stable soluble blue'

(c) When a solution of potassium feirocyanide, containing about 10 pc of sulphuric acid, is heated in an atmosphere devoid of oxygen, one half of the hydrocyanic acid is evolved and a pale-yellow crystalline powder of Eventt's salt K<sub>2</sub>Fe<sup>II</sup>(Fe<sup>II</sup>Cy<sub>6</sub>) remains behind. This salt is very much less readily oxidised than the precipitate obtained by mixing solutions of potassium ferrocyanide and a ferrous salt, it is not completely oxidised by several weeks' exposure to the air. It is readily oxidised by warm dilute intric acid (A W Williamson, Ann Chem Pharm. 1846, 57, 225), but a homogeneous product is prepared most certainly by suspending it in 1 pc sulphuric acid and adding about 10 times the theoretical quantity of hydrogen peroxide. The substance thus obtained is Williamson's blue (sometimes called violet), and it also has the composition

KFeIII(Fe Cy6)+H2O

Its properties are, however, totally different from those of the isomenic substances already described

PROPERTIES OF THE BLUE IRON-CYANOGEN COMPOUNDS.

Reagent	Ordinary soluble Prussian bluc (Turnbull'ssoluble blue)	Insoluble Prussian blue	K A Hof- mann's blue	Stable soluble blue	Williamson's blue or violet
Pure water .	Soluble, reddish-blue solution	Insoluble	Soluble, greenish-blue solution	Soluble	Insoluble, turbid green- ish-blue sus-
10 pc oxalic	Soluble, blue solution	Soluble, blue solution	Insoluble	Soluble	pension Insoluble
4 p c ammonia yields red- brown feiric hydroxide		In 10 seconds	In a tew se- conds	In 6 to 7 mm- utes	After some hours
Ferric chloride	Precipitates insoluble Prussian blue.	No change	(۶)	Gradually co- agulated in unchanged condition	No change
1 to 1½ p c. H <sub>2</sub> SO <sub>4</sub>	Slowly precipitated, moist precipitate soluble in water	No action	Quickly pre- cipitated, insoluble in water	Precipitated, insoluble in water	No action
Appearance of dry solids		Deep-blue pur- ple lustre			Purple-red

For comparison, the distinguishing properties of the different blues are tabulated above. The isomerism of these substances may be due to differences in the linking of the atoms—of the kind familiar in organic chemistry—or it may be due to differences in the size of the molecules, the data available do not appear to be sufficient to decide these questions with any degree of certainty.

In accordance with the commonly accepted view, the blues have been formulated as ferro-

cyanides P Woringer, in 1914 (let), however, advanced certain arguments in favour of the ferricyanide structure. He confirmed an observation, made by A W Williamson in 1846, that when ferric chloride acts on an excess of ferrocyanide the solution contains ferricyanide; he also states that Prussian blue, when decomposed by ammonium carbonate, yields 90 p.c. of ferricyanide. As E. Muller pointed out in 1909, it is easy to show, from the well-known oxidation potentials of solutions of ferrous

and ferric ions and of ferro- and ferri-cyanogen ions that, if these four ions could coexist in solution the ratio of their concentrations [Fe] [FeCy<sub>6</sub>"'] [Fe][Fe "Cy<sub>6</sub>""] would be about 10<sup>6</sup>, that is, ferrocyanide would be exidised

practically completely by ferric salts

Williamson, however, showed that the reverse reaction also takes place, ferricyanide being partly reduced by ferrous salts. It appears thus that ferri- and ferro-evanogen ions can coexist in approximately equal concentration, so that, in equilibrium, the concentration of ferric ion must be very small compared with that of ferrous ion These concentrations are determined by the solubilities of the precipitates formed, about which very little appears to be known; the mode of formation of a blue affords, therefore, no certain clue to its structure The same is true of its decomposition by strong alkalis, since alkaline ferricyanide solution oxidises ferrous hydroxide very readily mann's methods of preparation by means of hydrogen peroxide appear at present to be the best evidence available in favour of the ferrocvanide structure

It is of interest that precipitation from hot acid solutions always tends to produce substances (or mixtures) of a more stable type, approaching Williamson's blue more or less closely in properties, and also that all the blue iron cyanogen compounds contain both ferrous and feiric iion The compounds which contain only ferrous or only ferric iron are colourless or (compared with the blues) feebly coloured Solid pieces of ordinary Prussian blue assume a coppery lustre when rubbed on a smooth, hard surface The blue solution in oxalic acid was formerly used as an ink Prussian blue is reduced by hydrosulphurous acid, H2S2O4, or its sodium salt to white ferrous ferrocyanide (M. Rohn, Zeit Anorg Chem 1906, 49, 443) turns a suspension of Prussian blue in water green; the solution contains ferric chloride . the blue colour is restored by washing with water Concentrated sulphuric acid unites with Prussian blue to a white paste from which the original blue is obtained by diluting with water It is slowly decomposed by concentrated aqueous hydrochloric acid, but dissolves to a colourless solution in alcoholic hydrochloric acid, the solubility increases with the molecular weight of the alcohol used Water precipitates unchanged Prussian blue from these solutions By dissolving impure Prussian blue in a solution of hydrochloric acid in propyl alcohol, filtering, and reprecipitating with water, it may be separated from all commonly occurring impurities, such as barium sulphate, kaolin, alumina, and starch (C. Coffignier, Bull. Soc chim. 1904, 391) Potassium, sodium, and calcium hydroxides decompose Prussian blue into ferric hydroxide and a ferrocyanide, alkalı carbonates act more slowly dyed with Prussian blue gradually lose their colour in sunlight, but regain it in the dark When heated to about 170° in the air, it burns like tinder leaving a brown ash.

Colloidal solutions of Prussian blue (0.2 to 2 p.c) may be prepared by dialysis of the oxalic acid solution. The colloidal blue is negatively charged and is coagulated by cathions; hydrogen is especially active, otherwise the usual

increase of activity with valency obtains (W. Pappadà, Gazz. chim. ital. 1911, 41, ii. 454). K Å. Hofmann (Annalen, 1905, 340, 267) also observed that his soluble blue carried a negative charge, and did not depress the freezing-point

Commercial blues are usually mixtures of the compounds already described. J. G Gentele (Lehrbuch der Farbenfabrikation, 2nd ed. 1880) says that the best blues are obtained by precipitating a feirous salt with potassium ferrocyanide, and then oxidising the piecipitate Paris blue (the finest quality of commercial Prussian blue) is made as follows. 50 kilos of potassium ferrocyanide are dissolved in 250 kilos of boiling water, 42 5 to 45 kilos of green vitriol are dissolved in about the same quantity of water, preferably in the presence of scrap iron to prevent formation of ferric salt. The clear solutions are then run simultaneously into 250 kilos of water The almost white precipitate is allowed to settle and then drained on a cloth filter. The oldest method of 'blueing' the paste was to heat it to boiling in a basin, transfer it to a wooden tub, and add 25 5 kilos. of mtric acid (sp gr 1 23) and 18 kilos. of sulphuric acid (1 84 sp gr). Sometimes, red fumes were evolved only after some hours, but in presence of excess of green vitriol, they were always evolved at once and this gave the best colour After standing for 24 hours, the mixture was suspended in a large quantity of cold water and allowed to settle. The washing by decantation was continued until the blue was free from sulphuric acid. It was then collected on linen filters, pressed into thin cakes, and cut up into cubes which were dried in the an and finally at 30°-40°. The yield was 39 to 39 5 kilos of finished blue.

Another method was to treat the heated paste of ferrous ferrocyanides with ferric chloride, instead of with intire acid, until the solution contained ferric in addition to ferrous salts, but according to Gentele, the cheapest and best method is to acidify the paste slightly with hydrochloric acid and pass chlorine gas into it until the solution shows a distinct 'ferric' reaction with ferrocyanide.

From these descriptions it is clear that commercial Paris blue must contain, in addition to ordinary insoluble Prussian blue, one or more of the potassium ferric ferrocyanides presence of potassium appears to be of importance, a less satisfactory colour being produced when sodium ferrocyanide is used in its pre-paration H E Williams says that potas-sium may be replaced by ammonium with satisfactory results A Eibner and L Gerstacker (J Soc. Chem Ind 1912, 31, 1041) state that the blues with a high potassium content possess the technically desirable greenish shade, those poor in potassium being dull with a violet tinge. They have tound 12 p c K and 5 5 p c. H<sub>2</sub>O in 'steel-blue' and 'bronze blue,' 9 p c K and 105 pc H2O in 'Paris blue,' the lowest value found in a commercial blue being 15 p c K and 24 pc H<sub>2</sub>O. In the commercial pigments, Paris blue is diluted with starch, heavy spar, gypsum, zinc white, or burned and finely ground kaolin. The white admixture, after having been ground very finely by itself, is added to the Paris blue paste, and along with it passed through a colour mill. Very low qualities of

blue are faced by rotating the dry cubes in a cask with the fine dust of pure Paris blue.

Potassium ferrocyanide (yellow prussiate of potash, Blutlaugensalz, Ger) crystallises from aqueous solutions in large, well-formed, orangeyellow tetragonal pyramids of the composition  $K_4$ Fe(CN)<sub>6</sub>3 $H_2$ O; sp gr 186. The crystals do not change when exposed to the air at ordinary They begin to lose water at 60° temperatures and the finely powdered salt may be completely dehydrated at 100°, forming a white powder which begins to decompose, in absence of oxygen, slightly below a red heat to a mixture of potassium cyanide, carbon and iron, nitrogen escaping. The powder takes fire at a considerably lower temperature when heated in contact with air It is insoluble in alcohol The soluble ferrocyanides are completely decomposed by boiling with mercuric oxide

$$K_4$$
Fe(CN)<sub>6</sub>+3HgO+2H<sub>2</sub>O  
=3Hg(CN)<sub>2</sub>+FeO+4KOH

They are also decomposed by aurous evanide. hydroxide, and even by finely-divided gold in the presence of oxygen

$$\begin{array}{l} 3\mathrm{Au} + \mathrm{K_4Fe(CN)_6} + 2\mathrm{H_2O} + \mathrm{O_2} \\ &\quad = 3\mathrm{KAu(CN)_2} + \mathrm{Fe(OH)_3} + \mathrm{KOH} \end{array}$$

(E. Beutel, Zeitsch anorg Chem 1912, 78, 141) According to Etard (Ann Chim Phys 1894, [7] 2, 546), the solubility, expressed in grains of anhydrous salt dissolved by 100 grams of water, is 14 5 at 0°, 24 5 at 20°, 36 at 40°, 49 5 at 60°, 64 at 75°, 70 at 80°, 72 at 89°, 74 at 98°, and 88 at 157°. The salt is much less soluble in solutions of potassium salts The specific gravity of the aqueous solutions is given below (Schiff, Annalen, 1860, 113, 199) -

G1s  $K_4$ Fe(CN)<sub>6</sub>,3H<sub>2</sub>O  $\rbrace$  1 per 100 grs. of solution  $\rbrace$  1 Sp gr at 15° . . . 1 005 5 15 . 1 0058 1 0295 1 0605 1 0932 1 1275

Sodium ferrocyanide crystallises in large lemon - yellow monoclinic prisms or rhombohedra of the composition  $Na_4Fe((!N)_0, 10H_2O)$ (Conroy, J Soc Chem Ind 1898, 17, 103), which are permanent when exposed to the air at the ordinary temperature, but are completely dehydrated at a little above 100° The behaviour of the dry salt, when heated, resembles that of the potassium compound solubility in water (Conroy, J Soc Chem Ind 1898, 17, 103). grams anhydrous salt dissolved by 100 grams of water, is at 20°, 17 9; at 30°, 23 5, at 40°, 29, at 50°, 35 5, at 60°, 42 5, at 70°, 51 5; at 80°, 59 2; at 90°, 61, and at 100°, 63

Zinc ferrocyanide Zn<sub>2</sub>Fe(CN)<sub>6</sub>,6H<sub>2</sub>O is a white amorphous substance obtained by the action of calcium or hydrogen ferrocyanide on an excess of zinc chloride in aqueous solution With other soluble ferrocyanides the precipitate contains more or less of the metal of the ferrocyanide used, a fact referred to in more detail in the analytical section of this article. It is insoluble in dilute acids, completely soluble in caustic alkalis to a mixture of ferrocyanide and zincate, and only partially decomposed by alkali carbonates.

Potassium ferricyanide, red prussiate of potash, K<sub>3</sub>Fe(CN<sub>6</sub>), was discovered by Leopold Gmelin in 1822. He prepared it by passing chlorine into a solution of potassium ferro-VOL. II.-T.

eyanide until it no longer gave a blue colour with a ferric salt:

449

$$2K_{4}Fe(CN)_{6}+Cl_{2}=2K_{3}Fe(CN)_{6}+2KCl$$

The salt is always manufactured by this reaction; the ferrocyanide is sometimes used in the form of a dry powder, in which case a mixture containing potassium chloride is obtained Most commonly, a cold 10 pc. solution of potassium ferrocyanide is treated with chlorine until conversion is just complete. A little Prussian green is always formed by the action of chlorine on the ferricyanide, and as this passes through any filter it spoils the appearance of the product. The difficulty may be avoided by evaporating the solution to crystallisation and then adding a little caustic potash which decomposes the green into ferric hydroxide, which is easily removed by filtration, and potassium ferrocyanide, which is apt to crystallise out along with the ferricyanide The yield of ferricyanide, in this process, is 85 to 90 pc of the theoretical quantity

Λ W Williamson (Annalen, 1846, 57, 225) found that potassium ferric ferrocyanide (Wilhamson's blue), when boiled with potassium ferrocyanide, gives potassium ferricyanide and Everitt's salt

$$\begin{split} K_4 \mathrm{Fe}^{\mathrm{II}}(\mathrm{CN})_6 + K \mathrm{Fe}^{\mathrm{III}}[\mathrm{Fe}^{\mathrm{II}}(\mathrm{CN})_6] \\ = & K_3 \mathrm{Fe}^{\mathrm{III}}(\mathrm{CN})_6 + K_2 \mathrm{Fe}^{\mathrm{II}}[\mathrm{Fe}^{\mathrm{II}}(\mathrm{CN})_6] \end{split}$$

Since Everitt's salt is readily oxidised to Williamson's blue by warming with dilute nitric acid, the process might (as Dittmar suggested) be utilised to complete the conversion of ferrointo ferricyanide, chlorine being used up to the point at which Prussian green begins to be

Many other oxidising agents have been suggested in place of chlorine, such as bromine, lead peroxide, calcium plumbate, potassium permanganate and persulphate, and electrolytic oxidation (see Bertelsmann, Technologie der Cyanverbindungen)

Potassium ferricyanide crystallises from water in magnificent, deep - red, monoclinic prisms which may be very large. It is anhydrous. sp gr 1845. The aqueous solution has an intense yellow colour. The solubility (grams) of anhydrous salt dissolved by 100 grams of water) is 33 at 44°, 36 at 10°, 40 8 at 155°, 58 8 at 37 8°, 77 5 at 100°, and 82 6 at 104 4° (Wallace, Dingl. poly J 1856, 142, 52) Specific gravity of the solutions at 15° (Schiff, Annalen, 1860, 113, 199)

The aqueous solution is decomposed by light, potassium ferrocyanide being formed. caustic alkaline solution is a strong oxidising agent which decolourises indigo instantaneously The alkaline solution is also reduced by hydrogen

peroxide, oxygen being evolved

Ferric ferricyanide. The dark-brown solution, formed when solutions of a ferricyanide and of a ferric salt are mixed, contains ferric ferricyanide in the form of a highly disperse Ultramicroscopic examination show that the particles gradually increase in size, a green substance ultimately separating out

(R. Haller, Kolloid Zeit. 1917, 20, 76). The formation of a green substance by the action of chlorine on potassium ferricyanide was first noticed by Pelouze (Ann Chim Phys. 1838, [2] 69, 40). Green ferric ferricyanides are also obtained by boiling Prussian blue with strong nitric acid or by precipitating potassium ferricyanide containing a little ferrocyanide with ferric chloride (H E Williams)

# Potassium carbonylferrocyanide $K_3[Fe(CN)_5CO]H_2O$

is formed by the action of carbon monoxide on an aqueous solution of potassium ferrocyanide at 135°

 $K_4$ Fe(CN)<sub>6</sub>+CO+2H<sub>2</sub>O = $K_3$ Fe(CN)<sub>5</sub>CO+NH<sub>3</sub>+KHCO<sub>2</sub>

(Muller, Ann. Chim Phys 1889, [6] 17, 94) Carbonylferrocyanides are found in the cyanide mud and spent oxide of the gas works, in which from 2 to 5 p c of the cyanogen (exceptionally as much as 20 pc) is present in this form (H G. Colman, Analyst, 1908, 33, 261) When the caustic soda extract of these materials, mixed with 4 to 5 times its volume of methylated spirit, is allowed to stand for some hours, the sodium ferrocyanide crystallises out completely, leaving the carbonyl ferrocyanide in solution It is isolated, in the form of the amorphous, deep-violet ferrie salt, by adding ferric chloride to the acidified solution to the acidified solution. The deliquescent calcium salt  $\text{Ca}_3[\text{Fe}(\text{CN})_5(\text{O})]_2,8\text{H}_2\text{O}$  is obtained by boiling the ferric salt with milk of lime The carbonyl ferrocyanides resemble the corresponding ferrocyanides, but are paler in colour and more soluble in water The copper salt, a green precipitate soluble in excess of ammonia, is characteristic

Sodium nitroprusside  $Na_2[Fe(CN)_5NO]$   $2H_2O$  was first prepared by Lyon Playfair (Phil Mag 1850, [3] 36, 197) by the action of dilute intraction on a solution of a ferrocyanide. The primary products of the change, hydroferricyanic acid and nitric oxide, react thus  $H_3Fe(CN)_6+NO=H_2Fe(CN)_5NO+HCN$ . The salt is also formed by adding a concentrated solution of ferrous sulphate to a solution containing equal parts of sodium nitrite and potassium cyanide. It crystallises in dark-red prisms, soluble in  $2\frac{1}{2}$  parts of water at  $16^\circ$ . The solution is not precipitated by a ferric salt, and gives a deep violet colouration with alkali sulphides

#### Sodium aquopentacyanoferroate Na<sub>3</sub>[Fe(CN)<sub>5</sub>H<sub>2</sub>O],5H<sub>2</sub>O

is obtained by the action of reducing agents, such as phenylhydrazine or hydroxylamine, or of oxidising agents, such as potassium hypobromite and hydrogen peroxide on a solution of sodium nitroprusside at temperatures below 0° The action of hydrogen peroxide is analogous to its behaviour with a ferricyanide

 $2K_3$ Fe(CN)<sub>6</sub>+ $H_2O_2$ +2KOH

 $=2K_4Fe(CN)_6+O_2+2H_2O$ 

The salt crystallises in reddish-yellow needles, giving an intensely yellow solution, which does not yield a violet colouration with alkali sulphides.

## Sodium aquopentacyanoferriate

 $Na_2[Fe(CN)_5H_2O]$ 

is obtained by oxidising the foregoing compound with bromine. It is a deep violet-blue substance,

and Cambi has shown that the potassium perferricyanide obtained by Bong (Bull. Soc. chim 1875, [2] 24, 268) and Skraup (Annalen, 1877, 189, 368) by the action of potassium chlorate and an acid on a solution of potassium ferricyanide, is the potassium salt of the same acid. It is also obtained by the action of excess chlorine on potassium ferricyanide, a deep violet solution being formed, from which the salt is precipitated by alcohol.

A series of pentacyano iron compounds has also been prepared, which may be regarded as derived from the aquo-compounds just described by the replacement of the H<sub>2</sub>O group in the anion by one of the groups NO<sub>2</sub>, AsO<sub>2</sub>, SO<sub>3</sub>, NH<sub>3</sub>, or substituted ammonias.

Hexamethyl carbylamine ferro saits By the action of methyl sulphate on dry potassium ferrocyanide or of methyl iodide on silver ferrocyanide, E G J Hartley has obtained a series of salts of the general formula [Fe(CNCH<sub>3</sub>)<sub>6</sub>]R<sub>2</sub>, R being a univalent acid radical, in which the iron cyanogen complex plays the part of cathion. When heated with concentrated sulphuric acid, or boiled with aqueous caustic soda, these salts are decomposed, the whole of the nitrogen appearing in the form of methylamine, or of methyl carbylamine, which proves that all the nitrogen atoms are linked to methyl

Tetramethyl ferrocyanide  $\left[ \operatorname{Fe}^{(\operatorname{CNCH}_3)_4}_{(\operatorname{CN})_2} \right]$  is formed when hexamethylcarbylamine ferrochloride [Fe(CNCH<sub>3</sub>)<sub>6</sub>]Cl<sub>2</sub> is heated at 140°-150° in a vacuum for 6-9 hours, methyl chloride being Two isomeric forms, with the same split off molecular weight, have been separated from The a-isomer is much the reaction product more readily soluble in water, alcohol, and chloroform than is the  $\beta$ -isomer, and from water it crystallises with two molecules of water of crystallisation, the β-isomer combining with six They also differ in their behaviour towards methyl iodide, with which the α-compound combines at  $100^{\circ}$ , yielding hexamethylcarbylamine ferroiodide, the  $\beta$ -compound remaining un-No method of converting the one changed form into the other has been discovered (E. G. J. Hartley, Chem Soc Trans 1910, 1066 and 1725. ibid 1911, 1549, ibid 1912, 705; ibid 1913,

Constitution of the Iron Cyanogen Compounds.—When dissolved in water these compounds dissociate electrolytically into a complex ion containing the iron, cyanogen, and other groups, the sign and magnitude of the electric charge of this ion depend on the nature of its constituent groups of atoms. The ions Fe(CN)<sub>6</sub>"', Fe(CN)<sub>6</sub>"'', Fe(CN)<sub>6</sub>"'', Fe(CN)<sub>6</sub>"'', Fe(CN)<sub>6</sub>"'', Fe(CN)<sub>6</sub>"'' are examples of this These ions possess considerable stability, but are probably dissociated to a very small extent For example, the ferrocyanogen ion is supposed to dissociate thus, Fe(CN)<sub>6</sub>""'\sqrt{Fe}"+6(CN)' (F. Haber, Zeit. Elektrochem. 1905, 11, 846; Foster, Chem. Soc. Trans. 1906, 912). In the dark the concentration of ferrous ion is too small to produce

a precipitate of FeS with an alkalı sulphide, but the complete decomposition of the ferrocyanogen complex by mercuric oxide shows that the minute concentration of (CN)' in a solution of a ferrocyanide is greater than that in a solution of mercuric cyanide. The dissociation of the ferrocyanogen ion is increased by light, especially the ultra-violet rays, so that in alkaline solutions, oxygen produces a precipitate of ferric hydroxide. The increased dissociation is, however, so small that no appreciable increase in the conductivity of the solution can be detected

Measurements of the osmotic pressure and electrical conductivity of solutions of the ferrocyanides of calcium and strontium have been made by the Earl of Berkeley, Hartley and Stephenson (Phil Trans. 1909, 209A, 319), the results of which are incompatible with the assumption of a molecule Ca. [Fe(CN)<sub>6</sub>] dissociating into three ions, it is suggested that the undissociated molecules may be double. The non-electrolyte, tetramethyl ferrocyanide, exists as single molecules in aqueous solution, and, from measurements of the freezing-point, Buchbock (Zeitsch. phys. Chem. 1897, 23, 157) arrived at the same result in the case of tetraethyl ferrocyanide.

Several cases of isomerism have been recorded Locke and Edwards (Amer Chem. J 1899, 21, 193 and 413) observed that the ordinary anhydrous, red potassium ferneyanide is converted into a greenish-yellow modification, crystallising with 1 molecule of water by treatment with acids This \$\beta\cdot \text{ferricyanide gives no}\$ precipitate with bismuth nitrate, the ordinary α-modification giving a straw-coloured precipitate. The \beta-ferricyanide is converted into the a-salt by treatment with alkalis Briggs (Chem. Soc Trans 1911, 1019) describes similar behaviour on the part of the ferrocyanides. Faintly acid solutions deposit more deeply coloured crystals of the B-isomer, which are readily converted into the a-form by treatment with potassium cyanide or alkalis. The lmenthyl ammonium salts of the two isomers have different specific rotatory powers in alcoholic solution, otherwise only minute differences in density and solubility were observed Bennett (Chem. Soc. Trans. 1917, 490) finds that the  $\alpha$ - and  $\beta$ -ferrocyamides are crystalographically identical, and explains the difference of colour by slight decomposition of the acid solutions

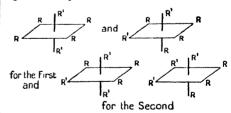

In addition to the isomeric tetramethyl ferrocyanides already mentioned, Hartley (Chem Soc Trans 1914, 521) has recorded the existence of two isomeric trimethyl cobalitivamides  $Co(CNCH_1)_3(CN)_3$  (attempts to prepare the ferricyanide derivative were unsuccessful), which differ considerably in solubility.

The synthesis of ferrocyanides from a feirous compound and of ferricyanides by boiling excess of ferric hydroxide with an alkali cyanide (Skraup, Annalen, 1877, 189, 376), show that these compounds and their direct derivatives contain divalent and trivalent iron respectively It is to be remembered that the iron cyanogen compounds here considered form one group of a great family of complex salts. Substances of the general formulæ

are known in which the metal is Co, Cr, Mn.

Ru, Rh, Ir, and Os, and in which the CN group may be replaced by SCN These are closely related in structure and chemical behaviour to large groups of metal ammonia and halogen complex salts Under the circumstances, Werner's formulation of these salts, although it lacks the definiteness of the structural formulæ of organic chemistry, appears to be the best available A Werner (Neuere Anschauungen auf den Gebiete der anorganischen Chemie, 3rd ed 1913) regards the complex salts as built up by the co-ordination of a maximum number of six groups of atoms round a central atom; carbon, nitrogen, and boron are exceptional, their maximum co-ordination number being four. The six groups are arranged symmetrically; at the angles of a regular octahedron, they are attached to the central atom, partly by the ordinary principal valencies, partly by secondary The nucleus so formed acts as a more or less stable whole, which may still be able to combine with other atoms at a greater distance from the centre or on an outer sphere. These more loosely held atoms dissociate electrolytically when the substance is dissolved; whether they are attached to the nucleus as a whole or to any particular atom in it is left undecided, although Werner inclines to the The number and nature of the former view ionogenic groups depends on the nature of all the atoms included in the nucleus For example, among the compounds described, we have

A further consequence of the theory is that complexes of the formulæ  $\left[ \begin{array}{c} M_{R'_2}^A \end{array} \right]$  and  $\left[ \begin{array}{c} M_{R'_3}^A \end{array} \right]$  should exist in the two stereoisomeric forms represented by '

Possibly Hartley's isomeric tetramethyl ferrocyamde and trimethylcobalticyamdes are examples of these forms of isomerism. Werner classifies the (somewhat uncertain) isomerism of the ferro- and ferricyamides as unexplained, but as Briggs has remarked (Chem. Soc. Trans. 1908, 1564), they would also come under the above heading if the potassium atoms are supposed to be attached to definite CN groups in the nucleus.

Manufacture of Potassium and Sodium Cyanides.—The methods of manufacture of these salts are most conveniently described together, since most of the processes used may equally well

be applied to making either salt. The most important technical processes have already been mentioned in the introduction to this article

Manufacture from Yellow Prussiate —Potassium cyanide was first prepared by Berzelius's method, which consists in heating dry potassium ferrocyanide to redness, when it decomposes thus:  $K_4 \text{Fe}(\text{CN})_6 = 4 \text{KCN} + \text{Fe} + 2 \text{C} + \text{N}_2$ . The loss of cyanogen, which occurs in this way, is partly avoided by fusing the ferrocyanide with potassium carbonate, as first described by F and E Rodgers (Phil Mag 1834, [3] 4, 91) Liebig showed that the product contains cyanate, formed thus:

 $K_4$ Fe(CN)<sub>6</sub>+ $K_3$ CO<sub>3</sub>=5KCN+KCNO+Fe+CO<sub>2</sub>

The fused salt is allowed to stand until the iron and carbon have settled out, and is then poured off into moulds. The comparatively small quantities of cyanide, which were used in electroplating and for other purposes up to about 1890, were made by this process. The product was sold in white, porcelain-like cakes, containing from 30 to 70 p.c. of KCN.

In 1876, E Erlenmeyer (Ber 1876, 9, 1840) pointed out that a very pure product, containing on the average 40 p c. of CN (equivalent to 100 p c KCN), was obtained by fusing dry prussiate with metallic sodium in the proportions required by the equation

$$K_4$$
Fe(CN)<sub>6</sub>  $+2$ Na=4KCN+2NaCN+Fe

This process was taken up first by the Deutsche Gold and Silber Scheide-Anstalt (F. Roessler, V. Inter Kongress für Angewandte Chemie, Berlin, 1903, 1, 638) in Frankfort-on-Main, in 1890, they obtained a practically quantitative yield by filtering off the spongy iron from the fused evanide and pressing the iron while red hot. The eyanide so obtained is east in cakes and forms a pure white crystalline mass. Since about 1905, sodium ferrocyanide has been used in this process in place of the potassium salt, and the product is almost pure sodium evanide. The excess of the gas works ferrocyanide over that required in the colour industries is converted into sodium evanide in this way.

It has been proposed to distil ferrocyanides with acids and to absorb the hydrocvanic acid in solutions of caustic alkalis. Grossmann (Eng. Pats 36 and 4513, of 1903, J Soc Chem. Ind 1903, 22, 1327) distils sodium ferrocyanide with 20 pc sulphuric acid in lead stills the Everitt's salt remaining is reconverted into sodium ferrocyanide by boiling it with caustic soda in a current of air The use of calcium ferrocyanide, which readily yields two-thirds of its hydrocyanic acid, was proposed by J. H. Paul (Eng. Pat. 72 of 1903). W. Feld (Eng. Pat. 24920 of 1901) converts insoluble ferrocyanides into mercuric cyanide, and then distils Dewrance and Williams this with an acid (Eng. Pat 28074 of 1908) distil the ferrocyanide, either soluble or insoluble, with 2-3 p.c. of its weight of cuprous chloride and a small excess of sulphuric acid, the whole of the hydrocyanic acid being evolved. None of these proposals is at present of technical importance.

The processes of Stepermann and Beilby were the first synthetic processes to produce cyanide in large quantities, they are most conveniently considered together because, although they differ

widely in the methods adopted in carrying them out, they are both based on the same chemical reaction which was also used by Scheele in the first synthesis of a cyanide ever made

In Siepermann's process (D. R. P 38012, March 10, 1886; Eng Pat 13697 of 1889; 9350 and 9351 of 1900) a dry mixture of about 2 parts of charcoal and 1 part of potassium carbonatethat is, a sufficient excess of charcoal to keep the mixture in the form of a dry unfused mass throughout the process—is heated in the upper part of a vertical iron tube to a dark-red heat and treated with dry ammonia gas, which is taken up, forming potassium cyanate. The product is then allowed to fall into the lower end of the tube, which is heated to bright red-At the higher temperature the cyanate is converted into cyanide, the carbon monoxide evolved escaping through the upper part of the tube along with the hydrogen formed from the ammonia, without taking any part in the reaction. The finished material is drawn off into air-tight receptacles where it is allowed to cool completely, after which it is systematically liviviated with water Potassium cyanide may be precipitated from the solution obtained (sp gr about 14) by adding excess of potassium carbonate, but according to the later patents it is preferable to evaporate it almost to dryness and extract the unchanged potassium carbonate with small quantities of The residue of potassium cyanide water at 66° and cyanato is then treated with water between -18° and +5°, which dissolves the cyanide and any residue of carbonate, leaving almost pure potassium cyanate The product of this process was first put on the market in 1892 (G. Beilby, potassium cyanate V Int Kongress angew Chem Berlin, 1903, 1, 630), but as the substance was in the form of a damp deliquescent mass, it could not be exported for use at the mines by itself but had to be fused with the product of the ferrocyanide process

In the Bellby process (Eng Pat 4820 of 1891), which began to produce in the same year, the quantity of charcoal used is very much smaller, very little more being employed than is necessary to convert the potassium carbonate into eyanide thus

$$K_2CO_3+4C+2NH_3=2KCN+3CO+3H_9$$

The charcoal is added gradually during the progress of the operation, so that the material is always in the form of a fused liquid through which the ammonia gas is forced under some This is continued until a sample pressure shows the conversion to be sufficiently complete: it is then only necessary to separate the small excess of charcoal by filtration in order to have a pure white saleable product Since the melting-point of pure potassium carbonate (890°) is inconveniently high, previously made cyanide was mixed with it in starting the process, or the more readily fusible mixture of sodium and potassium carbonates was used, so that the cyanide made by the process was very similar in composition to that produced by the Erlenmeyer process from potassium ferrocyanide. In 1899 the Beilby process contributed fully one-half of the total European production of cyanide

It is difficult to obtain a satisfactory yield on the ammonia in these processes, owing to the rapidity with which it decomposes into its

elements at temperatures above 500° and in contact with metals, especially iron (Ramsay and Young, Chem. Soc. Trans. 1884, 88; Beilby and Henderson, *ibid.* 1901, 1245). For this reason it is necessary to work at the lowest possible temperature. Siepermann, for example, obtained a yield of 86 p c on the ammonia when it was absorbed at a dark-red heat, but only 58 pc at a bright cherry-red heat Readman (J Soc. Chem Ind 8, 757, 1889) showed that almost theoretical efficiencies can be obtained at the low temperatures attainable in an ordinary organic combustion furnace, whilst ('onroy (ibid 15, 12, 1896), working at very high temperatures (1000°-1200°), could not get more than 30 to 33 pc of the ammonia in the form of cyanide. In practice the reaction velocity is cyanide also of great importance, in the Beilby process where the advantage of the large surface exposed by Siepermann's dry mass of alkalised charcoal is sacrificed, the reaction is too slow at tempera tures below 900°, the best results are obtained at  $980^{\circ}$ . In order to keep down the dissociation of the ammonia at this high temperature it is injected into the fused mixture through copperlined tubes of such diameter that it's time of contact with the hot metal is less than one-tenth of a second

The chemistry of the reaction has been investigated by J. Pfleger (F. Roessler, V. Int. Kongress angew. Chem. Berlin, 1903, 1, 638). Ammonia and potassium carbonate react, yielding potassium eyanate and hydroxide, a carbamate being most probably formed as an intermediate product.

$$\begin{array}{c} \text{CO(OK)}_2 + \text{NII}_3 = \text{CO} \\ \text{OK}^2 + \text{KOH} \\ \text{CO} \\ \text{OK}^{-1} = \text{KCNO} + \text{H}_2\text{O} \end{array}$$

When pure potassium cyanate is heated at 800°-900°, it decomposes, cyanide and carbonate being formed and introgen, carbon dioxide, and carbon monoxide evolved. The mechanism of this change is probably as follows. Drechsel (J. pr. Chem. 1877, [2] 16, 201) has observed that the cyanates of the alkaline earth metals decompose, when heated, into carbon dioxide and the corresponding cyanamide salts. Assuming that the alkali cyanates behave similarly, the first change will be

$$2KCNO = K_2CN_2 + CO_2$$

Potassium cyanamide, however, decomposes completely at lower temperatures than  $800^{\circ}$  into cyanide, potassium, and nitrogen .

$$K_2CN_2 = KCN + K + N$$

The carbonate and carbon monoxide observed are thus due to the reaction between the metallic potassium and carbon dioxide which are formed simultaneously. In presence of chatcoal in excess, the greater part of the cyanamide follows Drechsel's reaction (J pr Chem 1880,[2] 21, 77),  $\rm K_2CN_2 + C = 2KCN$ , instead of decomposing; so that the apparent induction of cyanate by carbon probably takes place in the two stages:

$$\begin{array}{c} 2KCNO\!=\!K_2CN_2\!+\!CO_2\\ \text{and } K_2CN_2\!+\!C\!=\!2KCN\\ CO_2\!+\!C\!=\!2CO \end{array}$$

The reactions occurring in the Beilby process are the same, except that, the whole process

being carried on at the higher temperature, the formation of cyanate and its conversion into cyanide take place simultaneously instead of being more or less sharply separated as they are in Siepermann's process

In the Siepermann process, it is easier to use the ammonia efficiently, owing to the lower temperature employed, but this is counterbalanced by the greater difficulty of working up the product into a marketable form.

The Castner Process—In 1894 H Y Castner (Eng Pat 12219 of 1894) patented a process in which sodium was fed in at the upper end of a column of red-hot charcoal through which a current of dry ammonia gas was passed from below, the reaction being expressed by the simple equation.

$$2Na + 2C + 2NH_{3} = 2NaCN + 3H_{2}$$

In a second patent (H Y Castner, Eng Pat 21732, 1894) it is shown that better results are obtained by first allowing the sodium and ammonia to react at a low temperature (300° to 400°), forming sodium amide NaNH<sub>2</sub>, and then running the amide on to an excess of red-hot charcoal with which it reacts thus:

Working in this way, it happened on one occasion that an excess of amide was accidentally run into the vessel containing the charcoal, and a product of unusual appearance was obtained, in which the writer found a large quantity of sodium cyanamide. The reaction, therefore, takes place in three stages, in which the introgenenters successively into more and more stable combinations. First sodium amide is produced, a compound which begins to decompose rapidly into its elements at 500° (Titherley, Chem. Soc. Trans. 1894, 504), this reacts either with carbon.

$$2NaNH2+C=Na2CN2+2H2$$

or, as Pfleger found, with sodium cyanide

forming sodium cyanamide, a compound which only decomposes slowly at 600°, and finally this takes up carbon, forming sodium cyanide which is quite stable at any temperature attained in the process

Like the Bellby process, this process yields a fused product containing very small quantities of solid impurities which are easily removed by filtration. After being cast in non moulds, the cyanide is obtained in the form of pure white cakes with crystalline fracture, containing 97½ to 98 p.c. of NaCN (equivalent to 129–130 p.c. of KCN)

The greater part of the world's cyanide requirements has been from its inception to the present date, 1920, supplied by this process in England. It was worked out, under Mr. Castner's direction, at the works of the Aluminium Co at Oldbury; the first manufacturing plant was erected, by the writer, at Frankfurton-Main, just before Mr. Castner's death in 1899, and the second at Glasgow in 1900. The experienced assistance of the staffs of the Frankfurt and Glasgow companies led to rapid improvement of working details A third installation started work near New York in 1901.

'Schlempe' Process -The juice of the sugar beet contains both inorganic and organic substances other than sugar, and these substances accumulate in the molasses In Germany, rather more than half of the molasses made are treated with strontia, which combines with the sugar to form an insoluble sucrate, the residue left after removing this, the concentrated essence of the impurities of the original juice, is known as 'schlempe' After concentration to sp.gr 14, it contains 75 pc of dry substances, 30 p c of which are inorganic (mainly potassium) salts and the remainder organic substances The 'schlempe' contains about 4 p c of nitrogen in the form of betaine

and decomposition products of the vegetable proteins. Of the molasses not treated by the strontia process, a large part is consumed as cattle food and a small part fermented to alcohol. The residue of the alcoholic fermentation is known in France as 'vinasses'

The first attempt to utilise the nitrogen of 'vinasses' was made by Vincent in 1877-1880 He distilled the 'vinasses' in horizontal iron retorts at a red heat, ammonia, a mixture of the three methylamines, monoethyl-, monobutyl, and monopropylamines, methyl alcohol, and combustible gases was evolved, and potassium carbonate mixed with some carbon remained behind (E Duvillier and A Buisme, Ann Chim Phys 1881, [5] 23, 289, H Ost, Zeitsch angew Chem 1906, 19, 609) In 1879 Ortheb and Muller devised a process for converting Vincent's methylamines into hydrocyanic acid, which was worked by the Société Anonyme de Croix (Eng. Pat. 3844, of 1879) The vapour of the methylamines was passed through a redhot retort, yielding ammonia, hydrocyanic acid, methane, and hydrogen The ammonia was absorbed by sulphuric acid, and the hydrocyanic acid by a suspension of ferious hydroxide in caustic potash. The manufacture of the methylamines was abandoned in 1881 for want of a market, and with it the production of cyanides.

The problem was again attacked by Bueb (Reichardt and Bueb, Eng Pat. 7171 of 1895, Bueb, Eng. Pat. 26259 of 1898) Instead of separating the products of distillation of the 'schlempe,' he passed them directly, after condensing some tar, into a series of firebrick channels which were heated to bright redness The ammonia and hydrocyanic acid were absorbed together in a solution of ferrous sulphate, and the product worked up in the same way as that made in the gas works The narrow flues were soon stopped up by deposits of carbon, so that they were replaced by chambers filled with fire-brick checker-work, which is heated up to 1000° by firing directly with producer gas, during this process, the deposit of carbon is burned Two such chambers are used alternately, the one being heated up whilst the gases from the retorts

chamber, the methylamines disappear and hydrocyanic acid is formed, the ammonia undergoing but little change. The ammonia is now removed from the gas by absorption in sulphunic acid, and the hydrocyanic acid absorbed in water in a suitable column. The solution of hydrocyanic acid is then distilled into a solution of caustic soda (A. Vasseur, Bull. Soc. Ind. Nord de la France, 1913, 41, 445) The solution of sodium cyanide is evaporated to crystallisation, the crystals dried, and briquetted by compressing them into blocks which are dried at 70° in vacuó (Eng. Pat. 18096, of 1907), and then contain sodium cyanide equivalent to 120 p.c. of KUN.

Of the nitrogen in the 'schlempe,' about onehalf is converted into nitrogen gas and so lost, a quarter is obtained as sodium cyanide and the remainder as ammonium sulphate

The decomposition of diand tri-methylamine, when passed through a heated porcelain tube filled with fragments of porcelain, fire-brick, or charcoal, has been studied by Voerskelius (Dissertation, Hannover, 1909). At temperatures lying between 800° and 1000°, as much as 98 p.c. of the trimethylamine decomposes into hydrocyanic acid and methane N(CH<sub>3</sub>)<sub>3</sub>=HCN+2CH<sub>4</sub>, the remaining 2 p.c. yielding ammonia N(CH<sub>3</sub>)<sub>3</sub>+3H<sub>2</sub>=NH<sub>3</sub>+3CH<sub>4</sub>. This result was obtained when the gaseous contents of the tube were changed once in 7½ seconds; with a slower current of gas and also with a contact material of large surface (fireday or charcoal) or with iron, a part of the hydrocyanic acid is decomposed into its elements. The rate of decomposition at 1000°, however, is small. At 720° the yield of hydrocyanic acid was only 78 p.c. and at 600° none was produced.

was only 78 p c, and at 600° none was produced. The formation of hydrocyanic acid from dimethylamine also begins between 600° and 700°, from 800° to 1100° the change takes place quantitatively in accordance with the equation NH(CH<sub>3</sub>)<sub>2</sub>=HCN+CH<sub>4</sub>+H<sub>2</sub>. If hydrogen is present, however, a second change occurs NH(CH<sub>3</sub>)<sub>2</sub>+2H<sub>2</sub>=NH<sub>3</sub>+2CH<sub>4</sub>. Using equal volumes of hydrogen and dimethylamine, this reaction is of no importance, but as the hydrogen present increases more and more of the dimethylamine is converted into ammonia until, with a mixture of 97 parts of hydrogen to 3 parts of dimethylamine, ammonia is the sole product

The behaviour of monomethylamine is probably analogous to that of dimethylamine A Wurtz (Ann Chim Phys. 1850, [3] 30, 443) found that, at a red heat, it decomposes in accordance with the equation

$$3CH_3.NH_2 = 2HCN + NH_3 + CH_4 + 3H_2$$

In practice, therefore, the losses of hydrocyanic acid and ammonia by decomposition will depend on the rate of passage of the gases and on the nature of the contact material—the deposit of carbon on the porous bricks diminishing the decomposition of hydrocyanic acid

this process, the deposit of carbon is burned. Two such chambers are used alternately, the one being heated up whilst the gases from the retorts are passing through the other. The gases has made practical application of these observations by passing the decomposing chambers contain 7 pc HCN; 7 pc, NH $_3$ ; 8 pc (mainly) CH $_4$ ; 12 pc H $_2$ ; 18 p.c. CO; 24 pc. CO $_2$ ; and 24 pc. N $_2$ . In passing through the decomposing

of the nitrogen is obtained as ammonia or hydrocyanic acid.

Manufacture of Sodium and Potassium Cyanides from Sulphocyanides.—The sulphocyanide is first conveited into ferrocyanide by one of the methods already described, and the ferrocyanide then worked up into cyanide; this is the method actually in use. Other more direct processes have been used to some extent

The earliest of these was D J. Playfair's process (Eng Pat 7764 of 1890) Playfair found that certain metals, lead and zinc especially, when fused with potassium sulphocyamide, abstract the sulphur, leaving potassium cyanide, which may be separated from the metallic sulphide by extraction with water. The fusion is carried out at 400°, and 70–80 p c of the sulphocyamide is converted into cyanide (D J. Playfair, J. Soc Chem Ind 1892, 11, 14, Conroy, *ibid.* 1896, 15, 8) The reaction is slower with lead, owing to the small surface offered by the fused metal, whilst with zinc the product is apt to be contaminated by the double cyanide of zinc and potassium. The process was worked about 1894 by the British Cyanides Co at Oldbury (Brussels Exhib 1910, Catalogue of British Chem. Section, p. 63).

of British Chem. Section, p. 63).

Raschen's process (Eng. Pats. 10476, 10956, and 21678 of 1895, 19767 of 1898, 12180 of 1900) is based on the oxidation of sulphocyanic acid to hydrocyanic and sulphuric acids which was first observed by E. A. Hadow (Annalen, 1858, 108, 380). Hadow found that permanganate, lead peroxide, manganese dioxide, and nitric acid bring about the same reaction fraction of the same reaction acid solutions only when an excess of the oxidising agent is present. If the oxidising agent is added to the sulphocyanide, solid yellow compounds are produced of variable composition, one of which, 'canaiin' (qv), has been used as a yellow dye

The Raschen process (J T Conroy, J. Soc Chem Ind 1899, 18, 432) was carried out by allowing a solution containing about 15 p e of sodium sulphocyanide to flow into dilute nitric acid kept at the boiling-point by means of live steam. The reaction:

#### NaCNS+2HNO<sub>3</sub>=HCN+NaHSO<sub>4</sub>+2NO

From 3 to 5 pc of the nitric acid was less completely reduced, N<sub>2</sub>O<sub>3</sub> being formed, so that the gases leaving the decomposer were first scrubbed with a little water The resulting solution of nitrie, nitrous, and hydrocyanic acids The gas, was returned to the decomposer which now contained about 1 volume of hydrocyanic acid to 2 volumes of nitric oxide, was passed through a solution of caustic soda (sp.gr. 137), which absorbed the hydrocyanic acid. It was found necessary to avoid saturating this solution completely with hydrocyanic acid because of the brown decomposition products which are formed from the free acid in presence of a cyanide The nitric oxide was then mixed with air and passed up-The nitric wards through towers packed with flints down which water trickled, in this way it was reconverted into nitric acid (sp gr. 1 12) which was returned to the decomposer. The solution of sodium cyanide was evaporated to dryness in vacuum pans without appreciable loss.

The reduction of sulphocyanides by hydrogen was studied by Playfaii (J. Soc Chem Ind. 1892, 11, 14). He found that hydrogen acts on potassium sulphocyanide at a dull-red heat, forming potassium cyanide and sulphide and sulphiretted hydrogen.

455

Conroy, Heslop, and Shores (J Soc Chem. Ind 1901, 20, 320) showed that the reaction takes place slowly at 500°, and fairly fast at 600°. Their results indicate that two reactions occur simultaneously:

 $KSCN+H_{2}=KCN+H_{2}S$ 

and

 $2KSCN + 2H_2 = K_2S + 2HCN + H_2S$ 

A little ammonia is also evolved, probably owing to the difficulty of drying the sulphocyanide completely. About 70 p c of the nitrogen is obtained in the form of cyanide and 20 p c as hydrocyanic acid. With barium and cuprous sulphocyanides, the reaction is similar to that represented by the second of the above equations, the principal introgenous product being hydrocyanic acid. With the cuprous salt, the reaction begins below  $300^\circ$ 

Rossiter, Crowther, and Albright (Eng Pats 4403 and 6226 of 1901) have patented a process based on the behaviour of the cuprous salt. It is mixed with finely divided copper and heated at temperatures rising from 150° to 650° in a current of hydrogen Hydrocyanic acid is evolved and cuprous sulphide remains behind

Synthesis of Cyanides from Uncombined Nitrogen. Up to the outbreak of the European War in 1914 the mtrogen of cyanides was almost exclusively derived either from organic matters of animal origin or from coal The persistent attempts to synthesise cyanogen compounds from atmospheric nitrogen, which date back to the first half of the nineteenth century, have been renewed during recent years, and important progress has been made. The deficiency of cyanide caused by war conditions has, to a small extent, been supplied by the product of one of the processes using atmospheric nitrogen, but it remains to be seen whether any one of them will be able to hold its own in competition with the older sources of supply under more normal conditions

The attacks on the problem of fixing free nitrogen in the form of cyanide have been made by several paths which sometimes intersect. For convenience of description, they may be arranged according to the raw materials used, the action has been studied of introgen on:—

- 1 a. Alkalı metal carbonates and carbon
  - b. Alkalı metals and carbon
- c. Barium carbonate and carbon
- 2 a. Carbides of metals.
- b. Acetylene
- 3. Metals forming nitrides, subsequently converted into cyanides.

#### 1 a. Action of Nitrogen on Alkali Metal Carbonates and Carbon.

Scheele may have been the first to fix atmosphere pitrogen in the form of a cyanide Writing in 1783, he says (Chemical Essays, 1901, reprint, 288). We know that charcoal powder, brought into fusion with fixed alkalis, yields likewise a kind of lixivium sanguinis, though weak.' The

source of the mtrogen is, however, doubtful, | since charcoal contains a little combined nitrogen. Desfosses (Ann Chim. Phys. 1828, 38, 158) mentions that notable quantities of cyanide are obtained by the action of nitrogen on a mixture of potash and carbon heated to redness, but the first thorough investigation of the reaction was made by Lewis Thompson, who was awarded the Gold Isis Medal of the Society of Arts, in 1838, for his improvements in the manufacture of Prussian blue. The chief improvement consisted in the substitution of atmospheric nitrogen for that contained in animal matters (Mechanics Magazine, 1839, 31, 92) (2 parts), coke (2 parts), and non tunings (1 part), were ground together to a coarse powder and heated in an open crucible, for half an hour, to a full red heat with occasional stirring, the end of the operation was indicated by the cessation of the jets of purple flame which arose from the surface of the mixture After cooling, the material was lixiviated, and Piussian blue precipitated in the usual way. The yield was better with larger quantities of material than it was with smaller batches, thus 6 oz of pearlash, containing 45 pc K<sub>2</sub>O, yielded 0.62 oz (295 grains) of Prussian blue, whilst 12 oz (1 lb) of the same material yielded 2.8 oz (1355 grains) of blue, 1 that is, 0 23 and 0 54 part of Prussian blue for 1 part of K2O used Assuming that the Prussian blue was dried at 30°-40', and contained 28 pc of water, the theoretical yield is 2 1 parts, so that Thompson cyanised from 11 to 26 p c of the potash used This calculation may underestimate the yield, because it is stated that the Prussian blue spoken of is the 'pure perferrocyanate of iron'. Coke was used (because wood charcoal burns away too quickly), and the 'carbonaceous matter may be worked over again many times, and is even improved by each operation.' The importance of the addition of iron is insisted on, when it is not employed a much higher temperature is required

The importance of Thompson's discovery of the catalytic action of iron was not fully appreciated for nearly three-quarters of a century, perhaps because the addition of iron for an entirely different purpose was a familiar feature of the current process of manufacture of ferrocyanide Contemporary criticism was concerned mainly with the source of the nitrogen, although Thompson's statement that carbonaceous matter improves on re-use would, if confirmed, have put the matter beyond doubt

G. Fownes, in a paper read to the British Association (The Chemist, 1841, 2, 261), insisted on the possible error due to the presence of nitrogen in the coke used, and found, like Scheele, that charcoal or coke yields 'abundance of cyanide' when heated with potash in a closed crucible at a moderate red heat, which is not the case when pure carbon is used When pure nitrogen was passed over a mixture of pure potassium carbonate and sugar charcoal heated, in a porcelain tube, he observed that carbon monoxide was evolved at first in much greater volume than that of the nitrogen passed in. When the evolution of carbon monoxide ceased he found in two experiments at a 'full red heat' that 111 and 121 pc. of the potash had been converted into cyanide. whereas at 'whiteness, much above the meltingpoint of copper,' the production of cyanide

appeared much greater

The repetition of Fownes' experiment by several chemists added little to our knowledge, and may be dismissed in a few words Erdmann and Marchand (J. pr Chem. 1842, 26, 407) observed only a doubtful trace of (yanide, Liebig and Wohler (Handworterbuch der Chemie, 1842, ii 384) could not confirm Fownes' result, and Delbiuck (J pr Chem 1847, 41, 161) also obtained a mere trace of cyamde. None of these authors gives details of then methods Bunsen and Playfan (But Ass. Rep 1845, 142), on the other hand, by heating a mixture of pure potassium carbonate and sugar charcoal in a gun bairel in a current of nitrogen at a temperature high enough to form potassium (about 1200°), obtained 6.982 grams of silver cyanide from an unmentioned quantity of potash It may be surmised that the different results noted were due to differences of temperature

In addition to these laboratory experiments, a most remarkable attempt was made to develop this process on a manufacturing scale Possoz and Boissière (Eng. Pat. 9985 of 1843, granted to their agent A. V. Newton) began their experiments at Grenelle, near Pans, in 1843, but transferred the plant in 1844 to the works of Messrs Bramwell & Co (one of the leading prussiate makers of that time) at Newcastleon-Tyne The experiments were carried on by Mr Bramwell and Mr F R Hughes until 1847, and a detailed account of them, furnished by Mi Hughes, was published by Giaham (Report of Junes, Exhib of 1851, 1, 95)

Wood charcoal was soaked in a solution of ordinary potash and dried, yielding a mixture containing about 20 pc K<sub>2</sub>O. This was, at first, heated in vertical fire-clay retorts of small diameter, which were fired externally. Owing to the low thermal conductivity of the retorts and of the charcoal, the heat penetrated the mass very slowly, and the output of a tube was  $_{
m small}$ It may be pointed out that this very serious difficulty is accentuated by the endo-thermic nature of the reaction, which was unknown at that time; it is not only necessary to heat the charge to the reaction temperature, but the large quantity of heat absorbed by the reaction

 $K_2CO_3+4C+N_2=2KCN+3CO-129$  Cals

must also be supplied

After a number of alterations, retorts were adopted, which were built of ordinary firebrick; they were 2 feet in internal diameter, and were heated for a length of 6 to 8 feet to a temperature sufficient to produce cyanide In an upper prolongation, the wet charcoal was dried and preheated, and in a lower, unheated extension, made of cast iron, the product was cooled down, and then discharged, by means of an arrangement which permitted a periodical withdrawal of a part of the charge, into a solution of a ferrous salt, into which the lower end of the cast-non tube dipped A ring of small slots was left in the brick retort at every third or fourth course of bricks, through which the hot

<sup>&</sup>lt;sup>1</sup> The bracketed figures are Thompson's; they are recalculated on the assumption that Troy weight was used.

mixture of nitrogen and carbon dioxide in the furnace was drawn into the retort by means of an aspirator attached to the upper end In this way the difficulty of heating the charge to its centre was overcome The highest temperature in the furnace was sufficient to soften a Stourbridge fireclay bink throughout its substance (1350°-1400°?) The hot gases were aspirated upwards, drying and preheating the fresh charge in the upper part of the retort As much as one-half of the alkalı in the cyanised charcoal produced was found to be in the form of cyanide, and 7 or 8 retorts of the dimensions given yielded 36-40 cwts of prussiate of potash per week, under favourable circumstances About onehalf of the charcoal used was consumed, and 3 parts of potash were used for 1 part of prussiate made About one-third of the potash was accounted for by the prussiate, one-third remained in the refuse charcoal, which could not be profitably lixiviated, and the remainder combined with the bricks of the retort, or was volatilised up the chimney. The financial failure of the process was due to the losses of potash and to the short life of the retorts

R Hoflmann (Report of Junes, Exhib of 1862, 59) also tried large-scale experiments at Occlenwald in the Black Forest, in 1858–1859, which may be referred to as a further illustration of the difficulties mentioned above. The alkalised coke was heated in wrought-iion tubes, not more than 1 foot in diameter, protected with fireday. The furnace was heated to a bright, white heat, which fused the common brick work behind the firebrick lining, but only minute quantities of cyanide were formed, the failure is ascribed to too low temperature, for it was found that the middle portion of the coke in a

tube was far from being white hot

In 1878, C A Fawsitt (Eng Pat 4544 of 1878) described a method of making ammonia by this process In his experiments, which were made at St. Rollox, Glasgow, he used sodium carbonate instead of potash (J Soc Chem Ind 1890, 9, 30) Using 3-inch or 4-inch wroughtnon tubes, he obtained as much as 50 p c of the theoretical yield of ammonia, but with 6-mch cast-iron tubes the yield was much smaller, because the east iron would not withstand the temperature needed. These experiments, therefore, indicate that a temperature exceeding 1100° (the approximate melting-point of cast iron) is required, although, in this case, the differences may have been due, in part, to the facts that a tube of larger diameter would give worse results even with the same external temperature, and that the nitrogen used with the 6-inch tubes contained from 3 to 5 p.c of

oxygen. The patents of Victor Alder of Vienna are of interest, because they contain a clear recognition of the catalytic rôle of iron, and of the necessity of obtaining intimate admixture of the reacting constituents, together with sufficient porosity to admit of free access of nitrogen Alder proposed to heat an intimate mixture of alkaline material and carbon in a closed vessel, in an atmosphere of nitrogen, and said. 'The addition of finely divided iron greatly promotes the conversion into cyanide, but is not absolutely essential to the success of the operation' (Eng. Pat. 1004 of 1880). In Eng. Pat. 5617 of

1881 he states that the reaction only succeeds in presence of carbonising gases, such as hydrocarbons or carbon monoxide, and that metals 'capable of fixing and transmitting the carbon, such as iron, chromium, manganese, nickel, or cobalt, greatly promote the conversion' The charge is prepared, for example, by mixing a solution of the alkali with charcoal and adding sawdust or other substance, which, when heated, will yield a porous mass, or a thin paste of the alkaline solution and finely ground charcoal containing some binding material is spread out on the surface of lumps of charcoal The 'car-bonising metal' is to be added as such, as oxide or in the form of a solution of a salt which, when heated in a current of steam, will decompose, leaving a deposit of the oxide, which, in the cyanising process, will be reduced to metal Alder appears, however, to have been under the impression that the success of a technical process depends on the employment of the cheapest raw materials, however unsuitable they may be, and a great part of the specifications consists of descriptions of the preparation of alkali-carbon mixtures from such substances as alkalı sulphates, limestone, and coal, as in the Le Blanc alkalı process, the failure of the process is not, therefore, surprising

The catalytic action of non was re-discovered by E Tauber in 1899 (Ber 1899 32, 3150, and more fully in Die Chem Ind 1903, 26, 26) Trials of different kinds of carbon and different alkalis showed that potash or soda and wood charcoal are the most active materials intimate mixture of alkali and charcoal was made by soaking sawdust in the alkaline solution and carbonising the mixture, non (reduced by hydrogen) in fine powder was added to this, 3 parts of iron to 1 part of soda giving the best The mixtures were heated, in iron boats enclosed in glass tubes, for 11 hours at temperatures between 'dark and moderate' red heats, a current of purified nitrogen being passed. In some cases more than 25 p.c. of the soda used was eyamsed, but usually a conversion of 10 p.c. was not exceeded. Magnesium, tungsten, chromium, and nickel were found to possess some catalytic activity, though much less than iron

Between 1843 and 1912 some 30 patents were granted in Great Britain for modifications of the process described by Possoz and Boissière, in which the blast furnace type of apparatus recurs frequently, no details of the results obtained, or of the causes of failure, appear to have been published Since 1912 the numerous patents of J E Bucher (especially Eng Pats 27713 of 1912, 23292 and 13332 of 1914; 2286 of 1915), which are being developed by the Nitrogen Products Co of Providence, Rhode Island, at their works at Saltville and Niagara Falls, have directed renewed attention to the catalytic action of iron Prof Bucher's results (J Ind Eng Chem 1917, 9, 233) surpass any which have previously appeared in print, this appears to be due partly to the fact that he has clearly realised that the necessary conditions, already known separately, must be fulfilled simultaneously, and partly to the ingenuity and care devoted to the detailed adaptation of means to this end

Carbon and iron oxide are separately ground

in a ball mill to pass 100-mesh sieve, and then re-ground together, after which dry sodium carbonate is added. The open-grained structure which is necessary to allow nitrogen to pass through the material is obtained by briquetting This is done by kneading the powder, at about 100°, with a little more water than is required to form the monohydrate Na<sub>2</sub>CO<sub>3</sub>,H<sub>2</sub>O, and squirting the paste into small rods about I inch long and 1 mch diameter These are dried at once, before cooling, because the expansion due to the formation of the decahydrate at temperatures below 35° causes them to fall to powder When heated above the melting-point of sodium carbonate (852°) these little briquettes become plastic to some extent, but retain their shape sufficiently well to permit free circulation of gases through a column several feet thick Mixtures of coke, non, and sodium carbonate in proportions from 2 2 1 to 2 2 2 give satisfactory results, the smaller proportion of sodium carbonate giving the fastest reaction owing to the greater accessibility of the active carbon-iron surfaces to nitrogen. The reaction is said to begin about 700°, and the eutectic temperature of iron-carbon (about 1150°) should not be exceeded because fusion of the particles of iron into larger globules diminishes their active The speed of the reaction, under surface suitable conditions, is considerable, for example, the 2 2 1 mixture heated, in 13 minutes, from 710 to 920 in a current of nitrogen, yielded a product containing 152 p.c. NaCN, 92 p.c. of the sodium being in the form of cyanide Sodium cyanide volatilises somewhat freely at 900°-950°, so that in a stationary column of material in a vertical tube, the upper layers are much richer than the lower ones, and a considerable loss of alkalı is observed, it is anticipated that this will not occur in a continuous process, since the incoming fresh charge will condense the evanide vapour.

In order to supply the necessary quantity of heat  $(Na_2CO_3+4C+N_2=2NaCN+3CO-138.5)$ Cals ) at a sufficient rate, Bucher proposes, for example, to use the hot charge itself as an electrical resistance (ef Readman's apparatus, below), or to use electrically heated molten iron saturated with carbon and to pass a mixture of nitrogen and sodium vapour through it

Producer gas may be used at high temperatures, but the cyanide disappears if the product is allowed to cool in an atmosphere containing carbon monoxide This may be due to the formation of carbon dioxide, as Buchei suggests, by the reaction 2CO=CO2+C, which is accelerated by iron, it is also possible that the reaction  $Na_2CO_3+4C+N_2=2NaCN+3CO$  is reversible, as has been proved in the analogous case of barium carbonate

Since this was written the reversibility of the reaction has been proved by J. B Ferguson and P. D. V. Manning (J. Ind Eng Chem 1919, 11, 946). Mixtures of sodium cyanide or of sodium carbonate (3 parts), charcoal (1 part), and iron (1 part) were heated in presence of definite mixtures of carbon monoxide and nitrogen. The composition of the product was not affected by the nature of the initial materials, but varied with the temperature and the com-position of the gas With 5 pc CO, for ex-ample, 75 p.c of the alkali was cyanised at

 $946^{\circ}$  and 80 pc. at  $1000^{\circ}$ ; with 48 p.c. CO, 27.5 pc and 59 pc were cyanised at the same temperatures Owing to volatilisation of cyanide it is probable that true equilibrium was not realised, the error will be greatest for products

rich in cyanide
C O Brown (J. Ind. Eng Chem 1919, 11, 1010) has described the plant which was erected by the Government of the United States in 1917-18 to produce 10 tons of sodium cyanide daily by the Bucher process Briquettes, made in the way described above, were heated at 1000° in vertical, gas-fired, steel, or mehrome tubes in a current of very pure nitrogen. The product, containing about 20 p.c. NaCN, was extracted with liquid, anhydrous ammonia; by this means the formation of ferrocyanide is avoided, and any unchanged alkali is left undissolved in the residues which are reground with sufficient carbon and soda and reused Evaporation of the ammonia solutions leaves sodium cyanide, containing 92 p.c. NaCN, as a white powder. The loss of ammonia was about 2 lbs per 100 lbs cyanide made. Each steel tube produced about 7½ lbs of sodium cyanido hourly, and had a life of 11-14 days. The work was abandoned after the armistice in 1918

It may be mentioned here that the Cassel Cyanide Co, of Glasgow, has used iron as a catalyst in the manufacture of cyanides from atmospheric nitrogen since the year 1909, when the writer first became fully aware of its great activity under suitable circumstances. The work in which sodium carbonate was employed as raw material was carried out entirely by Mr J. H Young Setting out from finely divided, precipitated ferric oxide and chaicoal (the purest and most active form of carbon available), the mixtures were made by grinding these substances separately and then together, finally adding the dry sodium carbonate The necessary porosity of the and re-grinding material to be treated with nitrogen was secured by adding a quantity of the very bulky charcoal obtained by carbonising shavings, the addition of 15 parts of this material to a ground mixture of 20 parts of sodium carbonate, 8 parts ferric oxide, and 15 parts charcoal, gave good results, 60-80 pc of the alkali being cyanised at 900°. The residual charcoal-iron mixture resulting from the lixiviation of the cyanised mass gave even better results than a fresh mixture. A larger scale, continuous plant was at work in 1913, in which the mixtures were heated in vertical steel tubes, of 6 inches bore and about 10 feet long, of which a length of about 5 feet was heated to the working temperature. The lower part of the tube served for cooling the product, which was withdrawn by means of a houzontal spiral conveyor, fresh material being fed in at the top of the tube Pure nitrogen was employed, and very careful measurements of the temperature showed that under satisfactory working conditions the temperature in the axis of the tube was 900°, near the inside wall of the tube it was 950°, whilst a thermocouple in the furnace in contact with the outer wall of the tube indicated 1010°. These measurements indicate quite clearly the necessity of using tubes of small diameter when external heating is relied on Temperatures higher than those mentioned were found to be undesirable

owing to their serious effect on the life of the steel tubes, and also on account of the danger of fusing part of the iron catalyst, and so diminishing its active surface. Each tube of the dimensions mentioned produced from 40 to 50 lbs of sodium cyanide in 24 hours, the product containing from 21 to 26 p.c. NaCN.

The results described, together with the older experience of the reaction between alkalis and nitrogenous organic matter, make it easy to understand the occurrence of cyanides in kelp, barilla, Le Blanc alkalı, and the residues from the preparation of potassium (which were known to Lewis Thompson in 1839), and especially in the blast furnace. Clark (Phil Mag 1837, 10, 729) described the occurrence of cyamde at the Clyde Iron Works, in a furnace using raw coal and hot blast, in quantities such that wheelbarrows full could be obtained Zincken and Bromeis (J pr Chem. 1842, 25, 246) found a quantity of potassium cyanide in the charcoal remaining in the hearth of a furnace in the Harz which had been closed down furnace had been worked with charcoal and a hot blast Redtenbacher (Annalen, 1843, 47, 150) described the formation of potassium cyanide in quantity (it was used for electroplating) in a charcoal non furnace at Mariazell in Steiermark, which was also worked with blast heated as high as 350° Bunsen and Playfair (But Ass Rep. 1845, 142) observed the production of more than 2 cwts per day of potassium cyanide in the coal-fired furnace at Alfreton, which worked with blast at 330°, they also showed that the potassium was derived mainly from the non ore used, the furnace charge containing sufficient potassium to produce 377 lbs of KCN per day The cyanide was found in the hottest part of the furnace, 2 feet 9 inches above the tuyeres, but some 7 feet higher there was very little Sir Lowthian Bell (J. Soc Chem Ind 1890, 9, 710) gives the following figures for the distribution of cyanogen in a more modern furnace at the Clarence Works, which was worked with coke and Cleveland iron ore and blast at about 700° .-Height escape

8 ft. 24 ft 52½ ft. 60 ft. pipe above hearth. Grams CN 49 06 15 76 7 67

5.94 4.73

per cb m gas It is generally assumed, probably correctly, that the blast furnace cyanide is produced from free nitrogen, but it is interesting to note that Sir L Bell's furnace consumed 50 tons of coke

per day, which probably contained at least I ton of combined nitrogen.

The mechanism of the reaction which occurs between carbon, alkalı carbonates, and mtrogen, and the rôle of iron, are still quite obscure. old view, that carbon and nitrogen ('nascent' or otherwise) unite to form cyanogen which is then fixed by alkalis, is extremely improbable in view of the nature of the equilibrium

$$2C+N_2 \gtrsim C_2N_2$$

(v. Cyanogen), and of the fact that no one has succeeded in isolating a trace of cyanogen gas made by the direct union of the elements. The possibility that a carbide may be an intermediate product is discussed later. It is, at least, an ascertained fact that some metallic acetylides do combine with nitrogen, although the behaviour of

the alkalı metal derivatives has hardly been investigated. The intermediate formation of free alkali metal has also been asserted to be necessary, but as the alkalı metals (except lithium) do not combine directly with nitrogen, whereas they do combine with carbon, this seems to be identical with the assumption of the intermediacy of a carbide. No valid experimental evidence appears to have been advanced in support of the existence of any intermediate compound

1b. Action of Nitrogen on Alkali Metals and Carbon.

This reaction appears to have been observed for the first time by R F Marchand (J pr Chem 1850, 49, 351) A statement that cast iron and steel contain from 05 to 12 pc of nitrogen induced him to test some 30 samples of cast iron by Lassaigne's method, that is, by heating the sample to redness, in a test tube, with potassium, extracting the product with water, and applying the Prussian blue test to the solution A copious precipitate was obtained in every case He found, however, that, when the residue of non was dried and again heated with potassium, there was a further production of Prussian blue, and that this continued so long that, with 8 grams of powdered iron, it was impossible to exhaust the reaction. This led Marchand to suspect that the nitrogen was derived from the air, and he proved that this was the case by carrying out the reaction in an atmosphere of hydrogen or of carbon dioxide, when no more than a doubtful trace of blue was obtained, and, further, by heating the mixture of cast iron and potassium (after drying it in a current of hydrogen) in an atmosphere of nitrogen in a closed tube, when he found that the nitrogen was completely absorbed He also showed that steel behaves like cast iron, but soft non Marchand did not obtain the reaction with a mixture of carbon and iron obtained by heating ferric succinate or benzoate, and therefore concluded that success depends on the carbon being in chemical combination with the iron.

The success of Lassaigne's test, when applied to organic substances containing sulphur, had been questioned by O Jacobsen, who recom-mended the addition of reduced non in such Making the test in this way, I. Remsen (Amer. Chem J. 1881, 3, 134) obtained Prussian blue from substances, such as pure cane sugar and sodium potassium tartrate, which contain no nitrogen After proving that the reduced iron employed was not the source of the nitrogen, Remsen heated a mixture of the tartrate, pure reduced iron and sodium, first in hydrogen to dry it, and then in nitrogen, obtaining a very large precipitate of Prussian blue. He also made the new observation that the iron powder loses its activity when it is superficially oxidised by exposure to air, which may perhaps explain Marchand's failure to obtain the reaction with his mixtures of iron and carbon

The reaction was re-discovered by E. Tauber (Ber. 1899, 32, 3150), whose experience coincided almost exactly with that of Remsen.

Y. Castner, in 1894, patented a process in which sodium was allowed to flow downwards over a column of red-hot charcoal in

an non vossel, a current of nitrogen passing upwards through it (Eng. Pat 12218 of 1894). It is doubtful whether this process received more than a cursory trial—It was taken up again by the Roessler and Hasslacher company about 1910—They find that a mixture of sodium vapour and nitrogen reacts with charcoal in the absence of non at 650°, and that the speed of reaction is sufficient for manufacturing purposes at temperatures above about 800°. (H. Philipp, Chem and Met Eng 1920, 22, 313, U.S. Pats 1249821, 1917, 1235887, 1917).

In 1912, J. E. Bucher applied for a patent

for the manufacture of evanide by the direct union of its elements in presence of iron (Eng. Pat. 11797 of 1913, U.S. Pats 1082845 of 1913, and 1116559 of 1914). A temperature of from 500° to 800° is said to be suitable, and iron and carbon are to be intimately mixed Like Marchand, Bucher also observed the removal of carbon from cast iron or steel by the action of sodium and nitrogen on them He also follows Marchand in adopting the view that iron acts as a solvent of carbon, the dissolved carbon being supposed to be capable of entering into combination with sodium and nitrogen When sodium carbonate is used, it is assumed that a little metallic sodium is formed by the action of carbon, even at the low temperature (700°) at which the reaction proceeds, the removal of this, by conversion into cyanide, distuibs the equilibrium and permits the decomposition of further quantities of sodium carbonate hypothesis appears to be open to the criticism that it makes the extremely rapid rate of formation of cyanide depend on the rate of solution of solid carbon in solid iron, it also fails to make clear why the usually meet mtrogen becomes so active

The Cassel Cyanide Co's experiments with this process were begun, as already stated, in 1909, in 1911 engineering difficulties had been so far surmounted that a unit plant producing about 50 lbs of cyanide hourly was at work. From the experience thus gained a larger industrial unit was designed and erected, which was producing cyanide for some time before war was declared in 1914.

# 1c. Action of Nitrogen on Barium Carbonate and Carbon.

In 1860 Margueritte and De Sourdeval (Eng Pat 1171, of 1860, Compt 1end 1860, 50, 1100) discovered that a mixture of barium oxide and carbon absorbs nitrogen readily forming barium cyanide. Ludwig Mond (Eng Pat 433 of 1882, J. Soc. Chem Ind 1889, 8, 505) experimented with this process in 1882. He found that a temperature of 1200° was required for the formation of cyanide, and that the reaction goes best about 1400°. The barrum compounds fuse readily at these temperatures and attack the fireclay retorts. To avoid this he briquetted them with an excess of carbon and pitch apparatus used was similar to that of Possoz and Boissière, and 40 p.c. of the bailum used was readily cyanised. The object of Mond's experiments was the production of ammonia, and he abandoned this process in favour of the more promising method of acting on coal with air and steam in large excess (see Ammonia).

As Mond pointed out, the reaction is endo-

$$BaCO_3+C=BaO+2CO-101\ 2\ Cals.$$
  
 $BaO+3C+N_2=Ba(CN)_2+CO-43\ 1\ Cals.$ 

The introduction of internal electrical heating by Readman (Eng Pat 6621 of 1894) therefore marks a very considerable step in advance His process was worked by the Scottish Cyanides Co at Leven in Fifeshire, between the years 1899 and 1907. Considerable quantities of sodium cyanide of excellent quality were produced, but the financial results were unfavourable. The following account of the process in its final form is believed to be substantially accurate.

Barium carbonate, produced in a later stage of the process, was intimately mixed with ground coal to a thick paste, which was dried and coked in ordinary gas retorts The granular mixture of barium oxide and coke so produced was then fed into an electric furnace, consisting of a vertical shaft of circular cross-section, lined with magnesia bricks A ring of carbon blocks in the wall of the shaft near its lower end formed one electrode, a carbon cylinder suspended in the mouth of the shaft formed the other The alternating current passed between these electrodes through the granular mass of coke and barium oxide, heating it to a high tempera-A current of producer gas with about 70 p c of mtrogen, passed upwards through the mass, which was constantly fed downwards into a cooling chamber by means of a plate and rotating arm which closed the lower end of the shaft, fresh material being fed in to the annular space found the upper electrode. The cooled product was lixivated with water, and the resulting solution, containing ballum cyanide, cyanamide, and hydroxide, treated with sodium bicarbonate After filtering off the barium carbonate, the solution of sodium cyanide was concentrated in racub and then passed over cooling coils depositing crystals of the hydrate NaCN,2H,O These were separated from the mother liquor in a centrifugal machine, and then dehydrated by heat and the powder briquetted The mother liquor, from which no further crystals could be obtained, was distilled with sulphuric acid to recover the residue of hydrocyanic acid

The chemistry of this process has been studied in some detail at temperatures up to 1150°, but little is known of it at higher temperatures. Undecomposed barium carbonate, as Finkelstein (Ber. 1906, 39, 1585) showed, does not melt at 1350°, but when heated alone or with carbon, it is partially converted into barium oxide, which yields readily fusible mixtures with the carbonate. Le Chatcher, for example, found that partly decomposed barium carbonate melts at 795°. The fusibility of the mixtures is increased by the formation of barium cyanide (which melts about 600°), so that the material under treatment in this process is a liquid phase of variable composition.

Kuhling and Berkhold (Ber 1908, 41, 28) found that when a mixture of barium carbonate and carbon is heated in a current of nitrogen under constant conditions, a little more than 40 pc. of the barium combines with nitrogen at 1150°, and that at lower temperatures the quantity combined diminishes, reaching zero at about 925°.

Ewan and Napier (J. Soc Chem. Ind. 1913, 32, 467) also found that the absorption of nitrogen begins at 925°. They showed, however, that it depends on the two reversible reactions  $BaCO_3+C \rightleftharpoons BaO+2CO$  and

$$\rm BaO + 3C + N_2 ~ \rightleftarrows ~ Ba(CN)_2 + CO$$

If carbon monoxide is allowed to accumulate, therefore, the change is brought to a standstill, if it is swept out with large quantities of pure nitrogen a considerable portion of the barium may be cyanised even at comparatively low temperatures Using 29 molecules of nitrogen to each molecule of BaO, for example, over 40 p c of the barium combined with nitrogen in 2 hours at 960°.

The pressure of carbon monoxide in equilibrium with pure barium carbonate and carbon is relatively large, it falls, however, to very low values for the dilute solutions of the carbonate in barium oxide or cyanide. For this reason the greater part of the barium carbonate decomposes before any cyanide is formed, but the decomposition is never complete.

When a mixture of BaCO3+BaO+C or of Ba(CN)<sub>2</sub> +BaCN<sub>2</sub>+C is heated in a mixture of carbon monoxide and nitrogen of definite composition until no further change occurs, the percentage of the barium in the product, which is combined with nitrogen (as cyanide or cyanamide), is independent of the composition of the initial mixture, and depends only on the temperature and on the composition of the gas used The maximum quantities of barium which can combine with nitrogen under different conditions, observed in this way, are given in the following table .-

c of CO	P c of the barum combined with n			
the gas	1000°	1100°	1150°	
0	50	50	50	
10	28	41	44	
20	5	32	38	
30		22	32	
40		13	26	
50		4	15	
70			9	

The curves drawn through the experimental points appear to be straight lines converging towards 50 pc. conversion for pure nitrogen, it is probable, however, that this is not their true form at very small concentrations of carbon monoxide, because a product in which 571 pc. of the barium had combined with nitrogen was obtained by continuing the heating for 82 hours at 1100° with nitrogen containing only 0.1 p c of GO For practical purposes, the rapid increase in the quantity of carbon monoxide required to reverse the reaction at higher temperatures is important

In addition to the two equilibria just mentioned, the reaction Ba(CN)<sub>2</sub>=BaCN<sub>2</sub>+C occurs Pure barium cyanide decomposes in this way even at 500°, the reaction is a slow one, which is accelerated by iron. The results appear to show that at temperatures between 600° and 1000°, and in absence of barium oxide, the decomposition ceases when about two-thirds of the

nitrogen is in the cyanamide form, in presence of barium oxide the change does not go so far. The relative quantities of cyanide and cyanamide produced by the action of nitrogen on mixtures of barium oxide and carbon are very erratic, anything from 0 to 70 p c. of the nitrogen fixed may be in the cyanamide form, the average of 36 experiments was 15 p.c.

The equilibrium pressure of carbon monoxide in the reaction  $BaO+3C \gtrsim BaC_2+CO$  was found to be 1 mm of mercury at  $1200^{\circ}$  Cyanide formation therefore proceeds freely in presence of quantities of carbon monoxide, which are quite incompatible with the existence of barium The suggestion that barium carbide is an intermediary in this process is, therefore, incorrect.

The effect of pressure was studied by Hempel (Ber. 1890, 23, 3388). The mixture of banum oxide and carbon was heated for 15 minutes by the same quantity of electrical energy in a closed bomb; the quantity of hydrocyanic acid obtained increased 16 times when the nitrogen pressure was increased from 1 to 60 atmospheres The improvement may have been due to greater reaction velocity of the more concentrated nitrogen or to a larger value of the ratio of nitrogen to carbon monoxide in the bomb Stahler (Ber 1916, 49, 2292), by a somewhat similar method, finds that with 60 atmospheres N pressure a product containing 74 p c of barium cyanide and no appreciable quantity of cyanamide is obtained.

The addition of barrum chloride or of potassium carbonate to the mixture of barium oxide and carbon neither reduces the minimum temperature nor increases the speed of the reaction

The effect of the addition of calcium and barium fluorides was studied by N (Zeitsch angew Chem. 1910, 3, 2405) at temperatures about 1100° and 1200° Since the Since the quantity of carbon monoxide in the nitrogen was not observed it is impossible to draw definite conclusions from the results, it is, however, of interest that in the 15 experiments recorded the quantity of the barium which combined with nitrogen never exceeded one-half of that

Very little information exists about the course of the reaction at higher temperatures From Eng Pats 2133 of 1907, and 22039 of 1906 (Badische Co), it may be gathered that 80 p c of the barium can be combined with nitrogen at 1500°, and, according to Kaiser (Fr Pats. 454237-8 of 1913), 90-95 pc of the theoretical quantity of nitrogen is absorbed, when barrum carbonate and carbon are heated '900° to 1400° ' in nitrogen and cooled in it under pressure It appears, therefore, that the inactivity of one-half of the barium, which has been shown to exist at temperatures below 1200°, may disappear at considerably higher temperatures; possibly because a different mechanism comes into play Ewan and Napier (lc), by applying Nernst's thermodynamic theorem to their measurement of the equilibrium pressure ( $p_{CO}$  in mm. of mercury) of the reaction BaO+3C  $\rightleftharpoons$  BaC<sub>2</sub>+CO, showed that, at absolute temperature T  $\log_{10} p_{CO} = -\frac{16250}{T} + 1.75 \log_{10} T + 5.48$ 

$$\log_{10} p_{00} = -\frac{16250}{T} + 1.75 \log_{10} T + 5.48$$

from which the value of  $p_{co}=100$  mm, at 1500° and 1026 mm at 1700°. M Kahn (Compt rend. 1907, 144, 913) found that barium carbide is formed from barium oxide and carbon heated in a well-closed crucible at the melting point of platinum (1760°), the equilibrium pressure at 1760° is, therefore, greater than I atmosphere, in approximate agreement with the calculated value It is therefore possible that barium carbide is an intermediate product at high temperatures.

# 2a Action of Nitrogen on the Carbides of Mctals.

F. R. Hughes (Report of Juries, Exhib of 1851, 1, 95) suggested that the first stage of the reaction between potassium carbonate and carbon might lead to the formation of potassium carbide, and that this might combine directly with nitrogen Potassium carbide is actually formed in this way, E Davy (Brit Ass. Report, 1836, n. 62), having discovered acctylene by treating with water, the black product of an unsuccessful attempt to prepare potassium Berthelot (Compt rend 1868, 67, 1141) was led to suggest the same mechanism by the analogy with his synthesis of hydrocyanic acid from acetylene and nitrogen. He also showed that the products of the action of potassium on potassium carbonate or on carbon monoxide contain potassium acetylide. The action of nitrogen on the alkali metal carbides has not been investigated in detail Frank and Caro (Eng Pat 15066 of 1895) mention that they combine at a 'dark red heat' forming cyanides

The absorption of nitrogen by the carbides of calcium, strontium, and barium has been much more completely studied. Moissan (Compt. rend 1894, 118, 503, and 684) found that pure, dry mitrogen did not react with the pure carbides even at 1200°, although the product obtained from barium carbide yielded a little ammonia when boiled with water In 1895 Frank and Caro (Eng. Pat 15066 of 1895), and T L Willson (Eng. Pat 21997 of 1895), discovered independently that the impure carbides absorb nitrogen According to Frank and Caro, moist nitrogen is necessary when the pure carbides are used, but not with impure substances, they also found that barium carbide yields the corresponding cyanide, but obtained an 'unsatisfactory result' with calcium carbide unless it was mixed with barium or sodium carbide Willson proposed to treat the carbides with nitrogen either during their formation in the electric furnace, or subsequently in a separate operation He also appears to have found difficulty with calcium carbide, and says that a cyanide or some more complicated nitrogen compound is formed. The fact that a large part of the combined nitrogen is in the form of a cyanamide salt was discovered by F Rothe, working under Frank's direction, in 1898 (Zeitsch angew Chem 1903, 658), and was published in Frank and Caro's Eng. Pat. 25476 of 1898. Frank and Caro at first attempted to apply

their discovery to the manufacture of cyanides.

Finely ground barium carbide, made in the electric furnace, was heated at about 700° in presence of pure mtrogen. The product contained about 11 p.c of nitrogen, 30 p.c of which was in the form of barium cyanide, the remainder

being barium cyanamide. In order to convert the cyanamide into cyanide, the material was heated with dry sodium carbonate and carbon. The sodium carbonate may convert the barium cyanamide into the sodium salt, which then takes up carbon in the way discovered by Dreschel,

$$\begin{array}{c} \operatorname{BaCN}_2 + \operatorname{Na}_2\operatorname{CO}_3 = \operatorname{Na}_2\operatorname{CN}_2 + \operatorname{BaCO}_3 \\ \text{and } \operatorname{Na}_2\operatorname{CN}_2 + \operatorname{C} = 2\operatorname{NaCN} \end{array}$$

By extracting the product with water, converting the sodium cyanide into ferrocyanide, and then fusing it with sodium, about 86 p.c. of the introgen fixed was obtained in the form of marketable sodium cyanide (G. Erlwein, V Int Kongress angew. Chem. Berlin, 1903, 1, 646) The process, however, even in this form, did not pay, and the cheaper calcium carbide was therefore tried. Commercial calcium carbide absorbs nitrogen at about 1100°, yielding a product containing from 20 to 23 5 pc. of nitrogen, which is wholly in the form of calcium cyanamide  $CaC_2 + N_2 = CaCN_2 + C$  Details of the manufacture of calcium cyanamide are given in the article on NITROGEN, ATMOSPHERIC, UTILISATION OF By heating this product with sodium chloride, from 90 to 95 p c of the cyanamide is said to be converted into sodium cyanido (G Erlwein, loc. ctt., G. Erlwein and Frank, U.S. Pat. 708333, 1902)

It is not easy to obtain such a high yield in the laboratory; Kıtawakı and Kusano, for example (J Chem Ind Tokyo, 1917, 20, 234), state that when 10 parts of calcium cyanamide (186 pc N) are heated with 16 to 24 parts of salt, and 2 parts of charcoal for 10 minutes at 900°-950°, and the fused product cooled in absence of oxygen, it contains more than 70 p.c. of the theoretical quantity of cyanide

Large-scale experiments were carried on in Germany with but little success; a description of these, up to 1914, has been published by W. S Landis (Chem. Met Eng. 1920, 22, 265) In the latest modification, from 2 to 3 parts of salt were fused separately, and 1 part of calcium cyanamide added gradually in order to control frothing. The highest temperature used was 960°, and from 40 to 75 p c of the nitrogen was

obtained in the form of cyanide In 1916 the process was installed at Niagara. It was soon found that the troublesome evolution of gas was almost suppressed by the addition of a little calcium carbide, and that much better results were obtained by raising the temperature to 1200°-1400° (H. P. Eastman, U.S. Pat. 1282395, 1918), and also that the cyanide disappears when the fused product is allowed to cool slowly, the reversion apparently occurring between 400° and 700° (H. Freeman, U.S. Pat. 1282405, 1918) In 1919 the process was, therefore, carried out by feeding a mixture of calcium cyanamide (1 part), salt (about 0.8 part), and calcium carbide (0.05 to 0.1 part) into a single phase electric furnace of the arc-resistance type with conducting hearth and a single suspended electrode. The furnace treats about 30 tons daily. The mixture fuses, and is run off almost continuously into a pan in which a water-cooled drum rotates, taking up a thin layer of the fused material which solidifies and is scraped off in thin flakes which contain cyanide (possibly the calcium salt) equivalent to 36 p.c. NaCN. The

efficiency on the nitrogen is about 90 p c. The equivalent of 975 tons of sodium cyanide was made in 1917, 1050 tons in 1918, and 1250 tons in 1919. The chemistry of this process is still incompletely known, Landis states that cyanide is formed even when little or no salt is used, which suggests that the principal change is represented by the reversible reaction

$$CaCN_2+C \ge Ca(CN)_2$$

The initial frothing may be due to the decomposition of sodium eyanamide

$$2NaCN_2 = 2NaCN + N_2 + 2Na$$

the graphitic carbon present not being sufficiently active at lower temperatures to convert it quickly into cyanide; the addition of calcium carbide is supposed to supply the necessary active earbon.

# 2b Action of nitrogen on acetylene

In 1863 Berthelot had shown (Ann Chim Phys 1863, [3] 67, 52) that acetylene is formed in the electric are between carbon electrodes in an atmosphere of hydrogen, and also that hydrocarbons in general yield acetylene when induction sparks pass through their vapours. The careful measurements of Bone and Jerdan (Chem Soc. Trans. 1901, 1042) indicate that, when equilibrium is established in the gas surrounding a carbon are burning in hydrogen or hydrocarbon vapour, it contains 90–91 p.c.  $H_2$ , 7.8 p.c.  $C_2H_4$ , 1.25 p.c.  $C_4H_4$  and 0.75 p.c.  $C_2H_6$ , no other

hydrocarbons being present In 1868 Berthelot (Compt 1end 1868, 67, 1141) discovered that acetylene and nitrogen combine, under the influence of strong induction sparks, to form hydrocyanic acid, and that the reaction  $C_2H_2+N_2 \gtrsim 2HCN$  is reversible. Taken together with his earlier observations on the formation of acetylene, this led him to the generalisation that hydrocyanic acid must be formed in the carbon are burning in mixtures of hydrogen and nitrogen or when sparks are passed through mixtures of nitrogen and hydrocarbons The cyanogen compound observed when the arc burns between carbon electrodes in an atmosphere of nitrogen is hydrocyanic acid, the hydrogen of which is derived from the electrodes or from water vapour A mixture of 10 vols C<sub>2</sub>H<sub>2</sub>, 14.5 vols N<sub>2</sub>, and 75.5 vols H<sub>2</sub> is suitable for the synthesis of hydrocyanic acid, since mixtures richer in acetylene deposit carbon. Dewar (Proc Roy Soc 1879, 29, 188, and 1880, 30, 85) confirmed Berthelot's observations on the formation of hydrocyanic acid in the are, and also showed that it is formed when a mixture of hydrogen and nitrogen is passed through a carbon tube heated externally by an electric The minute traces of hydrocyanic acid found in the slightly luminous flame of a Bunsen burner (Lüdeking, Annalen, 1888, 247, 122) are

Subsequent investigations add little to the information given by Berthelot, Hoyermann (Chem. Zett. 1902, 26, 70) passed a mixture of nitrogen (2 vols.) and acetylene (1 vol.) into the arc through tubular carbon electrodes and found that 60 to 70 pcoof the acetylene was converted into hydrocyanic acid. Gruszkiewicz (Zeitsch. Elektrochem. 1903, 9, 83) found that

doubtless due to this reaction

a mixture of carbon monoxide (2 vols ) hydrogen (1 vol ) and nitrogen (1 vol ) yielded small quantities of hydrocyanic acid when exposed to induction sparks between platinum points Lipinsky (Zeitsch Elektrochem 1911, 17, 761) passed mixtures of methane, introgen and hydrogen through a 2200 volt alternating current are between platinum electrodes. No carbon was deposited from a mixture containing  $\mathrm{CH_4}$  (20 pc),  $\mathrm{H_2}$  (10 pc), and  $\mathrm{N_2}$  (70 pc). Under the best conditions about 1.75 gram of hydrocyanic acid was produced per kilowatt hour. It is instructive to compare this with the 50 grams of nitric acid per kilowatt hour which Raleigh obtained, in apparatus of comparable dimensions, from mixtures of oxygen and nitrogen

E Biner and A Bacifuss (Helv Chim Acta 1919, 2, 663) have obtained as much as 7 39 grams HCN per kilowatt hour by circulating 8-10 litres per hour of a mixture of 1 part methane and 5 parts introgen through an arc at 505 volts between platinum electrodes 12 mm. apart.

According to H Philipp (Chem. Met. Eng. 1920, 22, 213), Lipinski's process was tried on a commercial scale in 1914 at Neuhausen, and a yield of 30 grams of HCN per kilowatt hour

attained.

Hutton and Smith (Eng Pat 23835 of 1906, and Trans Amer Electrochem. Soc 13, 359, 1908) showed that the temperature of the arc is not necessary, hydrocyanic acid being formed when a carbon rod is heated in a mixture of hydrogen and nitrogen to 1700°, and H v Wartenberg (Zeitsch anorg Chem 52, 299, 1907) carried out quantitative measurements with the following results (using a mixture of equal volumes of hydrogen and nitrogen)—

Temperature	P c HCN in the gas
1635°	1.95
1752°	3 10
1875°	4 70

Wallis (Annalen, 1906, 345, 353), by passing the same mixture through the electric arc at varying rates obtained a maximum of 33 5 p e of HCN in the gas. The estimated temperature of the arc is about 3250°

Cyanides from nitrides. At high temperatures, introgen combines directly with several elements to form intrides, and these, when fused with sodium carbonate and carbon, produce sodium cyanide. This has been shown to be the case with the nitrides of boron, calcium, magnesium, titanium, silicon, and aluminium, and with phospham PNH, Since none of these processes has emerged as yet from the experimental stage, it is sufficient to mention the possibility of producing cyanides in this way.

Hydrocyanic acid. Prussic acid (Ger Blausaure) HCN

This substance was discovered by Scheele in 1782 (Chemical Essays, London, 1786; reprinted 1901) He observed that Lixivium sanquims loses its power of forming Prussian blue when it is exposed to the air, and traced this effect to the atmospheric carbon dioxide. Other acids also produced it, and the blue-forming principle was found in the vapour given off. By distilling

the haverum with sulphuric acid, he obtained an aqueous solution of hydrocyanic acid. more convenient method of preparation was to heat potassium ferrocyanide with dilute sulphuric acid In doing this, he obtained a blue residue (oxidised Everitt's salt or Williamson's blue) Finally, he prepared mercuric cyanide by boiling Piussian blue with meicuric oxide; by treating this with iron and sulphuric acid, he decomposed it into mercury and hydrocyanic acid, which he distilled off In 1783, Scheele found that hydrocyanic acid is inflammable, its combustion yielding carbon dioxide proved that it contains nitrogen by synthesising it from ammonia Equal parts of charcoal and potassium carbonate were heated to redness, but not sufficiently to melt the potash, in a crucible and then some ammonium chloride stirred in (for 2 minutes only), the mass was then thrown into water and a solution obtained which gave 'a great quantity of Prussian blue,' whereas a similar experiment without the sal-ammoniac yielded a very small quantity.

exact quantitative composition of prussic acid was ascertained by Gay-Lussac (Annales de Chimie, 1815, 95, 156) He showed that it is similar in constitution to hydro-chloric and hydrodic acids, the hydrogen being united with a compound radical, CN, which he called 'cyanogène,' which plays the part of an element in so far as it passes through many transformations unchanged

Compounds of hydrocyanic acid are widely distributed in nature in plants The acid does not exist as such in the living plants, but is liberated after their death by the hydrolytic action of an enzyme on a glucoside, both of which are contained in the living cells, the glucoside may also be split up by boiling with dilute acids—Rarely a glucoside is found without an accompanying enzyme, as in the leaves of the common elder (Sambucus niger) chemistry of the cyanogenetic glucosides is described under GLUCOSIDES. Very different quantities of hydrocyanic acid are obtained from different parts of the same plant, the quantity also depends on the age of the plant (it is usually greatest in the young plants) and on the conditions of growth such as climate and rainfall, the use of nitrogenous fertilisers has been found to increase the quantity of hydrocyanic acid present. Plants raiely yield as much as one or two tenths of 1 pc of their weight of hydrocyanic acid, for example great millet (Sorghum vulgare) 0 013 to 0 044 pc in young plants, an exceptional North American sample gave 0 114 pc; wild cherry (Prunus padus) 0 03 pc, cherry laurel (Prunus laurocerasus) up to 0 2 pc m young leaves, cassava, sweet, 0 016 pc in the leaves, 0 043 pc, in the peel of the stem, 0 005 pc in the edible part of the root, the corresponding parts of the bitter variety contained 0.041 pc, 0.113 pc, and 0053 pc respectively, Rangoon beans (Phaseolus lunatus), 0 025 p c; linseed, 0 02 to 0 038 p c; Nandina domestica, 0 07 to 0 147 p c, bitter almonds 0 12 to 0 18 p c Cases of cattle poisoning are not infrequent in hot countries where sorghum is used as fodder, and linseed meal and white clover are also stance there is a certain temperature at which sometimes poisonous. The enzymes are detection the yield is a maximum. The following table

stroyed and the cyanogenetic glucosides rendered harmless by thorough boiling with water.

Minute traces of hydrocyanic acid have been observed in the products of incomplete combustion, for example, in the luminous flame of a Bunsen burner, in boiler flue gases, and in tobacco smoke

Preparation of Hydrocyanic Acid -Hydrocyanic acid was formerly prepared by distilling potassium ferrocyanide with dilute sulphuric A more convenient method, however, is to run a solution of sodium cyanide (97 to 98 pc NaCN) in from 2-21 times its weight of water into hot sulphuric acid of 75 p c. strength, about 11 mols of sulphuric acid to 2 mols sodium evanide is sufficient and the eyanide solution is preferably allowed to enter the acid a little below its surface, so as to avoid contact of the alkaline cyanide solution with hydrocyanic acid vapour.

The vapour may be dried by calcium chloride, kept at a temperature of about 30° and then condensed in a vessel cooled by ice, although the greater part of it is quite readily liquefied in an ordinary Liebig's condenser cooled by cold water. It may be purified from traces of water and ammonia by distillation over phosphorus pentoxide (Nef, Annalen, 1895, 287, 265)

Hydrocyanic acid is formed in many different ways, the synthesis from free nitrogen and acetylene has already been The oxidation of organic compounds by nitric acid often yields hydrocyanic acid in greater or smaller amount, and it has been proposed to manufacture hydrocyanic acid in this way The interesting reaction described by Huntingdon (Eng Pat 14855, 1895) may be mentioned A mixture of acetylene and nitric oxide is readily exploded by a spark, yielding very considerable quantities of hydrocyanic acid in accordance with the equation

$$2NO+2C,H_2=2HCN+2CO+H_2$$

When ammonium formate is distilled, water is first given off together with a little ammonia and formic acid, at 180° formamide begins to distil over, and, as the temperature gradually rises to 220°, this is accompanied by increasing quantities of carbon monoxide, but only traces of hydrocyanic acid are produced. In order to obtain a good yield of hydrocyanic acid, the vapour must be heated to much higher temperatures, and the result is greatly influenced by the nature of the substance with which it is in contact According to unpublished experiments by the writer, the principal changes which occur

$$\begin{array}{l} \text{H COONH}_4 = \text{HCO·NH}_2 + \text{H}_2\text{O (1)} \\ \text{H COONH}_4 = \text{NH}_3 + \text{HCOOH} \\ = \text{NH}_3 + \text{H}_2\text{O} + \text{CO (2)} \\ \text{HCO NH}_2 = \text{HCN} + \text{H}_2\text{O} \\ \text{H}_5\text{O} + \text{CO} = \text{CO}_5 + \text{H}_3 \end{array}$$

The ammonia and hydrocyanic acid in the product usually accounted for more than 95 p.c. of the nitrogen in the ammonium formate or formanide used. Under similar conditions, the yield of hydrocyanic acid obtained from formamide is much greater than that obtained from ammonium formate. For each contact sub-

contains the best temperatures and corresponding yields for several contact substances:—

	Amn	nonium formate	Formamide	
Contact, substance	Yield of HCN p c. of theoretical	Temperature	Yield of HCN p c of theoretical	Temperature
Porcelain chips . Copper gauze Iron wire . Charcoal .	41.5 43.0 39.0 21.0	700° just below 500° just below 500° 420°	75 78 — 55	800° 600° - 400°

With finely divided mickel, no hydrocyanic acid was obtained in any circumstances; at 273°, 92½ p.c. of the mitrogen was recovered as ammonia, but much less at higher temperatures

Formaldoxime CH<sub>2</sub> N OH, an isomeride of formamide, obtained by the interaction of formaldehyde and hydroxylamine, decomposes very readily when heated alone or with phosphorus pentoxide into water and hydrocyanic acid (Dunstan and Bossi, Chem. Soc. Trans 1898, 353).

Ammonia and carbon monoxide were said to yield hydrocyanic when passed over heated spongy platinum (Kuhlmann, Annalen, 1841, 38, 62), CO+NH<sub>3</sub>=HCN+H<sub>2</sub>O, and this apparently simple reaction has attracted several inventors. A careful investigation by Jackson and Laurie (Chem. Soc. Trans. 1905, 87, 433) has shown that a dry mixture of the two gases, when sparked, treated by the silent discharge or heated in presence of platinum (an electrically heated spiral of platinum wire gives the best result) yields ammonium cyanate thus:

and Kuhlmann's reaction does not take place. The reverse change,  $H(N+H_2O=CO+NH_3)$ , however, does occur very readily, even at  $200^\circ$ , when a mixture of steam and hydrocyanic acid is passed over broken brick as contact material, and at  $600^\circ$  it is practically quantitative. With iron oxide as contact substance, the conversion into ammonia is complete at  $285^\circ$ , and with Weldon mud at  $200^\circ$  (Carpenter and Linder, J. Soc. Chem. Ind. 1905, 63).

Cyanogen and hydrogen combine, forming hydrocyanic acid when a mixture of them is heated at 500°-550° (Beithelot, Ann. Chim.

Phys. 1879, [5] 18, 380).

Properties of Hydrocyanic Acid.—A colourless liquid possessing a characteristic smell (or rather taste), which produces a choking sensation in the larynx. It is one of the most poisonous substances known, the fatal dose for a full-grown man being about 0.06 gram of the acid or 0.15 gram of potassium cyanide. It may be absorbed through all parts of the body, even through the skin, and its action is very rapid, large doses causing death almost instantaneously. Air in which the smell of hydrocyanic acid is distinctly perceptible may be breathed constantly without ill effects. Experiments with cats showed that 3 to 4 volumes of the acid per 100,000 volumes of air could be borne, but 5 volumes

produced symptoms of poisoning In industrial cases of hydrocyanic acid poisoning the persons affected were usually working in continued spaces, for example, cleaning or repairing apparatus which had contained cyanides, removing damaged eargo from the holds of ships, or working in insufficiently ventilated buildings where cyanide solutions were used; in all these cases hydrocyanic acid is generated from alkali cyanide solutions partly by hydrolysis and partly by the action of carbon dioxide.

The first symptoms of poisoning are giddiness and darkness of the visual field (these symptoms disappear after a few minutes exposure to fresh air), they are followed by un-consciousness accompanied by muscular cramps and more or less complete cessation of respiration; the heart still acting, however, artificial respiration with oxygen may be successful at this stage. When a cyanide has been swallowed, hydrocyanic acid is liberated by the acids of the stomach. The simplest and most effective antidote is prepared by mixing solutions of ferrous sulphate and sodium carbonate (suitable quantities are 50 c c each of solutions containing 150 grams of FeSO<sub>4</sub>,7H<sub>2</sub>O and 57 grams of Na<sub>2</sub>CO
<sub>3</sub> per litie) Stimulants, such as ammonia, are also helpful The writer has seen a dog, which had swallowed some potassium cyanide, and was already partially paralysed in its hind quarters, recover in a few seconds when dosed with the above mixture which had been made up hastily from ferrous ammonium sulphate. Subcutaneous injection of hydrogen peroxide, which converts hydrocyanic acid into oxamide, has also been recommended

The action of hydrocyanic acid appears to consist partly of a direct effect on the nerve centres and partly of an inhibitory action on the enzyme of the red blood corpuscles, which brings about the transference of oxygen from oxyhaemoglobin to the oxidisable substances oxynacmognomic of the Galactic name of the body, the venous blood therefore becomes arterial, and death is due partly to a kind of internal suffocation Schonbein (J pr. 1868, 105, 202) showed that hydrocyanic acid inhibits the catalytic decomposition of hydrogen peroxide by plant ferments, and also by the red blood corpuscles, and suggested that its poisonous properties might be due to the inhibition of the oxidising power of the blood. Bredig and von Berneck (Zeitsch phys. Chem 1899, 31, 329) showed that hydrocyanic acid has the same effect on the inorganic ferment, colloidal platinum The ferments recover their activity when the hydrocyanic acid is removed. This property has been applied in the pieservation of fruit

The sp gr of the liquid acid is 0 7058 at 7° and 0 6969 at 18° (Gay Lussac) Freezing-point, -10° to -12° (Nef). The freezing-point is raised by pressure; it is -2 88° under 500 kilos per sq. cm. pressure (Tamman) The boiling-point at atmospheric pressure is 25° (Nef) The heat of evaporation is exceptionally large, 210 7 Cals. per gram. Heat of formation of the liquid acid from the elements (amorphous carbon) -218 Cals. per moi. (Thomsen), diamond -24 8 Cals. (Berthelot). Heat of solution, liquid acid in water, 0.4 Cal. per moi. The dielectric constant of hydrocyanic acid, 95, is the largest known,

with the exception of that of hydrogen peroxide (Schlundt). The acid is miscible in all proportions with water, alcohol, ether and many other substances; it is almost insoluble in light petroleum. It is an excellent solvent for many solid substances, among the inorganic salts the iodides are usually readily soluble. The solutions are good conductors of electricity, the conductivity of solutions of potassium iodide, for example, is about 31 times greater than that of the corresponding aqueous solutions

Hydrocyanic acid is one of the weakest acids; its dissociation constant in aqueous solution at 18°, 13×10<sup>-9</sup>, is 44 times smaller than that of sulphuretted hydrogen, and 230 times smaller than that of carbonic acid (Walker and Cormack, Chem Soc Trans 77, 16, 1900) In a 01N-solution, only 0011 pc. of the acid is dissociated into its ions, consequently it does not behave as an acid to indicators, and its salts are more or less completely decomposed by water; thus for example,

# KCN+H<sub>2</sub>O ≥ KOH+HCN

In 0 l N-solutions of the sodium or potassium salts, 1 1 p c is dissociated in this way, in N-solutions, only 0 3 p c at 24 2° (Shields, Zeitsch physikal. Chem. 12, 167, 1893). In solutions of pure sodium eyamide, containing no caustic soda, the hydrolysis is greater than that found by Shields. It may be calculated from the equilibrium constant K == [HaOH] HCN | NaCN |. the bracketed quantities representing concentrations of the substances in gram mols per htre The values of  $K \times 10^4$  are. at 0°, 0 135, at 5°, 0 15, at 10°, 0 16; at 15°, 0 20, at 20°, 0 27, at 25°, 0 484; and at 30°, 0 72 (F P. Worley and V R. Browne, Chem Soc Trans 1917, 1057) This is of importance it is required to concentrate an aqueous solution of a cyanide, the free hydrocyanic acid escapes until sufficient excess of the base has accumulated to reduce the hydrolysis to negligible proportions In the case of weaker bases, the result is a considerable loss of hydrocyanic acid; with calcium cyanide, for example, the quantity of lime formed is greater than can be retained in solution, consequently equilibrium is never attained, and when such a solution is evaporated, the whole of the hydrocyanic acid escapes, leaving a residue of pure lime

A large part (sometimes one-half) of the cyanide used in gold extracting is lost by the evaporation from the solutions of hydrocyanic acid set free by hydrolysis (H A White, J Chem Met and Min Soc. S. Africa, 1915, 16, 24)

Pure hydrocyanic acid, distilled over phos phorus pentoxide, can be preserved without change for considerable periods at the ordinary temperature; when heated to 100° or at the ordinary temperature in presence of alkaline impurities, such as ammonium or potassium cyanide, it changes into a solid, black mass from which a ter-molecular polymer, probably the nitrile of amino malonic acid, NH<sub>2</sub> CH(CN)<sub>2</sub>, can be separated Under imperfectly known conditions, the anhydrous acid cometimes explodes. G Salomone (Gazz. chim. ital Salomone (Gazz. chim. ital explodes. 1912, 42, 1 617) isolated, from the products of an explosion, colourless crystals of a substance having the composition of cyanic acid and a cyanic acid also resembles the nitriles rather

molecular weight, in benzene solution, corre-

sponding with (HUNO)<sub>5</sub>.

The aqueous acid also becomes brown rapidly in presence of alkali cyanides and deposits a dark brown amorphous substance, azulmın or azulmıc acıd, which contains carbon, oxygen, nitrogen, and hydrogen in variable proportions. The discolouration of solid alkalı

cyanide, when exposed to the air, is due to the hydrocyanic acid liberated at its surface under-

going this change

The only useful application of hydrocyanic acid, as an insecticide, was developed at the Agricultural Experiment Station of the University of California, largely by the labours of D W Coquillett and H D Bishop (California Station Bull. 122) They found that foliage is much less liable to injury at night than in sunlight, the hydrocyanic acid vapour is applied by electing a tent over the trees and generating the acid inside of it The safe concentration of hydrocyanic acid depends on the kind of tree and on the time of year In greenhouses less than 2 grams of hydrocyanic acid per 1000 cb. ft. of air space is said to kill green aphis, but as much as 30 grams may be needed for mealy bug or red spider Most plants are unaffected even by the larger quantity Since about 1918 98 p.c hydrocyanic acid has been placed on the market for the fumigation of orange trees; formerly the acid was always generated on the spot, from sodium cyanide and sulphune acid

The constitution of hydrocyanic acid has been the subject of much discussion arising largely from the observation that the reaction of potassium cyanide with an ester yields a nitrile, R-C: N, as principal product, whereas silver evanude yields a carbylamine, R-N C. On the hypothesis that the salts are formed by the substitution of an atom of metal for an atom of hydrogen without change of position, and that the alkyl derivatives are formed similarly, it is of course necessary to suppose that the hydrogen in hydrocyanic acid may be united either with carbon or with nitrogen. The cyanides are, however, in all probability more complex substances; silver cyanide, from its mode of formation, is probably silver dicyano argentaate, Ag[Ag(CN)2], and the reaction with methyl iodide is similar to that of silver ferrocyanide (described above) leading to the well-crystallised

substance  $\left[\mathrm{Ag}^{\mathrm{CN}}_{\mathrm{CNCH}_{3}}\right]$ , which, like the corre-

sponding ferrocyanide, splits off methyl carbylamine when heated or when acted on by a solution of potassium cyanide (see, for example, H. Guillemaid, Ann. Chim Phys 1908, [8] 14, 311)

The properties of hydrocyanic acid itself, however, leave little doubt that it is formonitrile; the isomeric substance H.N.C, has not been isolated. Like the nitriles, hydrocyanic acid is hardly affected by dilute mineral acids (it is frequently separated quantitatively by distilling acid solutions), the carbylamines are violently decomposed Anhydrous hydrocyanic acid and the nitriles do not dissolve silver cyanide, whilst the carbylamines dissolve it very readily its high dielectric constant, solvent and dissociating powers and physiological action hydro-

than the carbylamines (Wade, Chem. Soc.) Trans. 1902, 1613).

# THE PRINCIPAL CYANIDES.

Potassium cyanide KCN crystallises in anhydrous, colourless octahedra from aqueous solutions, or in cubes when the fused salt solidi fies; sp gr. 152 It melts at a dull red heat, and volatilises without decomposition at high temperatures It is readily soluble in water, the saturated solution contains 122 2 grams of KCN to 100 grams of water at its boiling-point (103 3°). At 19.5°, 100 grams of absolute alcohol dissolve 0 88 gram, 100 gr methylalcohol dissolve 4.91 grams (Landolt, Bornstein and Meyerhoffer, Tabellen, Berlin, 1905). It is moderately soluble in anhydrous ammonia at -38° (Fianklin and Kraus, Amer. Chem. J 1898, 20, 820) It deliquesces in moist air

Sodium cyanide NaCN crystallises from the fused liquid in apparently cubic crystals, from aqueous solutions below 35° large colourless plates of the hydrate NaCN,2H<sub>2</sub>O are deposited Joannis (Ann Chim Phys. 1882, [5] 26, 484) obtained a hydrate NaCN, H2O from cold 85 p.c. alcohol F Roessler (Eng. Pat. 279, 1899) showed that the hydrate NaCN,2H<sub>2</sub>O decomposes at 33° (34.7° according to the writer's measurements) into the anhydrous salt and a saturated solution, about 40 pc of the sodium cyanide separating in the anhydrous The solubility of the hydrate (in grams of NaCN to 100 grams of water) is, 35 4 at  $-20^{\circ}$ , 43 4 at  $0^{\circ}$ ; 58 3 at 20° and 82 at 34 7°. The solubility of the anhydrous salt is almost independent of the temperature (82 grams per 100 grams of water) Sodium cyanide appears to be more soluble in ethyl and methyl alcohol and anhydrous ammonia than the potassium salt The sp gr of aqueous solutions of sodium cyanide at 25° is given by the expression 1+0.00534p, where p is the percentage of NaCN Sodium cyanide (96 p c) melts at 540° The pure salt, when heated in a glass tube so as to be out of contact with metals, in a current of dry air free from carbon dioxide, remains entirely unchanged at temperatures up to 370°; if, however, it is in contact with iron or nickel, or if traces of the oxides of these metals are added to it, oxidation proceeds rapidly, cyanate and carbonate being formed and carbon dioxide evolved The carbonate is formed by the oxidation of the cyanate, which is the primary product Sodium cyanate behaves towards oxygen in exactly the same way as the cyanide, it is quite unaffected by dig air (free from CO2) even at 400°, but when mixed with 1 p c. of nickel oxide it oxidises rapidly, thus.

$$2NaCNO+3O=Na_2CO_2+CO_2+N_2$$

(writer's unpublished experiments)

Sodium cyanide absorbs moisture with great avidity from ordinary moist air The writer has found that it takes up water from purified air saturated with aqueous vapour at 20° at all temperatures below 44°, but not at higher temperatures. This is of importance in sampling and analysing the salt

Dilute solutions of potassium or sodium cyanide decompose slowly in confact with the air, the loss being due to evaporation of the hydrocyanic acid formed by hydrolysis, which

permits the decomposition to proceed further; absorption of carbon dioxide acts in the same direction by neutralising the caustic alkali

Liebig's statement that metallic non is dissolved by hot solutions of potassium or sodium cyanide with evolution of hydrogen is true of the finely divided metal, but iron vessels may be used for years for boiling concentrated solutions of cyanides without requiring repair, and iron tanks are regularly used in the treatment of gold ores with cyanide solutions

With the exception of lead and platinum, all ordinary metals are dissolved by cyanide solu-

tions in presence of oxygen

Zinc is slowly dissolved without oxygen, but if a piece of zinc is half immersed in a cyanide solution, it is eaten through at the surface of the liquid before any appreciable action has taken place on the submerged portion

Alkalı cyanıdes yıeld ammonia and a formate when boiled with water or treated with strong sulphuric acid, in the latter case the formic acid produced is at once decomposed

into carbon monoxide and water

Mercuric cyanide Hg(('N)2 was first prepared by Scheele, in 1782, by boiling Prussian blue with mercuire oxide, and, in 1783, by dissolving mercuric oxide in hydrocyanic and and evapo-rating to crystallisation. He also found that mercurous salts, when treated with soluble cyanides, yield mercuric cyanide and metallic mercury. The decomposition of the ferromercury The decomposition of the ferro-cyanides, as already mentioned, depends on the extremely small electrolytic dissociation of mercuric cyanide in aqueous solution For the same reason, it is not decomposed by caustic alkalis, and hydrocyanic acid can only be expelled from it by boiling with a strong acid The concentration of the mercury ions is, however, sufficient to permit of the precipitation of the extremely insoluble mercuric sulphide by sulphuretted hydrogen

Mercuric cyanide crystallises in anhydrous, colourless crystals of sp gr. 40 The saturated solution contains 93 grams per litre at 20°, 111 grams per litre at 25°, 100 grams of absolute alcohol dissolve 10 l grams of it at 195°, and 100 grams of absolute methyl alcohol take up

44 2 grams at 19 5°

Small quantities of mercuric eyanide are sometimes used in addition to alkali cyanide in the treatment of ores containing silver sulphide (Clennel, Cyanide Handbook, London, 1910, 297), the dissolution of which is accelerated, probably owing to the formation of mercuric sulphide:

 $Hg(CN)_2 + Ag_2S + 2KCN = HgS + 2KAg(CN)_2$ 

Calcium cyanide has never been prepared in the pure state An aqueous solution of lime in hydrocyanic acid decomposes completely into its constituents when boiled (Scheele) By evaporating such a solution in vacuô, Joannis obtained a crystalline compound, 3CaO Ca(CN)2,15H2O, which decomposed completely in a vacuum, leaving nothing but lime. Dry reactions, at high temperatures, yield calcium cyanamide, but no cyanide •

Barium cyanide Ba(CN)<sub>2</sub> When a concentrated solution, made by adding hydrocyanic acid to baryta in theoretical quantities, is evaporated in vacuô, crystals of the hydrate

Ba(CN)<sub>2</sub>,2H<sub>3</sub>O are deposited (A Joannis, Ann Chim. Phys. [5] 26, 484, 1882). This is a very deliquescent substance which, when dried *in* vacuó over sulphuric acid, yields an amorphous monohydrate which can be completely dehydrated by heating it very gradually to 100° in a good vacuum. The writer has failed to obtain a pure product in this way Some 7 or 8 p c of the hydrocyanic acid escapes during evaporation, and the product contains a corresponding quan-By drying pure tity of barium hydroxide Ba(OH)<sub>2</sub>,8H<sub>2</sub>O in a good vacuum at 100°, a very finely divided powder of Ba(OH)<sub>2</sub> is obtained which is suspended in dry light petroleum and treated with a small excess of dry hydrocyanic acid also mixed with light petroleum. In this way, the solid hydrated barium cyanide is obtained without evaporation:

$$Ba(OH)_2 + 2HCN = Ba(CN)_2 2H_2O$$

When dehydrated in vacuô, it still contains a little hydroxide, but by shaking it with a little hydrocyanic acid and light petroleum and again drying, practically pure anhydrous barium cyanide is fairly easily obtained

By saturating a solution of baryta in methyl alcohol with hydrocyanic acid, a compound Ba(CN)(OCH<sub>3</sub>) + CH<sub>3</sub>OH is obtained, which, when heated, first loses methyl alcohol and then methyl ether, leaving BaO + Ba(CN), (Diechsel, J. pr. Chem [2] 21, 77, 1880).

Dry methods of preparation yield mixtures of cyanide and cyanamide When barrum terrocyanide is heated it begins to decompose about 500°, yielding a mixture of barium evanide and evanamide (with carbon and iron) in which nearly 60 p c. of the nitrogen is in the form of cyanamide, practically the same product as that obtained by the action of nitrogen on barium carbide Even the action of cyanogen on barium amalgam yields a mixture (Drechsel), the reason being that barium eyanide decomposes into barium cyanamide and carbon, thus . Ba(CN)<sub>2</sub>=BaCN<sub>2</sub>+C. The change is very slow at 500° to 600°, but it is accelerated by iron (Ewan and Napier, J Soc Chem Ind 1913, 32, 467)

Barium eyanide is colourless, 100 grams of cold water dissolve about 80 grams of it (Joannis) It melts about 600° It is distinctly volatile, even at its melting-point, but when mixed with

barium oxide it is much less so.

The precipitate ob-Silver cyanide AgCN tained by adding excess of silver nitrate to a solution of a soluble cyanide is probably the silver salt of the complex acid  $H[Ag(CN)_2]$ The solubility of silver cyanide in pure water lies between those of the chloride and sulphocyanide, as the following table shows

> Solubility at 25° in gram-mols per litre AgI  $0.01 \times 10^{-6}$  $0.81 \times 10^{-6}$ AgBr AgSCN  $1.08 \times 10^{-6}$ 4 40  $\times$  10-6 AgCN AğCl 14 10×10-6

It is hardly attacked by cold dilute natric acid, but is decomposed quantitatively on boiling (Plimmer, Chem Soc Proc. 1903, 285) When

cyanogen C<sub>2</sub>N<sub>2</sub>. Further heating in presence of oxygen yields a residue of metallic silver, which usually contains a little carbon. It is slightly soluble in a solution of hydrocyanic acid, forming the unstable acid HAg(CN)2. It dissolves very readily in alkali cyanides to salts such as KAg(CN), in which the silver is contained in the complex amon Ag(CN)'<sub>2</sub>. Owing to the excessively small dissociation of this anion, all silver salts except the sulphide are dissolved by cyanide solutions, and in presence of oxygen, metallic silver and the sulphide are also dissolved.

Gold cyanides. Aurous cyanide and the soluble aurocyanides are of technical importance. The former, AuCN, a yellow crystalline powder, insoluble in water and acids, is formed by the action of hydrocyanic acid on auric hydroxide. It is readily soluble in solutions of alkali or alkaline-earth cyanides, yielding aurocyanides such as KAu(CN)2. solution of the potassium salt, which is used for electroplating with gold, is readily obtained by precipitating a solution of gold chloride with ammonia and dissolving the fulminating gold in a solution of potassium cyanide, or by precipitating gold chloride with magnesia, dissolving out the excess of magnesia in the precipitate with nitric acid, and then dissolving the auric hydroxide in potassium cyanide as before

Potassium aurocyanide is also formed when gold is dissolved in a solution of potassium cyanide in presence of oxygen or other oxidising

agent:

 $4KCN+2Au+O+H_2O=2KAu(CN)_2+2KOH$ 

(Clennel, Cyanide Handbook, 1910, 10-32 gives a full account of the discovery of this reaction.)

The dissolution of metallic gold is primarily due to the great stability of the aurocyanogen ion Au(CN),'. Metals, like all other substances, have a tendency to dissolve in water. In contact with its aqueous solution, a salt will dissolve if the solution is unsaturated, or crystallise out if it is supersaturated Metals behave sumilarly, with the important difference that they dissolve in the form of positively charged ions, so that when a metal is placed in contact with a solution containing fewer of its ions than corre spond with equilibrium, it gives out positively charged atoms, becoming itself negatively charged, until the electrical attraction stops further change, and vice versa. In this way, a definite potential difference always arises between a metal and a solution of it, the sign and magnitude of which depend on the nature of the metal and on the concentration of the positively charged ions of the metal in the solution

In order for a metal to dissolve at all, therefore. it is necessary that the solution shall contain less than the saturation quantity of positive ions; and for the dissolution to continue, the positive charges of the ions and the negative charge of the metal must be got rid of in some way.

These conditions are fulfilled in the case of the dissolution of gold in a cyanide solution containing oxygen, because the dissociation of the complex ion,  $Au(CN)'_2 \gtrsim Au' + 2CN'$  is extremely small, and solutions of it therefore dry silver cyanide is heated about one-half contain infinitesimal quantities of gold ion, and of the CN is given off in the form of further the electrical charges produced by the

dissolution of the gold are removed by the reactions:

and Au'+2(CN)'=Au(CN)' $O+H_2O+2(-)=2OH'$ 

the result of which, written in the ionic form, is  $4K'+4(CN)'+2Au'+O+H_2O+2(-)$  =  $4K'+2Au(CN)_2'+2OH'$ 

The potential difference between a metal like zinc (which has a greater tendency to dissolve than gold) and a cyanide solution is much greater than the natural potential difference between gold and the solution; hence gold ions are drawn out of the solutions to the zinc, where their positive charges are neutralised by the negative charge of the zinc. This disturbs the equilibrium between zinc and the solution and also between aurocyanogen ions and gold ions, causing fresh quantities of zinc to dissolve and of aurocyanogen ions to dissociate, processes which continue until the whole of the gold is precipitated.

As W. Skey (Trans. and Proc. New Zealand Inst. 8, 334, 1876) first showed, gold in cyanide solutions is electro-positive to silver and silver to mercury, so that gold will precipitate silver and mercury from their solutions in cyanides. This has been confirmed by Bodlander (Ber 1903, 36, 3933). This reversal of the usual order is, as will be understood from the above explanation, due to the increasing stability of the mercury, silver, and gold complex cyanogen

ions.

It is of interest to note that most of the minerals which accompany gold in its ores are electro-negative to gold in cyanide solutions, and therefore accelerate its dissolution in the way which is familiar in the solution of zinc in sulphuric acid in presence of copper or platinum

Barium platinocyanide BaPt(CN)<sub>4</sub> 4H<sub>2</sub>O is

Barium platinocyanide BaPt(CN)<sub>4</sub> 4H<sub>2</sub>O is most readily made by electrolysing a solution of barium cyanide (270 grams per litre) with platinum electrodes and an alternating current (0.4 ampere per sq. cm.), about 0.6 gram platinum is dissolved per ampere hour. After removing the excess of barium by CO<sub>2</sub> the solution is concentrated to crystallisation (A Brochet and J Petit, Bull Soc chim. 1904, [3] 31, 630) The salt crystallises in monoclinic prisms, which are yellow by transmitted, violetblue by reflected, light—It dissolves in 33 parts of water at 16°. By recrystallisation from a solution containing barium cyanide it is obtained in small crystals which are highly fluorescent when exposed to X-rays, and are suitable for making fluorescent screens for X-ray work

Copper cyanides. When potassium cyanide is added to the solution of a cupric salt, a brownish precipitate of cupric cyanide Cu(CN), is produced, which gradually evolves cyanide. When heated, this loses a further quantity of cyanogen and yields white cuprous cyanide CuCN, the constitution and reactions of which appear to resemble those of silver cyanide.

Cuprous cyanide is soluble in solutions of potassium cyanide, about 2½ molecules of KCN being required to dissolve 1 molecule of CuCN; the solutions contain the complex anions Cu(CN)," and Cu(CN)," (Kunschert, Zeitsch. anorg Chem. 41, 359, 1904) These anions are so little dissociated into copper ions that sul-

phuretted hydrogen will not produce a precipitate in the solutions, and therefore copper itself (in presence of oxygen) and all its compounds dissolve readily in cyanide solutions. Solutions of the sodium or potassium cupro-cyanides are used in the electro-deposition of copper on iron.

469

Zinc cyanide Zn(CN)<sub>2</sub> is a white substance, insoluble in water, but soluble in acids and in cyanide solutions. It is not easily prepared in a perfectly pure condition, because water decomposes it partially. When dry it is very stable, decomposing only at a bright-red heat.

The complex salt potassium zinc cyanide  $K_2Zn(CN)_4$  crystallises in large well-formed octahedra from aqueous solutions; 100 grams of water at 20° dissolve 11 grams of it. It is anhydrous, and may be fused at a red heat without decomposition. The sodium salt  $NaZn(CN)_3, 2\frac{1}{2}H_2O$  is very readily soluble in water. The complex zinc cyanogen ions are much less stable than those containing copper, gold, silver, and mercury; a small excess of an alkali sulphide precipitates the zinc completely.

Cyanogen (Ger Cyan) C<sub>2</sub>N<sub>2</sub> was discovered by Gay-Lussac It is prepared by heating perfectly dry mercuric cyanide at a dull red heat, Hg(CN)<sub>2</sub>=Hg+C<sub>2</sub>N<sub>2</sub> A part of the cyanogen is always polymerised to dark-brown, non-volatile paracyanogen. Paracyanogen appears to be the stable form at ordinary temperatures, at high temperatures it is converted into cyanogen. The velocity of the change is very small at temperatures below 300°, so that cyanogen gas can exist in the cold without change.

Cyanogen itself is a gas which burns with a peach-blossom-coloured flame Liquid cyanogen boils at  $-20.7^{\circ}$  under atmospheric pressure and freezes at -34 4° Its critical temperature and pressure are 128 3° and 59 6 atmos respectively (Cardoso and Baume, Compt rend 1910, 151, 141). Its heat of formation from graphite and nitrogen is 70,000 cals. per molecule Water dissolves 4 95 times its volume of the gas at 0°. At 18° the dissolved cyanogen is hydrolysed to hydrocyanic and cyanic acids, the latter yielding ammonia and carbon doxide so that no definite solubility is observed (Naumann, Zeitsch Elektrochem. 16, 772, 1910) After some time the solution deposits dark brown azulmic acid and contains also oxalic acid and urea dissolves in caustic alkalis, yielding cyanide and eyanate:  $2KOH + C_2N_2 = KCNO + KCN + H_2O$ . Silver nitrate solution has no action on it. By means of these two reactions, it may be separated from hydrocyanic acid and estimated quantitatively in mixtures of the two gases (Wallis, Anna-

len, 345, 353, 1906) Cyanogen is very poisonous.

A knowledge of the exact conditions under which cyanogen can be formed from its elements is of interest in the theory of several technical processes for the manufacture of cyanides

Wallis loc cit has shown that the electric arc burning between electrodes of very pure carbon in an atmosphere of nitrogen produces no cyanogen at all H. v. Wartenberg (Zeitsch anorg. Chem 52, 299, 1907) pointed out, however, that a very intense cyanogen spectrum is seen, and that carbon is deposited at some distance from the arc. Nernst's theorem indicates that very considerable

quantities of cyanogen should exist in equilibrium with carbon and nitrogen at the temperature of the arc:

Temperature	Per cent C <sub>2</sub> N <sub>2</sub> in the gas calculated from Nernst's theorem
2000°	0.01
2500°	0 9
3000°	17 0
39500	45.0

The probable explanation is that evanogen is essentially unstable at low temperatures, that it can exist at all is due to an excessively slow rate of decomposition. Berthelot (Force des Matières Explosives, Paris, 1883, 113) has Matières Explosives, Paris, 1883, shown that it can be detonated by mercury fulminate, and, when heated, its rate of de-1200°. composition becomes measurable at v Wartenberg supposes, therefore, that cyanogen is really formed at the high temperature, but that it decomposes again completely before it can cool to temperatures at which it can continue to exist. It is obvious from the figures given above that the direct union of carbon and nitiogen to evanogen can play no part in the formation of cyanides in processes which are carried out at ordinary furnace temperatures

Cyanogen chloride ('NCl is formed by the action of chlorine on mercuric cyanide (Serullas, Ann Chim. Phys 1827, 35, 291), zinc cyanide (A Held, Bull Soc chim 1897, [3] 17, 287), or aqueous hydrocyanic acid (Berthollet, 1787; A Wurtz, Annalen, 1847, 64, 367) Alkali cyanides are unsuitable, because, except in cold, very dilute solutions, they react violently with cyanogen chloride, yielding dark-brown, amorphous products. The preparation of cyanoamorphous products gen chloride in considerable quantities is described by T S Price and S J Green (J Soc Chem Ind 1920, 39) A 12 to 15 pc solution of pure hydrocyanic acid is treated with chlorine at about 40°, the slow absorption of chlorine is hastened by injecting it into the solution of a finely divided condition through porous carthenware. The cyanogen chloride distils off as it is formed, together with hydrocyanic acid, the product containing 10-20 p c. of the latter It is purified by retreatment with chlorine, or by shaking it with zinc oxide, which removes hydrocyanic acid almost completely Hydrochloric acid is removed by distillation over sodium bicarbonate

Cyanogen chloride is a colourless liquid, which boils at 12 66°, 760 mm, and solidifies at Its vapour pressure (mm) is  $-30^{\circ}$ ;  $148.2^{\circ}$ at  $-20^{\circ}$ ;  $270.5^{\circ}$  at  $-10^{\circ}$ ;  $441.1^{\circ}$ at 0°, 681 9 at 10°; 1001 9 at 20°; 1427 4 at 30°, 1988 0 at 40°, 2719 3 at 50°; 3664 2 at 60; 4873 2 at 70° (Regnault). The vapour attacks the eyes violently The cold, saturated aqueous solution contains about 6 pc CNCl. The heat of formation of liquid CNCl from its elements is -26.9 cals, per molecule. Dry cyanogen chloride may be preserved indefinitely when pure; in presence of hydrochloric acid it polymerises to cyanuric chloride C3N3Cl3. Aqueous hydrochloric acid (stronger than about 2N) hydrolyses it thus.

 $CNCl + 2H_2O = NH_4Cl + CO_2$ 

Its behaviour towards alkalıs is the same as that of cyanogen bromide described below. Hydriodic acid hardly attacks it in the cold, and it is without action on metals, such as iron and copper, at ordinary temperatures.

Cyanogen bromide CNBr. A solution containing cyanogen bromide in addition to a cyanide dissolves gold more rapidly than one containing cyanide alone (Sulman and Teed, Eng Pat 18592, of 1894, and J Soc Chem. Ind 1897, 961) Cyanogen bromide is therefore used in the treatment of a few refractory ores, the West Australian tellurides especially The final result of the reaction is expressed by the equation:  $2Au + 3KCN + BrCN = 2KAu(\tilde{C}N)_2 + \hat{K}Br$ 

Cyanogen bromide is formed by the action of bromine on a cyanide or on hydrocyanic acid. Owing to the difficulty of transporting either bromine or cyanogen bromide, it is always prepared at the place where it is to be used by liberating bromine from a mixture of a bromide and a suitable oxidising agent by the addition of sulphuric acid, and then adding a concentrated solution of an alkali cyanide. By the use of a suitable quantity of the oxidising agent, the whole of the bromine is utilised, with sodium bromate, for example, the reaction is (C Gopner, Zeitsch angew Chem 1901, 14, 355):

 $2NaBr + NaBrO_3 + 3NaCN + 3H_2SO_3$ 

 $=3Na_2SO_4+3BrCN+3H_2O$ 

Cyanogen bromide is a colourless, crystalline substance, which melts at 52° and boils at 61°; 100 grams of water dissolve from 5 to 6 grams of it at the ordinary temperature. It has an intensely irritating effect on the mucous membranes and eyes, and is said to be very poisonous The perfectly pure substance can be kept without change, but traces of bromine (or hydrobromic acid) cause it to polymerise rapidly to cyanuric bromide, partial decomposition always occurring It is very slowly decomposed by water: CNBr+H<sub>2</sub>O=HCNO+HBr, the cyanic acid decomposing further to ammonia and carbon dioxide Caustic alkalis bring about the same change instantaneously, alkali carbonates much more slowly, and bicarbonates have no action at all Cyanogen bromide and potassium cyanide react in aqueous solution, yielding cyanogen; thus:

CNBr+KCN=KBr+C<sub>2</sub>N<sub>2</sub> (private communication from Mr C. J Ellis). In solutions containing 0.2 to 08 pc of potassium cyanide and 01 to 02 pc of cyanogen bromide, the latter is completely decomposed in from 3 to 6 hours at the ordinary temperature

In aqueous solution cyanogen bromide reacts with hydriodic acid and with sulphuretted hydrogen according to the equations

$$\begin{array}{c} \text{CNBr+2HI=HCN+HBr+I}_2\\ \text{nd} \quad \text{CNBr+H}_2\text{S=HCN+HBr+S} \end{array}$$

The first reaction provides a convenient method for the quantitative estimation of cyanogen bromide. Chattaway and Wadmore (Chem. Soc Trans 1902, 191) have shown that these reactions are characteristic of compounds in which the halogen atom is directly linked with nitrogen, and that cyanogen bromide therefore has the constitution C. N Br.

Cyanamide NH<sub>2</sub> CN was first prepared by the action of ammonia on an ethereal solution of cyanogen chloride (Cloez and Cannizzaro, Compt rend 1851, 32, 62); ammonium chloride crystallises out and cyanamide remains when the ether is evaporated. The same reaction

occurs in aqueous solution. The formation of the disodium salt,  $Na_2CN_2$ , by the action of sodamide on carbon or on sodium cyanide has already been described The same substance is also produced when sodamide acts on sodium cyanate, sodium carbonate or carbon dioxide at a low red heat; it is also formed when either sodium cyanate or sodium cyanide is fused with sodium hydroxide.

The calcium and barium salts, CaCN, and BaCN<sub>2</sub>, may be prepared from nitrogen and the carbides, by heating the corresponding ferrocyanide or by heating the carbamates or cyanates to redness (Drechsel, J pr. Chem. 1877, [2] 16, 188, 1880, [2] 21, 77) thus:

and 
$$\begin{array}{c} \operatorname{Ca(OCONH_2)_2} = \operatorname{CaCN_2} + 2\operatorname{H_2O} + \operatorname{CO_2} \\ \operatorname{Ca(OCN)_2} = \operatorname{CaCN_2} + \operatorname{CO_2} \end{array}$$

Cyanamide is also obtained by the action of mercuric oxide on a solution of thiourea

$$CS(NH_2)_2 + HgO = NH_2CN + HgS + H_2O$$

Several guanidine derivatives yield evanamide when boiled with water or alkalis, for example, nitroso guanidine decomposes thus:

(Thiele, Annalen, 1893, 273, 136)

Cyanamide is easily prepared from the disodium salt by neutralising its cold, aqueous solution with nitric acid, and evaporating to dryness on the water bath in a vacuum, the dry residue is extracted with ether Werner (Chem Soc Trans 1916, 1323) describes a convenient method of preparing it from the readily accessible calcium salt; 100 grams are mixed with 125 gr of acetic acid and 120 gr of water, the mixture well kneaded and left for 24 hours The friable mass is then powdered and extracted with ether in a Soxhlet apparatus. Yield 94-96 p c of theory

Cyanamide forms colourless, deliquescent crystals which melt at 43°-44° (E. Colson, Chem. Soc. Trans. 1917, 555), it is readily soluble in water, alcohol and ether, very sparingly soluble in carbon disulphide, benzene, and chloroform. When heated it polymerises very readily to dicyanodiamide,  $\mathrm{NH}_2$  (C NH) NH CN, it boils at 140° at 19 mm, much melamine left behind; the neutral aqueous being solution possesses considerable stability, but polymerisation occurs in presence of either acids or alkalis. The process has been studied carefully by Morrell and Burgen (Chem. Soc Trans 1914, 576) and by Grube and Kruger (Zeitsch phys. Chem 1914, 86, 65), who find that in alkaline solutions the reaction takes place between undissociated cyanamide molecules and cyanamide ions,  $H_2CN_2+HCN_3'=H_3C_3N_4'$ . The rate of polymerisation is therefore a maximum when one-half of the cyanamide is in the ionised form, a condition which is practically attained when a quantity of a strong base (soda or lime) equivalent to one half of the cyanamide is added, the salts of a weak base such as ammonia being largely hydrolysed, the necessary concentration of cyanamide ion is not readily attained, and weak bases, therefore, have a much smaller polymerising action than strong ones.

The action of acids is more complicated,

polymerisation and hydrolysis to urea occurring

simultaneously. According to Carlson (Zeitsch. angew. Chem 1914, 27, 724) cyanamide, treated with 10 to 20 p.c sulphuric acid, is converted almost wholly into urea at the ordinary temperature, whereas near the boiling-point polymerisation predominates In acid solutions the reaction is further complicated by the hydrolysis of the dicyanodiamide to dicyanodiamidine

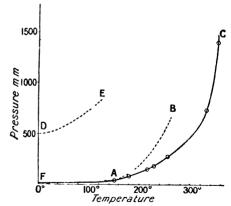

471

 $NH_{2}(C \cdot NH)NHCN + H_{2}O$ = NH<sub>2</sub>(C; NH) NH CO NH<sub>2</sub>

a strong base which neutralises the acid

Cyanamide is an extremely weak acid, its dissociation constant, for H2CN2=H+HCN2 is of the order 10-11 (Grube and Kruger) sodium salt NaHCN2 crystallises from a solution of cyanamide in absolute alcohol when sodium ethylate is added to it, but the salt Na<sub>2</sub>CN<sub>2</sub> can only be prepared by one of the dry fusion methods mentioned above. The calcium salt CaCN, also decomposes when treated with water yielding a solution of  $\text{Ca}(\text{HCN}_2)_2$ The silver salt Ag<sub>2</sub>CN<sub>2</sub> is a canary-yellow precipitate obtained by adding a solution of silver nitrate to a dilute ammoniacal solution of cyanamide, it is readily soluble in cold dilute nitric acid. The lead salt PbCN<sub>2</sub> is an orange-yellow precipitate Cyanamide, also combines with acids, a white crystalline substance H2CN2 2HCl is formed when dry hydrochloric acid is passed into a solution of cyanamide in dry ether (Mulder and Smit, Ber 1874, 7, 1634).

Cyanic acid HCNO is prepared by distilling cyanuic acid (Wohler) or by warming urea with phosphorus pentoxide (Weltzien, Annalen, 1858, 107, 219) and condensing the vapour at -18° It is a volatile liquid, the smell of which It is a volatile liquid, the smell of which resembles that of strong acetic acid It is extremely unstable, changing rapidly even at 0° into the white amorphous polymeric substance cyamelide The solution in dry ether is comparatively stable. The interesting restance cyamelide lationship of cyanic acid HCNO, cyanuric acid

 $(HCNO)_3$ , and cyamchide  $(HCNO)_x$ , has been studied by Troost and Hautefeuille (Compt rend. 1868, 67, 1340), van't Hoff and van Deventer (Studies in Chem Dynamics, 1896). The dia (Studies in Chem Dynamics, 1896) gram represents the approximate relative positions of the vapour pressure curves of cyanic acid (HCNO), cyanuric acid (HCNO)<sub>3</sub>, and cyamelide  $(HCNO)_x$ , all of which yield the same vapour.

(The few points determined experimentally are indicated by small circles.) At the triple

point A (150° and 50 mm.) the two solid phases cyamelide and cyanuric acid coexist together with the vapour phase. Above 150° cyanuric acid is the stable phase (vapour pressure curve AC), at lower temperatures cyamelide (curve FAB) The position of the vapour pressure ıs stable curve of cyanic acid itself (very roughly indicated by DE) shows that eyanic acid is quite unstable relatively to cyamelide. If the curve DE cuts the curve AB and AC the points of intersection would represent the melting-points of cyamelide and cyanuric acid respectively. They obviously he at temperatures at which these substances decompose.

In aqueous solution eyanic acid is hydrolysed, slowly in cold dilute solutions, rapidly when warmed, to ammonia and carbon dioxide,

HCNO+H<sub>2</sub>O=NH<sub>3</sub>+CO<sub>2</sub>.

The formation of cyanates by the action of cyanogen on alkalis, by oxidation of cyanides by the action of alkalis on cyanogen bromide, and from carbon monoxide and ammonia, has already been described

Ammonium cyanate NH4 CNO is prepared in the form of a white snow, by mixing the vapours of cyanic acid and ammonia well diluted with an indifferent gas. When warmed it is converted into urea NH<sub>4</sub>CNO=CO(NH<sub>2</sub>)<sub>2</sub> The same reaction occurs in aqueous solutions, in which, however, it is reversible, 3.2 p.c of the cyanate remaining unchanged at 32° and 65 p c. at 100' (Walker and Hambly, Chem Soc. Trans 1895, 746)

Potassium and Sodium cyanates KCNO and NaCNO are easily prepared by grinding together the dry cyanides and the theoretically necessary quantity of lead oxide, and heating the mixture gently until the lead is melted. The salt is then recrystallised from water or dilute alcohol According to Paterno and Pannain (Gazz. chim ital 1904, 34, ii 152) when a solution of 4 to 6 mols KCN and 1 mol. KOH per litre is electrolysed with 4-6 volts and 1-4 amps per sq dcm of anode surface and the solution at the anode agitated, the evanide is oxidised almost quantitatively to cyanate. Milbauer (Zeitsch anoig Chem 1904, 42, 433) observed that potassium sulphocyanide, when heated at 300° with lead oxide, gave cyanate thus: KSCN+PbO=KCNO+PbS

The decomposition of the alkali cyanates at high temperatures and their reduction by carbon are described above.

Potassium cyanate crystallises in thin transparent plates of sp gr 2 05, readily soluble in water, and anhydrous ammonia, insoluble in absolute alcohol, and fusible without decomposition below a red heat

Sodium cyanate. 100 grams of water at 16° dissolve 10.68 grams; it fuses without decomposition about 500°. Lead cyanate is a crystalline precipitate, which is formed when solutions of a soluble cyanate and of a lead salt are mixed The dry salt is stable, but it decomposes when boiled with water, yielding urea and lead carbonate.

Silver cyanate is very slightly soluble in cold water, 100 c.c. at 12° dissolve 0 006 gram, but it is much more soluble in hot water. It is readily soluble in aqueous ammonia, and sparingly soluble in cold dilute nitric acid

Sulphocyanides or Thiocyanates. (Ger. Rhodanide or Schwefelcyanide.)

At the present time sulphocyanides are obtained exclusively from the hydrocyanic acid of coal gas, but a modification of Gélis' synthetic process was working in 1907.

A. W Hofmann (Reports by the Juries, Inter Exhib of 1862, 59-63), said that at that time ammonium sulphocyanide obtained by washing the spent oxide of gasworks was only treated to recover its ammonia, the sulphocyanide being thrown away. In 1863 P. Spence (Eng. Pat 2364 of 1863 (provisional only)) proposed to separate the sulphocyanides in gas liquor (after distilling off the ammonia) in the form of cuprous sulphocyanide by adding copper and ferrous sulphates, and the idea has been revived in various forms since that time, but it does not appear to have become of any Gas liquor is really a very dilute importance solution of sulphocyanide, as the following figures, calculated from Linder's analyses of various English gas liquors (Chief Inspector of Alkalı Works, 42nd Rep 1905, 35), show :-

Grams per litre

HCN as ferrocyanide . 1 0 008 0 0 0 576 0 460 0 HCN as sulphocyanide . 1 088 4 457 1 238 1 029 1 042 HCN as hydrocyanic acid 0 680 0 0 0 000 0 050 0 355

These liquors had all been stored for some perfectly fresh gas liquor contains ammonium sulphide and cyanide By the action of the air, the former is oxidised to ammonium polysulphides, which convert the cyanide into sulphocyanide; thus:

$$(NH_4)_2S_2 + NH_4CN = NH_4SCN + (NH_4)_2S$$

The recovery of the whole of the hydrocyanic acid of coal gas in the form of a concentrated solution of ammonium sulphocyanide is possible by applying this reaction in a suitable way

A very large part of the gas liquor produced is distilled and the gases evolved, consisting of ammonia, carbon dioxide, sulphuretted hydrogen, and a little hydrocyanic acid, passed into sulphuric acid for the production of ammonium The unabsorbed gases, mixed with sulphate steam, are first cooled, which yields an aqueous solution of hydrocyanic acid and sulphuretted hydrogen, known as 'Devil liquor,' which is run to waste.

The cooled gases are passed usually into a heap of ferric hydroxide, in order to absorb the sulphuretted hydrogen, or occasionally they are burned in a Claus kiln, in which, as Carpenter has shown, the hydrocyanic acid is converted by steam into ammonia

The waste liquors from the ammonia stills contain relatively considerable quantities of calcium sulphocyanide (about 0 15 p.c SCN) and phenols, and are usually discharged into Frankland and Silvester (J Soc Chem. Ind 1907, 231), and Fowler, Ardern and Lockett (*ibid* '1911, 174), have published detailed accounts of the bacterial oxidation of these impurities in the septic tank system of sewage treatment. It appears that sulphocyanides are practically completely oxidised in the contact beds, if sufficient time is allowed Fowler and Holton (J. Soc Chem. Ind. 1911, 180) have shown that 92-98 pc of the impurities in the ammonia still effluent can be oxidised by allowing it, after dilution to one-tenth of its original strength, o trickle through a column of clinker inoculated with bacterial material from a contact bed of a sewage work; one cubic yard of filter is required

or 10 galls. per day of effluent.

Synthesis of sulphocyanides from ammonia ind carbon disulphide—In Gélis' original process A. W Hofmann, Reports by the Juries, Inter. Exhib of 1862, 59-63; A Gélis, Eng. Pat 1816 of 1860), a concentrated solution of ammonia and ammonium sulphide was agitated with arbon disulphide, yielding a solution of amnonium sulphocarbonate

$$(NH_4)_2S + CS_2 = (NH_4)_2CS_3$$

which was then heated to 90°-100° with potasium sulphide

 $2(NII_4)_2CS_3+K_2S=2KCNS+_22NH_4IIS+3H_2S$ I very large amount of sulphuretted hydrogen is produced in this way, the disposal of which would ccasion much trouble and expense Gunsburg nd Tchernkiae (Eng. Pat. 1148 of 1878, 1359 f 1879; 1261 of 1881) heated a 20 p c solution f ammonia with carbon disulphide in autoclaves provided with stirrers at 100° until a pressure f 15 atmos. was reached, which indicated the nd of the reaction As Conroy (J Soc Chem nd. 1896, 15, 8) has shown, ammonium sulphoyanide is formed quantitatively under these onditions, the large pressure developed being ue to the formation of the volatile ammonium ulphide  $4NH_3+CS_2=NH_4SCN+(NH_4)_S$ 

Subsequent improvements were all in the irection of diminishing the quantity of amionia required and reducing the pressure in the utoclaves The simplest and most effective ray of doing this is to add lime to the charge Prowther and Rossiter, Eng Pat 17846 of 893, Brock, Hetherington, Hurter, and taschen, Eng. Pat 21451 of 1893), the reaction hen taking place in accordance with the equation.

 $\begin{array}{l} \mathrm{NH_3} + 2\mathrm{CS_2} + 2\mathrm{Ca(OH)_2} \\ = \mathrm{Ca(SCN)_2} + \mathrm{Ca(SH)_2} + 4\mathrm{H_2O} \end{array}$ 

A certain excess of ammonia over the uantity required by the equation must be used prevent the formation of calcium sulpho-The excess of ammonia is distilled ff, the residual mixture treated with carbon ioxide to remove sulphuretted hydrogen (in the ay used in the treatment of Leblane alkali aste), and the calcium carbonate filtered off. he clear solution of calcium sulphocyanide is sily converted into other salts

#### THE PRINCIPAL SULPHOCYANIDES.

Potassium sulphocyanide KSCN crystallises anhydrous, striated prisms or needles of sp gr 9, which melt at 172 3°. It resembles saltetre in appearance and taste It is delinescent and very soluble in water, 100 grams of hich dissolve 177 2 grams at 0°, 217 grams at )°, and 239 grams at 25°. It is also soluble in thydrous ammonia and in many organic liquids he solubilities (in grams per 100 grams of olvent) are:

Acetone, 20.8 at 22°; 20 4 at 58°. Ethyl acetate, 0 44 at 0°; 0 4 at 14°; 0 2 at

Amyl alcohol, 0 18 at 13°; 2.14 at 100°.

Pyridine, 6.75 at 0°; 4.97 at 58°, and 3.21 at 115°.

The fused salt becomes deep blue at 430°; the colour is said to be due to the liberation of sulphur. The sulphocyanides are plant poisons. Frankland and Silvester found that gold-fish were not affected in 24 hours by quantities of potassium sulphocyanide up to 260 parts SCN per 100,000 of water, but even as little as 10 parts of SCN per 100,000 is sufficient to stop the multiplication of, and eventually to kill, Bacıllus coli communis.

Ammonium sulphocyanide NH<sub>4</sub>SCN crystallises in anhydrous, colourless leaflets of sp gr. 1 3, which melt at 159°, 100 grams of water dissolve 122 grams at 0° and 162 grams at 20°, it is readily soluble in alcohol When heated a little above its melting-point, it is partly converted into the isomeric thiourea. At 220° decomposition takes place, ammonia, sulphuretted hydrogen, and carbon disulphide being evolved, and guanidine sulphocyanide remaining

Thiocyanogen is obtained by the action of a solution of a halogen in an anhydrous solvent on a suitable thiocyanate, a dry ethereal solu-tion of bromine cooled to 0° and lead thiocyanate give good results By cooling an approximately N/2-solution in carbon disulphide to  $-70^{\circ}$ thiocyanogen is obtained in almost colourless crystals, melting at  $-3^{\circ}$  to  $-2^{\circ}$ , and decomposing at the ordinary temperature chemical behaviour thiocyanogen resembles the halogens, it is at least as strongly electronegative as iodine. The molecular weight has not yet been determined, but the constitution of thiocyanogen is probably CN-S-S-CN (E Soderback, Annalen, 1919, 419, 217)

# ANALYSIS OF CYANIDES.

The methods of analysis described here are those commonly employed in technical labora-

Detection of hydrocyanic acid -The material is distilled with an acid and the distillate ex-The Prussian blue test may be applied amined by evaporating the solution (after the addition of a little sodium hydroxide) in vacuô at temperature below 70°, to 1 cc, 02 cc. of 3 pc FeSO<sub>4</sub> and 0 05 gram KF are added, and, after 10 minutes, a small excess of 30 p c. HNO<sub>3</sub>. The blue colour is compared with that produced by a known quantity of KCN under similar conditions (A Viehoever and C O Johns, J Amer Chem Soc 1915, 37, 601). The sulphocyanide test is also characteristic; distillate containing 0 1-8 milligrams HCN is made alkaline with KOH, treated with 1 cc. ammonium polysulphide solution and evaporated to dryness. The residue is extracted with acetone, which dissolves KSCN only. After removing the acetone by evaporation the aqueous solution of the residue is treated with 2 c c. of 0 5 p.c FeCl<sub>3</sub>, and the colour matched by means of a standard sulphocyanide solution (M O Johnson, J Amer Chem Soc. 1916, 38, 1230). Ferric sulphocyanide may be extracted from the aqueous solution by ether; meconic acid gives a similar colouration in ether, which, however, is not destroyed by 10 pc. AuCla (P. Lavialle and L. Varenne, J. Pharm. Chim. 1915, 12, 74)

Other sensitive colour tests have the disadvantage that they may be produced by

substances other than HCN. An alkaline solution of pieric acid yields a reddish-violet colouration with NaCN, which is due to sodium iso-purpurate C<sub>6</sub>H<sub>2</sub>(NO<sub>2</sub>)<sub>2</sub> N(CN)<sub>4</sub> ONa, when excess of cyanide is used, but to amino-nitro-phenols when pieric acid is in excess, as is usually the case (A. C. Chapman, Analyst, 1910, 35, 469) The liquid to be tested is mixed with an equal volume of a solution containing 0 05 pc pierre acid and 0.5 p.c. Na<sub>2</sub>CO<sub>3</sub>, and digested at 40° for 1 hour. The colour is then compared with that produced by a standard HCN solution, I part of HCN in 500,000 parts water can be detected (A. D Waller, Proc Roy Soc. 1910, B 82, 574)

The cyanogen liberated by the action of HCN or a cupric salt oxidises many substances to coloured products, the tests are highly sensitive, but uncertain owing to the difficulty of excluding other oxidising agents For details, see Thiery (phenolphthalin), J Pharm Chim 1907, 25 Chem. Zeit 1913, 37, 609, G W Anderson (gualacum), J Soc Chem Ind 1917, 36, 195, J Moir and J Gray, J Chem Met and Min Soc S Africa, 1910, 11, 152, and J Moir, Chem Soc Proc 1910, 26, 115 (hydrocœrulignone, tolidine, dianisidine)

Owing to the hygroscopic Alkalı cyanıdıs nature of sodium and potassium cyanides when cold, samples, taken from different parts of a cake, should be transferred at once and without touching them with the hands to a hot iron mortar, broken up coarsely, and transferred to a hot perfectly dry bottle If the sample has to be kept for any length of time before it is analysed, it is preferable to use glass-stoppered bottles and to grease the stopper with a little Errors due to absorption of moisture in sampling are more common and more serious than those due to maccuracies in testing.

Estimation of cyanogen -5 grams of the sample are weighed out and made up to 500 c c; 25 c c of the solution are diluted to 200-300 c c and titrated with a solution of pure silver nitrate until the faintest visible turbidity results. The silver nitrate must be neutral and free from lead and zine especially venient strength of solution is obtained by dissolving 13 l grams of silver nitiate in 1 litie of distilled water 1 e c of this solution is equivalent to 0.01 gram of KCN The solution is standardised by means of a solution of pure sodium chloride (dried by heating to redness before weighing) containing 4 487 grams per litre, 1 c c of the silver solution should exactly precipitate 1 c.c. of the sodium chloride solution using pure potassium chromate as indicator impure solutions of cyanides, the end point is often more easily observed if a little caustic soda (or a few drops of ammonia) and a crystal of potassium iodide are added before running in the silver nitrate solution Sulphides interfere with the test, but they are easily removed by shaking the solution with a little lead carbonate and filtering it.

Estimation of sulphide -10 grams of the finely powdered sample are dissolved in 15 c.c. ot ordinary water and a solution of lead nitrate (2 4 grams per litre) run in gradually. The mixture is stirred until the colloidal lead sulphide at first formed has coagulated into brown flocks;

a drop of the solution is then placed on blotting paper beside a drop of the lead nitrate solution, and the two allowed to run together. When no difference can be detected between the colour of the paper where the drops have mixed and where they have not, the titration is considered to be at an end; 1 cc of the lead solution=0 001 gram of K<sub>2</sub>S (T Ewan, J. Soc Chem Ind. 28, 10, 1909, Rossiter, ibid 30, 583, 1911)

Water is estimated by weighing out about 1 gram of the coarsely powdered sample into a small distilling flask (10-20 cc) which is then evacuated by a good water pump or preferably by a mercury pump The sample is then warmed, gently at first, and finally to 200°-300°. The whole of the moisture is expelled in a few minutes without appreciable decomposition of

the cyanide

Carbonate is conveniently estimated by precipitating a suitable portion of the solution with barium chloride in the cold (to avoid decomposition of cyanate). The precipitate is washed and titrated, together with the paper, with normal hydrochloric acid and methyl

orange

The solution is neutralised with Chloride dilute nitric acid, and methyl orange and boiled for about 1 hour (in a draught cupboard, of course) to drive off the hydrocyanic acid and decompose evanate The chloride remaining (Richards and Singer, Amer Chem. J. 27, 205, 1902) is then precipitated by a known excess of standard silver nitrate solution, the silver chloride filtered off and the excess of silver titrated with ammonium sulphocyanide and iron alum in the usual way.

If ferrocyanide is present, it may be precipitated with excess of silver nitrate in ammoniacal solution; by acidifying the filtrate with nitric acid, silver chloride is precipitated and may be

weighed

Cyanamide in presence of alkali cyanides is easily estimated by exactly neutralising the solution of 1 gram of the substance in 100 to 150 cc of water with nitric acid, and then boiling for 20 minutes to expel hydrocyanic acid. After cooling, 2 or 3 drops of ammonia are added, and then excess of silver nitrate canary-yellow precipitate of silver cyanamide  $\mathrm{Ag}_2\mathrm{CN}_2$  is filtered off and dissolved in cold dilute nitric acid (which usually leaves a small residue of undissolved silver cyanide). The silver in the solution is then titrated by means of ammonium sulphocyanide, using ferric alum as indicator The method is applicable to most substances containing cyanamide, the boiling with acid being, of course, omitted when little or no cyanide is present.

When cyanamide is the principal constituent this method is insufficiently accurate, because the composition of the precipitate is not exactly that required by the formula Ag<sub>2</sub>CN<sub>2</sub>, the silver content depending to a small extent on the excess of silver nitrate used in precipitation. Caro (Zeitsch. angew Chem 1910, 23, 2405) has shown, however, that it contains the whole of the cyanamide nitrogen, which is very readily

estimated by Kjeldahl's method

Cyanate The solution is acidified with nitric acid and boiled for 20 minutes at least to expel hydrocyanic acid, and convert the cyanate into ammonium nitrate and carbon dioxide

The ammonia is then distilled off, after adding | treated with 4 to 5 times its volume of methyexcess of caustic soda, and estimated by titration with N-hydrochloric acid as usual. In presence of cyanamide, the method is not available, because some ammonia is formed from the cyanamide when it is boiled with caustic soda In this (rather uncommon) case, the cyanate must be estimated by collecting the carbon dioxide evolved when the sample is boiled with acid (Ewan, J. Soc Chem Ind 1904, 23, 244)

Ferrocyanide is most conveniently estimated, either alone or in presence of cyanides, by titration with a standard solution of zinc sulphate until a drop of the solution no longer gives a blue colour when brought in contact with a drop of ferric solution on paper A zinc alkalı ferrocyanide of somewhat variable composition is precipitated, and H G ('olman (Analyst, 33, 261, 1908; and J Soc Chem Ind 27, 806, 1908) has shown that the quantity of zinc solution required to precipitate a given quantity of ferrocyanide depends, to some extent, on the nature of the metal in the ferrocyanide used effect can be eliminated almost entirely by adding an excess of potassium sulphate. The adding an excess of potassium sulphate method is carried out as follows a solution containing 10 2 grams of ZnSO<sub>4</sub>,7H<sub>2</sub>O and 10 c c of concentrated sulphuric acid per litre is standardised against pure potassium ferroevanide, 25 c c of a solution containing 10 grams of K4Fe(CN)6 3H2O per litre, mixed with 25 c c of a saturated solution of potassium sulphate, 25 c c of water, and 10 c c of 1 10 sulphuric acid, are convenient quantities Equal volumes of the standard zinc and ferrocyanide solutions are required, the precipitate formed having the composition Zn<sub>3</sub>K<sub>2</sub>(FeCy<sub>6</sub>)<sub>2</sub> (R Meurice, Ann Chim anal 1913, 18, 342) Subsequent titrations should be made as nearly as possible under the same conditions

A more accurate method is that of W Feld (Journ fur Gasbeleuchtung, 47, 565, 1903). Ferrocyanide, equivalent to 03 to 05 gram of yellow prussiate is boiled for 5 minutes with 10 c.c. of N-NaOH and 15 c.c. of 3 (molecular)  $\widetilde{N}$ -HgCl<sub>2</sub> If eyanide is present, the boiling is continued for 10 minutes and the hydrocyanic acid distilled into caustic soda and titrated with silver intrate with potassium iodide as indicator 100 c.e of boiling 0.1N-Hg(I<sub>2</sub> are now run in, and the boiling continued for 10 minutes to convert ferrocyanide into mercuiic This is then distilled with 30 cc of cvanide 3N-sulphuric acid for 20-30 minutes, and the hydrocyanic acid collected in caustic soda and The conversion of the ferrotitrated as before cyanide into mercuric cyanide is avoided by H. E Williams' procedure (J Soc Chem Ind 1912, 31, 468). After distilling off hydrocyanic acid in the way just described (lead nitrate may be used instead of magnesium chloride), 0 05-0.1 gram of pure cuprous chloride dissolved in HCl is added, and the hydrocyanic acid distilled off by I hour gentle boiling Even insoluble ferrocyanides are completely decomposed

The estimation of the valuable constituents of gasworks products (cyanide and ferrocyanide) is performed by triturating 30 to 40 grams of the material in a mortar with excess of a cold solution of caustic soda for several hours. A little ferrous sulphate may be added to convert cyanide into ferrocyanide. The filtrate is

lated spirit. Carbonyl ferrocyanide (from 2 to 5 p c. of the cyanogen is usually present in this form, but exceptionally as much as 20 pc may be present), sulphocyanide, sulphide, and excess of caustic soda remain in solution, whilst the whole of the sodium ferrocyanide is precipi-tated. The precipitate is then treated by one of the methods described above (H G. Colman, Analyst, 33, 261, 1908, and J Soc Chem. Ind. 27, 806, 1908, F. W. Skirrow, *ibid.* 29, 319, 1910)

Sulphocyanide. Ferrocyanide, if present, is first removed from the solution by adding iron alum after acidifying slightly. The filtrate is treated with acid sodium sulphite in excess and then with copper sulphate and boiled for 1 or 2 minutes. The precipitate of cuprous sulphocyanide, which may be mixed with copper sulphide, is filtered off and washed with boiling water It is then digested with excess of caustic soda which gives cuprous hydroxide and a solution of sodium sulphocyanide. This is separated by filtration, acidified with nitric acid, and titrated with silver nitiate, using a ferric salt as indicator (Linder, 43rd Alkali Report,

The small quantities of cyanogen compounds in concentrated ammonia liquor may be estimated by converting them into ferric sulphocyanide and measuring the depth of colour by means of the tintometer (P. E. Spielmann and H. Wood, J. Soc. Chem. Ind. 1919, 38, 43T, and 369T) Sulphocyanide is first estimated by acidifying the diluted sample, in the cold, with sulphuric acid, and removing ferrocyanide by means of a small excess of non alum; a large excess of non alum is added to the filtrate and the depth of colour measured Cyanide is converted into sulphocyanide by digestion at 30°-35° with ammonium polysulphide, and a second estimation made as above described. Thiocarbonate is converted into sulphocyanide by digestion at 70°-75° for 45 minutes, cyanide and ferrocyanide remaining unaffected

Alkalı metals ın commercial cyanides 1 gram of the substance is evaporated to dryness with excess of hydrochloric acid. Traces of iron and calcium are removed by re-dissolving, adding a drop of ammonium carbonate, and filtering The solution is again evaporated to dryness, and the residue is gently fused and weighed The mixture of alkaline chlorides is dissolved in water and an aliquot portion titrated with silver nitrate, using chromate as indicator If n gram of cyanide has yielded a gram of the pure mixed chlorides containing b gram of chlorine, the percentage of potassium in the cyanide is given by the formula

$$\left(\frac{2\ 431a-4\ 012b}{n}\right)$$
100

This method is sufficiently accurate for most purposes, but the gravimetric estimation of the potassium as potassium platinichloride must be resorted to if a greater degree of accuracy is T. E. required.

CYANIBIN, CYANIN v Anthocyanins CYANINE and CYANINE DYESTUFFS v. QUINOLINE COLOURING MATTERS

CYANITE v KYANITE. CYANOMACLURIN. C15H12O6, a colourless compound existing in Jakwood is closely allied to the catechins, and may possibly belong to the same group. In its general reactions, indeed, it is very similar to these compounds, but differs from them in that by alkali fusion it yields  $\beta$ -resorcylic acid and not protocatechuic acid.

A full description of the properties of this compound is given in the article on JAKWOOD,

 $\hat{\mathbf{C}}$ YANOSINE v Triphenylmethane colouring matters.

Iso-CYANURIC ACID v. FULMINURIC ACID.
CYCLOFORM. The trade name of isobutyl ester of p-amino benzoic acid

# NH2.C6H4.COOC4H9

used as a local an esthetic. A white crystalline powder, mp. 65°. Sparingly soluble in water (0 022 pc), readily soluble in alcohol and other.

CYLINDRITE. (Kylindrit, Ger) A complex sulphide ore of tin, Pb<sub>3</sub>FeSn<sub>4</sub>Sb<sub>2</sub>S<sub>14</sub>, containing, according to this formula, Sn 25 85 p.c It forms very peculiar cylindrical rolls of thin folia, the concentric shells parallel to the axis of the cylinder readily separating under pressure The smooth, bright surfaces of separation no doubt represent the cleavages of cylindrically curved crystals The colour is blackish leadgrey, with a brilliant metallic lustre. mineral marks paper, and is difficult to pulverise, in these respects resembling graphite. The ore consists of numbers of these rolls, which measure up to 3 cm in length and 1 cm in diameter, confusedly aggregated together, or sometimes with a sub-parallel grouping, the interspaces being filled with massive material It has been found in some quantity in the Santa Cruz mine, at Poopó, Bolivia. The above formula, written in the form

# 3PbSnS<sub>2</sub>+SnFeSb<sub>2</sub>S<sub>8</sub>

brings out a relation between cylindrite and the allied Bohivian minerals, teallite (PbSnS<sub>2</sub>) and franckeite (3PbSnS<sub>2</sub>+Pb<sub>2</sub>FeSb<sub>2</sub>S<sub>3</sub>) Analyses I and II by G T Prior (1904), III. by A Frenzel (1893)

CYMARIN. The physiologically active constituent of the root of Apocynum cannabinum and A and rosoemi folium, is a glucoside,  $C_{30}H_{46}O_{10}$ , colourless glistening prisms, mp  $135^{\circ}-140^{\circ}$ , which, when boiled with alcohol containing hydrochloric acid, is resolved into cymarose  $C_7H_{14}O_4$ , colourless prisms, mp  $88^{\circ}$ , a substance resembling digitoxose, of which it is probably a methyl ether, and cymarigenin  $C_{23}H_{10}O_5$ , a lactone which appears to be identical with apocynamarin (Moore, Chem. Soc Trans. 1909, 95, 734); it crystallises from aqueous methyl alcohol in rhombic tablets, mp  $171^{\circ}$  (decomp). With a solution of a diazonium salt, cymarigenin forms dyes; it reduces ammoniacal silver nitrate, forms a

benzoyl derivative  $C_{30}H_{36}O_{7,\frac{1}{2}}H_{2}O$ , pearly leaflets, m.p. 230°, and when treated with hydrogen chloride in chloroform solution, is converted into anhydro cymaragenin  $C_{23}H_{28}O_{4}$ , rosettes of crystals, m.p. 246° (decomp) (Windaus and Hermanns, Ber. 1915, 48, 979).

According to Impens (Pfluger's Archiv. 1913, 153, 239), cymarin is not a glucoside. It corresponds in activity with digitalis, being slightly more potent as a diuretic and slightly less so as a cardiac stimulant. The 'cynotoxin' of Finnemore and 'apocynamarin' are probably decomposition products of cymarine. V. Digitalis and Strophanthus.

CYMENES. Cymols. The name cymene was first applied to the hydrocarbon isolated by Gerhardt and Cahours (Ann Chim. Phys [3] 1, 102 and 372) from Roman oil of cumin, which is the ethercal oil of Cuminum cyminum. Until 1891 this hydrocarbon was wrongly called p-methylpropylbenzene, but in that year Widman (Ber 1891, 439, 970, 1632) proved it to be the isopropyl-compound (see also Filet, J. pr Chem [2] 44, 150) Frequently, however, the various benzene hydrocarbons of the formula C<sub>10</sub>H<sub>14</sub> are grouped together under the collective name of cymenes No fewer than 22 of these are theoretically possible, of which 18 have been prepared; but only the most important, namely, cymene proper (p-methylisopropylbenzene) and the tetramethylbenzenes are described here

p-Methylsopropylbenzene (Cymene)

$$^{\prime}\mathrm{CH_{3}})_{2}\mathrm{CH}\ \mathrm{C_{6}H_{4}}\ \mathrm{CH_{3}}\ (1,\ 4)$$

occurs in Roman oil of cumin (Gerhardt and Cahours, lc.; Bruhl, Ber 1892, 149; Wolpian, Chem Soc Abstr 1897, 1 357), in the volatile oil from the seeds of the water-hemlock (Cicuta virosa) (Trapp, Annalen, 108, 386); in the oil from Phychotis arowan (H. Muller, Ber 2, 130); in oil of thyme (Lallemand, Annalen, 102, 119; Labbé, Bull Soc. chim. 1898, [111.] 1009) along with thymol C<sub>10</sub>H<sub>14</sub>O and thymene C<sub>10</sub>H<sub>16</sub>, in eucalyptus oil (from Eucalyptus Globulus) (Faust and Homeyer, Ber. 7, 1429); in oil of caraway (Wolpian, Chem Soc Abstr. 1897, i 17), in bitter fennel oil (Tardy, J. Pharm. Chim. 1897, 98), in oil of lemon grass (Barbier and Bouveault, Compt. rend, 121, 1159; Stiehl, J pr Chem. 1898, 51); in oil of origanum (Gildermeister, Arch Pharm 1895, 174); in geranicl (Semmler, Ber 1891, 205); and in American petroleum (Mabery, Amer Chem. J 19, 419). Considerable quantities of crude cymene, known as sulphite turpentine, collect on the surface of the liquid in the separator used in recovering sulphur dioxide in the manufacture of wood May be obtained from camphor by pulp abstracting from it the elements of water

$$C_{10}H_{16}O = C_{10}H_{14} + H_2O$$

by heating it either with phosphorus pentoxide (Dumas, Ann. Chim Phys 50, 226; Delalande, *ibid.* [3] 1, 368) or with phosphorus pentasulphide (Pott, Ber 2, 121), or with phosphorus pentachloride (Lippmann and Lougunine, Bull Soc. chim. [2] 7, 374; *see also* Bruhl, *l.c.*; Tiemann, Ber. 1895, 1089). Various isomerides of camphor yield cymone by the same treatment. The terpones C<sub>10</sub>H<sub>16</sub> may be converted into cymone by withdrawing two atoms of hydrogen; this

CYSTINE. 477

may be effected in the case of oil of turpentine, for example, by distilling it with bromine (Oppenheim, Ber. 5, 94 and 628), or better, with iodine (Kekulé, ibid 6, 437). Old turpentine generally contains cymene (Wallach, Chem. Zentr. 1898, 1 572; Kondakow and Schindelmeier, Chem. Zeit 30, 722). It has been obtained synthetically from p-bromisopropylbenzene by means of methyl lodide and sodium (Widman, l.c.). To prepare cymene, camphor is warmed with an equal weight of phosphorus pentoxide, the cymene is poured off, treated again twice with a little phosphorus pentoxide, and finally rectified from sodium. The yield varies from 50 to 80 pc (Fittica, Annalen, 172, 307) It can also be prepared from isopropyliodide, and p-bromotoluene (Reuter, Chem Zentr 1892, 1 625, Bruhl,  $l\,c$ ) or from Liquid boiling at 177°-1775° (corr); sp gr. 0 8670 at 7.9°/4° (Perkin, Chem Soc Trans 1896, 1125; 1900, 267) With chromic acid it yields paratoluic acid (CH<sub>3</sub>  $C_6H_4$  CO<sub>2</sub>H) and terephthalic acid  $C_6H_4$ (CO<sub>2</sub>H)<sub>2</sub> (1, 4); with potassium permanganate, hydroxyssopiopylbenzoic acid (CH<sub>3</sub>)<sub>2</sub>C(OH)C<sub>6</sub>H<sub>4</sub> CO<sub>2</sub>H (1, 4) Taken internally, it appears in the urine as cumic (p-isopropylbenzoic) acid

$$(CH_3)_2CH \cdot C_6H_4 CO_2H (1, 4)$$

The preparation of cumene (q v) from propylbromide, benzene, and aluminium chloride, and that of cymene from p-bromotoluene, normal propylbromide, and sodium (Fittig, Schafer, and Konig, Annalen, 149, 331) was for a long time the cause of great confusion in ascertaining the constitution of members of the cumene and cymene groups, as it was not realised that in each case the propyl- group changed into the isopropyl- group owing to the temperature of the reaction not being regulated

Tetramethylbenzenes

Consecutive tetramethylbenzene (Prehmene)  $C_6H_2(CH_3)_4$  (1, 2, 3, 4) When sodium durene-sulphonate

 $C_6H(CH_3)_4SO_3Na(CH_3$ -groups 1, 2, 4, 5, v infia) is dissolved in concentrated sulphuric acid and allowed to stand for 12 hours, prehnitenesulphonic acid is formed. The mixture is diluted with water, saturated with barium carbonate, the barrum salts converted into sodium salts, and these, by treatment with phosphorus pentachloride and ammonia, transformed first into sulphonic chlorides and then into sulphon-Prehnitenesulphonamide is separated amides by means of its sparing solubility in alcohol, and is then hydrolysed by heating with concentrated hydrochloric acid to 170°, when it yields prehiitene (Jacobsen, Ber 19, 1213; see also V. Meyer and Molz, Ber. 1897, 30, 1278). Also obtained by heating bromocumene

 $C_6H_2Br(CH_3)_3(CH_3,Br,CH_3,CH_3:1,2,3,4)$ with methyl iodide, benzene, and sodium, in a sealed tube at  $150^{\circ}$  for 12 hours —Liquid boiling at 204° (corr); solidifies in a freezing mixture, and melts at -4° Dilute nitric acid oxidises it to prehnitylic acid C<sub>6</sub>H<sub>2</sub>(CH<sub>3</sub>)<sub>3</sub>CO<sub>2</sub>H.

2. Unsymmetrical testamethylbenzene (Isodurene) C<sub>6</sub>H<sub>2</sub>(CH<sub>3</sub>)<sub>4</sub> (1, 2, 3, 5). From bromomesitylene (v Cumenes), methyl 10dide and

sodium in presence of benzene (Jannasch, Ber. 8, 356). Best by passing methyl chloride into a mixture of mesitylene and aluminium chloride.

$$\substack{ \text{C}_{\pmb{6}}\text{H}_{\pmb{3}}(\text{CH}_{\pmb{3}})_{\pmb{3}} + \text{CH}_{\pmb{3}}\text{Cl} = \text{C}_{\pmb{6}}\text{H}_{\pmb{2}}(\text{CH}_{\pmb{3}})_{\pmb{4}} + \text{HCl} \\ (1, \, 2, \, 3, \, 5) }$$

(Jacobsen, Ber 14, 2629) -Liquid boiling at  $195^{\circ}$ – $197^{\circ}$ , solidifies in a freezing mixture. With dilute nitric acid it yields  $\alpha$ -isodurylic acid,  $\beta$ -isodurylic acid, and mesitylenecarboxylic acid, isomeric acids of the formula

and dimethylisophthalic and dimethylterephthalic acids, isomeric acids of the formula C<sub>6</sub>H<sub>2</sub>(CH<sub>3</sub>)<sub>2</sub>(CO<sub>2</sub>H)<sub>2</sub> (Jannasch and Weiler, Ber. 1894, 3441, 1895, 531), potassium permanganate ultimately converts it into mellophanic acid

C<sub>6</sub>H<sub>2</sub>(CO<sub>2</sub>H)<sub>4</sub> (1, 2, 3, 5) Symmetrical tetramethylbenzene (Durene) C<sub>6</sub>H<sub>2</sub>(CH<sub>3</sub>)<sub>4</sub> (1, 2, 4, 5) (Schulze, Ber 18, 3032) Occurs in coal tar By the action of sodium on a mixture of bromopseudocumene  $(^1_6H_2(\mathrm{CH}_3)_3\mathrm{Bi}$  (1, 2, 4, 5), methyl iodide and sodium (Jannasch and Fittig, Zeitsch Chem 1870, 161) From toluene and methyl chloride in presence of aluminium chloride (Friedel and Crafts, Ann Chim Phys [6] 1, 461) o- or p-xylene, methyl chloride and aluminum chloride (Jacobsen, Ber 14, 2629) From pseudocumene, methyl iodide, and aluminium chloride (Rugheimer and Hankel, ibid 1896, 2173) - Crystalline mass, smelling like camphor, melte at 79°-80°, and boils at 189°-191° (Jacob-Yields by oxidation with potassium permanganate, finally pyromellitic acid

 $C_8H_9(CO_3H)_4$  (1, 2, 4, 5)

CYMOLS v CYMENES.

CYMOPHENOL v CAMPHORS CYPRIAN VITRIOL. Copper sulphate (v.

COPPER'

CYPRIDOL. Trade name for a suspension of mercuric iodide in sterilised oil.

CYRTOLITE v ZIRCON

CYSTAMINE, CYSTOGEN. Syns for hexamethylenetetramine

CYSTAZOL. An additive compound of hexamethylenetetramine and sodium benzoate. Used as a urmary antiseptic

CYSTINE, B-disulphido-a-aminopropionic acid HO<sub>2</sub>C CH(NH<sub>2</sub>)·CH<sub>2</sub> S S·CH<sub>2</sub> CH(NH<sub>2</sub>) CO<sub>2</sub>H first discovered by Wollaston in a urmary calculus (Phil. Trans 1810, 223), is a product of proteid metabolism under certain pathological conditions (Blum, Beitr chem Physiol Path. 1903, 5, 1, Wolf and Shaffer, Amer J Physiol. 19, Loebisch, Annalen, 182, 231, Niemann, *ibid* 187, 101; Thiele, Trans Path Soc 1907, 788, 255), which, according to Abderhalden (Zeitsch. physiol. Chem. 1903, 38, 557), are hereditary. Dreschel found cystine as a normal product of metabolism in the liver of horse (Arch. Anat Physiol 1891, 243) and porpoise (Zeit Biol 1896, 33, 85) It was found by Kulz (*ibid.* 1890, 27, 415) among the soluble products of an artificial pancreatic digestion of fibrin; and is a constant product of hydrolysis of keratın (Mörner, Zeitsch physiol. Chem. 1899, 28, 595): Buchtala (*ibid*. 1907, 52, 474) obtained the following percentages of cystine from the materials mentioned: human hair, 13-14.5; human nails, 5.15; horsehair, 7.98;

478 CYSTINE.

horse's hoofs, 3 20, ox hair, 7 27, hoofs of oxen, 5 37; pigs' bristles, 7 22; pigs' hoofs, 2 17
According to Folin (J. Biol. Chem. 1910, 8,

According to Folm (J Biol Chem 1910, 8, 9), cystine is most readily prepared from wool by boiling it in a reflux apparatus for 5-6 hours with twice its weight of stiong hydrochloric acid, or until it ceases to give the biuret reaction, on removing the free hydrochloric acid by the addition of solid sodium acctate, a dark heavy precipitate of cystine is obtained, this is purified by decolourising a solution in 3-5 pc hydrochloric acid with bone-black, and precipitating the cystine in the hot filtrate by hot concentrated sodium acctate solution (see also Denis, J Biol Chem 1911, 9, 305)

The cystine of urinary calculus is identical with that obtained from protein hydrolysis (Rothera, J. Physiol. 1905, 32, 175., Alsberg and Folin, Amer. J. Physiol. 1905, 14, 54; Fischer and Suzuki, Zeitsch. physiol. Chem. 1905, 45, 405), and was proved to be \$\beta\delta\subsymbol{u}\text{bulletholo-a-amino-propionic acid.}\$ by Friedmann (Bett. Chem. Popular Cystine from ethyl monobenzovlserine, obtained by reducing ethyl monobenzovlserine, obtained by reducing ethyl formylhippurate, the product of the condensation of ethyl formate and ethyl hippurate. On heating othyl monobenzoylserine with phosphorus pentasulphide, and hydrolysing the product, cystein is obtained and this is readily converted into cystine by oxidation with air in an ammoniacal solution:

H CO₂Et+NHBz CH₂ CO₂Et →CHO CH(NHBz) CO,Et

→OH CH, CH(NHBz)CO,Et →SH CH, CH(NHBz) CO,Et

 $\rightarrow$ SH CH<sub>2</sub> CH(NH<sub>2</sub>) CO<sub>2</sub>H  $\rightarrow$ CO<sub>2</sub>H CH(NH<sub>2</sub>) CH<sub>2</sub>S S CH<sub>2</sub> CH(NH<sub>2</sub>) CO<sub>2</sub>H

(Erlenmeyer, Ber 1903, 36, 2720) Fischer and Raske (ibid 1908, 41, 893) also obtained incystine from dl-α-amino-β-chloropropionic acid hydrochloride by heating it with barium hydrosulphide at 100° in sealed tubes, and oxidising the product by atmospheric oxygen in the presence of ammonia From the natural leserine the authors obtained, by a similar process, an optically active cystine which is identical with the l-cystine obtained from natural sources. Removal of sulphur by ammonium copper solution gives dl-α-aminopropionic acid, and removal of sulphur by zine dl-alanine (Mauthner, Zeitsch physiol Chem. 1912, 78, 30–32)

For the importance of cystine in nitrogen metabolism, see Abderhalden (Zeitsch physiol Chem 96, 1-147, Ber 1916, 49, 2449-2473), and in humin formation, Roxas (J. Biol. Chem.

1916, 27, 71-93)

Cystine crystallises in thin colourless hexagonal plates; it has no melting point, but decomposes slowly at  $258^{\circ}-261^{\circ}$  (Nouberg and Mayer, Zeitsch physiol Chem 1905, 44, 472) It is sparingly soluble in water, insoluble in alcohol or acetic acid, soluble in acids or alkalis. The heat of combustion at constant pressure is 4 137 calories (Emery and Benedict, Amer J Physiol 28, 301–307). The cystine molecule contains two asymmetric carbon atoms, and lavo-cystine, the naturally occurring variety, has  $[a]_{D}-97$  5° in ammonia,  $-223^{\circ}$  in hydrochloric acid solution (Gaskell, J. Physiol. 1907, 36, 142), or  $-205\cdot28^{\circ}$ 

in a hydrochloric acid solution containing 112 grams hydrochloric acid in 100 cm (Mauthner, ibid 29) l-Cystine is converted to the extent of 50 p c into r-cystine by heating with excess of hydrochloric acid of sp.gr. 1124, at 165° for 12–15 hours, this decomposes at the same temperature as the active isomeride is three times as soluble in water and can be resolved into the active components by the action of Aspergillus niger; the l-compound being consumed

Cystine is readily reduced to cystein (a aminoβ-thiolpropionic acid) HS CII, CH(NH.) CO<sub>2</sub>H (Baumann, Zeitsch physiol. Chem. 1882, 8, 300, Mauthner, Zeit Biol 1901, 42, 176), which can be converted by the action of bromine water into cysteic acid (a-amino-B-sulphopro-pionic acid) HO<sub>3</sub>S CH<sub>2</sub> CH(NH<sub>2</sub>) CO<sub>2</sub>H, and from this, by loss of carbon dioxide, taurine NH2 CH2 CH2 SO3 II is obtained (Friedmann, Chem Physiol Path 1902, 2, 433). According to Von Bergmann (ibid 1903, 4, 92), the normal taurine in the bile originates from the cystin groups contained in the ingested protein Cystem yields cystine on oxidation the change occurring spontaneously in alkaline solution, although the rate is increased by the addition of a mixture of ferric chloride and potassium cyanide (Mathews and Walker, J. Biol Chem 1909, 6, 289) For the behaviour of cystine on oxidation, see Dems (J. Biol Chem. 1911, 9, 373), and for its breakdown under the action of certain bacteria, see Burger (Arch Hyg 1914, 82, 201-211, from the abstr. Amer. Chem Soc 1916, 10, 2911)

Slyke's reaction (Ber 1910, 43 3170) for  $\alpha$ -amino acids does not give absolutely quanti-

tative results in the case of cystine

Cystine and tyrosine can be quantitatively separated by means of absolute alcohol saturated with hydrogen chloride (Plimmer, Bio-Chem J. 1913, 7, 311-317).

When cystine is given with food, it is completely oxidised to sulphate and excreted as such (Rothera, J. Physiol 1905, 32, 175). Baumann and Preusse (Zeitsch physiol Chem. 1881, 5, 309, Ber 18, 258) found that when bromobenzene was administered to animals it was excreted as bromophenyleystein.

a compound crystallising in glittering needles or plates , m p  $180^{\circ}-182^{\circ}$ , and yielding a blue crystalline copper salt (C<sub>9</sub>H<sub>9</sub>BiSNO<sub>2</sub>)<sub>2</sub>Cu

Derivatives.—Cystine forms sparingly soluble salts with copper,  $C_6H_{10}O_4N_2S_2Cu$ , or mercury

$$\begin{array}{c} {\rm C_6H_8O_4N_2S_2Hg_2,HgCl_2}\,;\\ {\rm 2C_6H_{10}O_4N_2S_2Hg,HgCl_2,7H_2O}\,;\\ {\rm 2C_6H_8O_4N_2S_2Hg_2,Hg(NO_3)_2} \end{array}$$

With 30 p c nitric or hydrochloric acid (at room temperature) it yields compounds

$$\rm C_6H_{12}O_4N_2S_2$$
 2HNO3 and  $\rm C_6H_{12}O_4N_2S_2{\cdot}2HCl$ 

(Morner, Zeitsch physiol Chem. 1914, 93, 203-208) Benzoylcystine  $C_6H_{10}O_4N_2S_2Bz_2$ , m.p.  $156^\circ-158^\circ$ , crystallises in needles and forms a sparingly soluble sodium salt (Goldmann and Baumann, Zeitsch. physiol. Chem. 1888, 12, 254). Cystinephenylhydantoin is a well-defined

crystalline compound, and is used for identifying cystine. Cystine ethyl ester hydrochloride

S<sub>2</sub>[CH<sub>2</sub>·CH(NH<sub>2</sub>) CO<sub>2</sub>Et]<sub>2</sub>,3HCl

forms colourless needles, mp 185°, with decomposition (Friedmann, Beitr. Chem Physiol Path. 1902, 3, 1) Numerous acyl-derivatives of cystine have been described by Fischer and Suzuki (Zeitsch physiol Chem 1905, 45, 405; Fischer and Gerngross, Ber 1909, 42, 1485; Abdeihalden and Wybert, Ber 1910, 2449-2473) Of these dr-l-leucyl-l-cystine S<sub>2</sub>[CH<sub>2</sub> CH(CO<sub>2</sub>H)NH CO (CH(NH<sub>2</sub>)(<sup>2</sup>4H<sub>0</sub>] is a granular powder, turns yellow at 200°, and decomposes at a higher temperature, has  $\left[\alpha\right]_{D}^{20}$  -136 6°, or, when obtained in a crystalline

form, has  $[a]_D^{20}$ -111 4°, it gives a reddish-violet colour with copper sulphate, is precipitated by ammonium sulphate, and may be termed M A W

CYSTOGEN. Syn for hexamethylenetetramine

CYSTOPURIN. A compound of sodium acetate and hexamethylenetetramine

**CYTISINE**  $C_{11}H_{11}ON_2$ , prisms, m.p. 153°, b.p.  $218^{\circ}/2$  mm,  $[\alpha]_D^{17^2} - 120^{\circ}$ , readily soluble in water, alcohol, or chloroform, insoluble in ether and petroleum, is a diacid base forming well-crystalline salts It is found in the seeds of Cytisus laburnum, Ulese curopaus, Baptisia spp, Sophora spp, Genisla spp, and Anagyris fætida in amounts varying from 1 to 2 pc

Cytisine is a secondary-tertiary base Electrolytic reductions gives a base, tetrahydro deoxycytisine  $({}^{\circ}_{11}H_{18}N_2)$ . Hydrodic acid and phosphorus at 230° yields cytisoline  $({}^{\circ}_{11}H_{11}ON, \beta$ -cytisolidine  $({}^{\circ}_{11}H_{11}N)$  (this on reduction giving a cytisolidine  $({}^{\circ}_{11}H_{11}N)$ ), hydrocarbons, and ammonia The constitutions of  $\alpha$ - and  $\beta$ cytisolidines have been established by synthesis (Ewins, Chem Soc Trans 1913, 103, 97) B-Cytisolidine is 6 · 8-dimethyl quinoline, αcytisolidine the corresponding tetrahydro quino-Cytisoline, which on distillation with zinc-dust gives \(\beta\)-cytisolidine, is 2-hydiexy-6 8-dimethyl quinoline and has I cen synthesised 244, 20)

by Spath. On these grounds it has been suggested that cytisine is constituted by the fusion of three rings.

The following constitution is considered the most probable of the fourteen possibilities -

Cytisine is a violent poison. Cases of infantile poisoning from eating laburnum seeds are by no means infrequent Dale and Laidlaw (J Pharm Expt Therap 1912, 3, 502) have shown that the physiological action of this alkaloid is qualitatively and almost quantitatively indistinguishable from that of nicotine See Spath, Monatsh 1919, 40, 15, 93, Partheil, Ber 1890, 23, 3201, 1891, 24, 634; Freund and Friedmann, A 1901, 1 288, Freund, A 1904, 1. 263, Freund and Horkheimer, A 1906, 1 302, Freund and Gauff, Arch Pharm 1918, 256, 33

Methylcytisine  $C_{12}H_{16}ON_2$ , prismatic needles, m p 137°,  $\lfloor \alpha \rfloor_D - 221$ 6°, readily soluble in water and organic solvents, occurs in Caulophyllum thalictioides (Linn) (Power and Salway, Chem. Soc Trans 1913, 103, 191), it may also be obtained by methylating cytisine. The salts are crystalline

The physiological action of the base is similar to that of cytisine (q v), but the alkaloid is less potent

Caulophylline (Lloyd, Proc Amer Pharm.

Assoc 1893, 41, 115) is methyl cytisine

Anagyrine C15H22ON2 (1), amorphous, occurring along with cytisine in the seeds of Anagyris fortida, is possibly butyl cytisine (Klestermann, Diss Marburg, 1898, Chem Zentr 1899, 1 1130; Partheil and Spasski, Apoth Zeit 1805, 10, 903, Goessmann, Arch Pharm 1906, AJE

occurs in the seeds of Nigella damascena (Linn.) (Schneider, Pharm. Centrb 1890, 31, 173) and N. arıstata (Keller, Arch Pharm. 1908, 246, 1). Its constitution was established by synthesis (Ewins, Chem. Soc. Trans. 1912, 101, 544), and shown to be methyl-2-methylamino 3-methoxy benzoate ·

Keller's 'methyl damascenine' is identical with damascenine and 'damascenine acid' C<sub>9</sub>H<sub>11</sub>O<sub>3</sub>N, said by Pommerchne (Arch. Pharm. 1900, 238, 531) to be isomeric with damascenine, is obtained on hydrolysis of the alkaloid. Damascenine is mildly narcotic. A. J E.

DAMMAR RESIN, DAMMARYL, DAM-MARYLIC ACID v. RESINS.

DANAITE v. MISPICKEL.

**DANALITE.** A rare sulpho-silicate mineral, with the formula  $3R_2\mathrm{SiO_4}$  RS, where R represents Fe, Zn, Be, Mn, containing BeO about 14 pc. The flesh-red or grey cubic crystals are octahedral or tetrahedral in habit; sp gr 3.35-3.43; H.= $5\frac{1}{2}-6$  It occurs in granite at Rockport and Gloucester, in Massachusetts, and large crystals have been found in Connwall Closely allied is the tetrahedral-cubic mineral helvite, which contains about the same amount of beryllium, but with a preponderance of manganese and no zinc L J. S.

DANDELION ROOT. Taraxacı radıx, B.P; Taraxacum, USP. (Pissenlit, Fr.; Lowenzuhnwurzel, Ger) The root of the common dandelion, Taraxacum officinale (Weber) (Bentla Trim 159), is used in medicine for its mild laxative and tonic properties. It is administered either in the form of expressed juice or weak spirituous extract. The roots employed should

be collected in the autumn

The latex contains two crystalline bitter principles, laraxaxin and laraxacerin (Polex, Arch Phaim. 19, 50, Kiomayer, ibid. 105, 6). The root further contains inulin, 24 pc in October, according to Dragendorff (Sachsse's Farbstoffe, 125), but only 1.7 p.c in Maich, when, however, 17 pc of uncrystallisable sugar and 19 pc of levulin is present. The latter carbohydrate is soluble in cold water to a sweet solution, without any action on polarised light.

The leaves and stalks, but not the root of the dandelion, contain inosite (Marmé, Annalen, 129, 222)

G B

**DAPHNETIN.** Daphnetin is present in the form of its glucoside daphnin in the bark of the Daphne alpina (Linn) and D mezereum (Linn)

The concentrated alcoholic extract is digested with boiling water, filtered, and treated with lead acetate solution. The precipitate is removed, basic lead acetate added to the filtrate, the lead compound of the glucoside decomposed with sulphuretted hydrogen, and the solution evaporated (Zwenger, Annalen, 115, 8).

Daphnin  $C_{15}H_{16}O_{9},2H_{2}O$  crystallises in prisms, melting at 200°, and dissolves in alkaline solutions with a yellow colour. It is hydrolysed by boiling dilute acids with formation of daph-

netin and glucose.

C<sub>16</sub>H<sub>16</sub>O<sub>9</sub>+H<sub>2</sub>O=C<sub>0</sub>H<sub>6</sub>O<sub>4</sub>+C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>
Daphnetin C<sub>9</sub>H<sub>6</sub>O<sub>4</sub> forms pale yellow needles, is soluble in alkalis with a yellow colour, and gives a yellow precipitate with lead acetate solution. On acetylation, a diacetyl-derivative C<sub>9</sub>H<sub>4</sub>O<sub>4</sub>(C<sub>2</sub>H<sub>3</sub>O)<sub>2</sub> is obtained, and by means of ethyl iodide a diethyl ether C<sub>9</sub>H<sub>4</sub>O<sub>2</sub>(OEt)<sub>2</sub> is produced. When daphnetin diethyl ether is boiled with caustic soda solution, the diethyl other of daphnetinic acid

$${\rm (OEt)_2C_6H_2} \begin{array}{c} OH \\ CH = CH COOH \end{array}$$

is produced in the form of its sodium salt, which when ethylated gives the *triethyl* derivative:

By oxidising daphnetic acid triethyl ether triethoxybenzaldehyde is formed, which is readily converted into triethoxybenzoic acid. The

silver salt of this acid, when destructively distilled, gives pyrogallol triethyl other. Daphnetin is accordingly a dihydroxycoumarin, and has the following constitution:—

(Will and Yung, Ber 1884, 17, 1081).

It has been synthetically prepared by heating pyrogallol with malic acid in the presence of sulphuric acid (Pechmann, Ber 17, 933):

 $C_4H_6O_5+C_6H_3(OH)_3=C_9H_6O_4+CO_2+2H_2O+H_2$  and by the condensation of pyrogalic aldehyde with sodium acetate (Gattermann and Koebner, Ber 1899, 32, 287):

C<sub>6</sub>H<sub>2</sub>(OH)<sub>3</sub> CHO+CH<sub>3</sub> COOH=C<sub>9</sub>H<sub>6</sub>O<sub>4</sub>+2H<sub>2</sub>O
Daphnetin is a yellow colouring matter, and
gives with mordanted woollen cloth the following
shades .—

DATE. The fruit of the date palm, Phænix dactylifera A palm of the tropics of Africa and the East Indies It furnishes food to a large population in Egypt and Arabia

The fruit grows in bunches of from 15 to 20 lbs weight, and a tree usually produces about 20 bunches annually. The date palm also yields a sweet sap, which flows, when incisions are made in the trunk, almost continuously from November to March, the sap is clarified and boiled down, when a brown sugar, known as jaggery, is obtained (Bied Zenti 1884, 284).

Analyses of the flesh of dates give .

Dried dates, according to Konig, have the mean composition.

Water Protein Fat Sugar acid hydrates Fibre Ash 185 19 06 672 13 43 38 18

Among the 'soluble carbohydrates' is included about 3 p c of pentosans, while the date stone contains about 2.7 p c. of the same substances (Wittmann, Zeitsch landw Versuchs. Oesterreich 1901, 4, 131)

König gives, as the composition of the date stone:

Water Protein Fat free extract Fibre Ash 7.7 5 2 9 0 53 0 24 0 1.1

7.7 52 90 530 240 1.1

Dates are sometimes used as coffee substitutes, the whole fruit being occasionally employed, but more usually the stones only.

König gives as the composition of 'date-coffee':

Water Protein Fat Sugar hydrates Fibre Ash 6 6 5 5 7.9 2 2, 48.7 278 1.3 yielding about 14 p.c. of its weight to water H I.

#### DATHOLITE v DATOLITE.

DATISCA CANNABINA (Linn). This is a tall, erect herb, resembling hemp, belonging to the Datisceæ, and met with in the temperate and sub-tropical Western Himalayas from Kashmir to Nepal The root, known as Akalbir, has been extensively used in Kashmir and throughout the Himalayas as a yellow dyestuff chiefly on alum-mordanted silk; but the colouring matter appears to be present in the whole plant, for the leaves and twigs can also be employed for the same purpose

The leaves of the Datisca cannabina were first examined by Braconnot (Ann. Chim Phys [2] iii 277), who isolated from them a crystalline substance which he named datiscin. Somewhat later it was shown by Stenhouse (Annalen, 1856, 98, 167) that this compound is a glucoside, and when hydrolysed is converted into a sugar, together with a yellow colouring matter, datis-

cetin C15H10O6

Schunck and Marchlewski (Annalen, 278, 261), however, considered that the formula C<sub>15</sub>H<sub>12</sub>O<sub>6</sub> was preferable, and showed that, on fusion with alkali, datiscetin gives salicylic acid By the action of dilute nitric acid, a nitrosalicylic acid was produced, whereas with strong nitric acid, pieric acid, as already indicated by Stenhouse, was formed Datiscetin appeared to contain methoxyl groups, and was at that time considered by the authors to be most probably a xanthone derivative

Korczynski and Marchlewski (Ann. d. Akad Krakau, 1906, 95) have shown that pure datiscetin  $C_{15}H_{10}O_6$ , however, does not contain methoxy-groups It consists of yellow needles, methoxy-groups It consists of yellow needles, mp 268°-269°, soluble in alkaline solutions, with a yellow colour, and gives, with sulphuric acid, a yellow liquid possessing a green fluorescence When boiled with strong alkaline solutions, phenol and salicylic acid are produced

Tetraacetyldatiscetin C15H6O6(C2H3O)4 forms colourless needles, and melts at 138°, and

tetrahenzon/klatiscetin C<sub>15</sub>H<sub>6</sub>O<sub>6</sub>(C<sub>7</sub>H<sub>5</sub>O)<sub>4</sub> gives colourless needles, mp 190°–191°.

Leskiewicz and Marchlewski (Ber 1914, 47, 1599) by the action of bromine on datiscetin in boiling acetic acid solution obtained tribromphloroglucinol, and as a result suggest that this colouring matter is the 1 3 1'-trihydroxyflavonol -

A substance indeed of this constitution in the form of its trimethyl ether has been synthesised by Bargellini and Peratoner (Gazetta, 1919, 49, 64) by the usual methods of flavonol synthesis Thus 2 hydroxy 4:6-dimethoxy phenyl methyl ketone (phloracetophenone dimethyl ether) condensed with salicylic aldehyde methyl ether yields 2 hydroxy 4:6:2' trimethoxy phenyl styryl ketone I :-

I. MeO 
$$\stackrel{\mathrm{OH}}{\longrightarrow}$$
 CO—CH : CH— $\stackrel{\mathrm{OMe}}{\longrightarrow}$  Vol. 11.— $T$ .

which by means of dilute alcoholic hydrochloric acid gives 5 7:2' trimethoxy flavanone II :-

The iso-nitroso derivative of this latter when heated with hydrochloric acid in acetic acid solution gives the trimethoxy flavanone

crystallising in pale yellow needles, mp 158°-160°, and giving with sulphuric acid an intensely green fluorescent solution. This is probably a trimethyl ether of datiscetin

Datiscin  $C_{21}H_{24}O_{11}$  (S and M), the glucoside crystallises in silky needles, which melt at about 190°, and dissolve in alkaline solutions with a yellow colour Hydrolysis with dilute sulphuric acid yields datiscetin and rhamnose, not datiscetin and glucose, as stated by Stenhouse (lc)

The dyeing properties of datisca root on wool are very similar to those of old fustic. It is, however, slightly inferior in dyeing power, On cotton it dyes more like quercitron bark, in so far that the olives obtained on iron mordant are bluer in shade, as though some tannin matter It appears to have about the were present same colouring power as quercition bark, but gives a brighter yellow with aluminium mordant Applied to wool, it differs from querestron bark by giving with chromium mordant an oliveyellow which is not of such a reddish tinge, and with tin mordant a bright yellow instead of an orange It is an excellent dyestuff, and worthy to rank with the natural yellow mordant colouring matters at present in use (Hummel and Perkin, J Soc Chem Ind 1895, 14, 458) A G. P.

DATISCIN v Datisca Cannabina. DATISCETIN v DATISCA CANNABINA

**DATOLITE.** A native boro-silicate of caleium HCaBSiO<sub>5</sub>, containing B<sub>2</sub>O<sub>3</sub> 218 p.c. Monochnic crystals, with a profusion of small brilliant faces, many with five-sided outlines, are of common occurrence; these are usually transparent and colourless, or with a faint greenish tinge, sp gr 30. The mineral most greenish tinge, spgr 30 often occurs associated with zeolites in the amygdaloidal cavities of basaltic rocks, e g in the neighbourhood of Edinburgh and Glasgow, and at Bergen Hill and West Paterson in New It, however, presents several other Jersey modes of occurrence, viz in granite at Baveno in Piedmont, in diorite at Rosskopf in Baden; in gabbro with copper ores at Monte Catini in Tuscany; in 'limurite' (an axinite-pyroxenite) at Dundas in Tasmania; in serpentine in the Lizard district in Cornwall, in calcite veins in sandstone at Sonthofen in Bavaria; in veins of silver ore at Andreasberg in the Harz Mountains; in the Lake Superior copper mines (here in a compact, opaque, white form resembling unglazed porcelain); in beds of magnetite in gness at Arendal in Norway L. DECHENITE v VANADIUM

DECOIC ACID, CAPRIC ACID v. DECATOIC

DECOLOURISING CARBONS. This term has been applied to nearly pure forms of carbon, possessing remarkable decolourising powers, and manufactured only within the last ten In this article it will be convenient to groups these special carbons separately from those which have been employed as decolorants for over a century

# (a) Vegetable Charcoals

The decoloursing property of wood charcoal was first observed by Lowitz in 1791, and was used for treating beet-syrup An improved charcoal, produced by washing and grinding, was patented by Louis Constant in 1812, and employed in the refining of sugar. Wood charcoal is manufactured by burning wood in special ovens, or in heaps, air being excluded Oven charcoal has the composition: carbon, 81 p c, hydrogen, 4 p c; oxygen and mineral matters, 15 p c Charcoal burnt in heaps has the composition carbon, 90 pc; hydrogen, 2:5 pc, oxygen and mineral matters, 75 p.c. Klasen and Bergh (Chem. Zeit 1910) state that the oven-charcoal absorbs 15 pc. by weight of oxygen at 100° C. The decolourising power of most vegetable charcoals is very slight, but superior qualities are obtained from cherry stones, cocoanut, and certain grasses wood be treated with certain chemicals before being carbonised, the resulting charcoal is a very efficient decolorant (see group (c) below)

# (b) Animal Charcoals.

In 1811, Figurer proved that bone charcoal was a far more effective decolorant than wood In 1815, Messrs P and J Martineau charcoal patented the use of bone charcoal for refining and clarifying sugar solutions In 1817, De Cavaillon patented the calcining of bone charcoal after it has been used as a decolorant, rendering it 'superior to new charcoal, and the operation may be repeated any number of times with equal effect' Up to the year 1828, bone charcoal was used in the form of fine powder, mixed with the liquid to be decolourised, and, finally, separated therefrom by filtration Payen, in 1828, introduced an important improvement, the 'bone-char' being produced in a granular form, permitting the syrup (or other liquid) to be filtered through the bone-char in 'char cisterns' or 'char filters,' first designed by Dumont. The granular charcoal acted as efficiently as the powder, and avoided the tioublesome filtration to separate the powder from the liquid. The granular form was also more suitable for burning in order to restore its activity after it becomes charged with organic impurities absorbed from the liquid under treatment Dumont's 'char filter' was of the open type, operating by gravity. The modern vessels are closed, and operate under pressure, and the same liquid may pass through two or even three filters, if necessary

Formerly, bone-char was employed for decolourising both beet and cane juices, in order to produce white sugar direct from the plant. Less costly methods of purifying these juices have led to the abandonment of bone-char in the raw sugar factory, and its application in the refinery

Manufacture of Animal Charcoal The bones employed should be carefully selected, hard, and free from extraneous matter Whale and fish bones are not of a suitable character, as they yield a soft char Bones which have been exposed to atmospheric action for a long time, or which have been buried in the ground, cannot be successfully employed, as, owing to the alteration in their composition, they produce a char deficient in carbon

Before proceeding to carbonise the bones, the fat is removed by boiling, or by means of a suitable solvent such as benzene By the first-named treatment from 4 to 5 p c of fat is extracted, and by the second from 8 to 12 p c

The crushed bones are carbonised in apparatus similar to that used in a gasworks, in vertical or horizontal iron retorts of a round, oval, or D section, the latter by preference The length of the horizontal retort is usually from 8 to 10 feet, the long diameter being 18 inches and the short diameter of the oval retort 12 inches There are usually five or seven retorts in each The retorts are connected in the same way as gas retorts, with a hydraulic main, and this again with condensers or scrubbers filled with coke, in which the bone oil separates, and from which the gases are exhausted The gases are then forced through a series of washers containing water to remove the ammonia, the residual gases, which are employed for heating and lighting purposes, finally passing into a gasholder Charges of about 2½ cwt of bones are carbonised in vertical, and 5 cwt in horizontal retorts, the operation taking about 6 to 8 hours with the former, and 8 to 10 hours with the latter The bone oil, collected in the condenser, amounts to from 3 to 5 p c on the bones carbonised, and the ammonia in the ammoniacal liquor is equal to about 8 pc of ammonium sulphate, into which it is converted in the usual way the bones are completely carbonised, the charcoal is removed from the retorts and cooled in strong sheet-iron canisters, which are at once covered with closely fitting lids and luted round the edges, either with charcoal paste, or a water The char, when quite cold, is crushed in a suitable mill (any iron it may contain being removed by passing over the poles of an electromagnet), and then sifted into various sizes to suit the requirements of the sugar-refiner is usually moistened before guinding, to keep down the dust Good bones yield about 65 p c of char, but from 20 to 30 pc of this is dust, which fetches a lower price than the larger grist

The following is the approximate composition of a good sample of new bone charcoal

Carbon		10 51
Calcium and magnesium pho	s-	
phates, calcium fluoride, &c		81 21

40 to 50	,,	• ,,	,,		11
Through 50	,,	,,	or	dust	2

New charcoal of good quality should, in the dry state, contain not less than 9 and not more than 11.5~p~c of carbon The silica should not exceed 0.5~p~c, the oxide of iron 0.15~p.c, the calcium sulphate 0.2 p.c., and the moisture Its weight should not exceed 52 lbs per cubic foot It should be of a dull black colour, and, when incinerated, leave an ash of a uniform white or cream colour, the presence of grey or reddish particles indicates that the sample has been mixed with old charcoal When brought in contact with the tongue, it should adhere to it somewhat strongly The size of grain depends upon the use to which it is to be applied grain charcoal is preferable for strong liquors, such as that used for washing loaf sugar Refiners, as a rule, prefer small grain, if, however, it be very small, it impedes the passage of liquor and also gives considerable trouble in washing (har may be used over and over again, and sometimes lasts several years, being revivified from time to time by reburning in special kilns (see Sugar) When, by continued use, it has lost its power of removing colour, it is known as spent char, and is then used as a manure, generally after treatment with sulphuric acid, so as to form superphosphate of lime

The carbon always contains a certain proportion of nitrogen, amounting to about onetenth of its weight, also a minute proportion The nitrogen present decreases of hydrogen whilst the bone charcoal is being used for sugarrefining

When char is repeatedly reburned, it becomes less porous and shrinks in volume, so that a ton, which measures 48 to 54 cubic feet when new, may be reduced to 28 cubic feet after being reburned many times, in other words, its apparent density may be nearly doubled

Wallace has, however, shown that the real sp gr varies but little, thus, a new char, occupying 50 6 cubic feet per ton, or having an apparent sp gr of 071, has a real sp gr of 2 822, whilst a moderately old sample, occupying 35 cubic feet per ton, or having an apparent sp gr of 1 03, has a real sp gr of 2 857, or only a trifle over that of the new.

Another proof that char loses its porosity by long-continued use and reburning, is afforded by the fact, pointed out by Wallace, that dry new char will absorb from 80 to 100 pc of its weight of water, whereas old char will only retain

from 30 to 45 p c

Properties —Although the decolourising property is the most important, bone-char absorbs other organic and mineral substances from their Tilhot was the first to prove that the absorption of organic matter increases with the temperature, and Kohlrausch first demonstrated that the absorbed colouing matters remain chemically unchanged, and can be extracted from the charcoal by washing it with ammonia, in which the colouring matters dis-It was proved by Graham that various mineral substances are removed from solution by animal charcoal, thus the lime is taken up from lime water, and metallic salts are absorbed from their solutions in water. According to Chevallier, lead nitrate and acetate are completely removed by animal charcoal. Weppen has shown that this action extends to a great variety of metallic salts, including cupric, zinc, chromic and ferrous sulphates, nickel, cobalt, silver, mercurous and mercuric nitrates, tartar ometic, stannous chloride, and ferric acctate

As the result of a number of experiments on the absorption of different salts by animal charcoal, Bodenbender arrived at the following conclusions

1 The power of absorbing salts is a physical

- 2 A given weight absorbs a larger proportion of salts from a concentrated than from a diluted solution, on the other hand, the proportion absorbed from a constant quantity of salts is more considerable when this quantity is in a dilute, than when it is in a concentrated, solution.
  - 3 The presence of sugar has only a slight

influence on the absorption of salts

4 The salts of potassium are absorbed in smaller proportion than those of sodium

5 Among the salts experimented with, the amount taken up is in the following order, beginning with that least absorbed · potassium chloride, sodium chloride, potassium nitrate, sodium nitrate, potassium acetate, sodium acetate, potassium sulphate, sodium sulphate, magnesium sulphate, potassium carbonate, sodium carbonate, sodium phosphate

6 A chemical action of charcoal has been observed with respect to some carbonates, oxalates, and other salts, being brought about by the presence of calcium sulphate and phosphate

in the charcoal

7 Charcoal, saturated with one salt, is capable, within certain limits, of withdrawing another salt from solution

8 There is less absorption of a salt when the contact is brief than when the contact is prolonged. The difference due to time of contact ceases when the contact has lasted some hours

Investigations by W. B. Clark (J. Soc. Chem. Ind 1912, 262) indicate that the decolourising power of bone-char depends very largely on the quantity of mineral matter and reducing sugar in the liquor treated in the sugar refinery first portion of syrup leaving the char filter contains only about 60 pc of the reducing sugar, and 30 p c. of the mineral matters originally in After these have been absorbed by solution the char, they are subsequently set free, so that the final portions of syrup contain even more reducing sugar and mineral matters than were originally in solution At this stage there is a gradual decrease in the decolourising power of After the syrup inlet has been closed, the char hot water is passed through the char to displace In this wash-water, the reducing the syrup sugars and mineral matters are present in con-This washing treatment siderable quantities restores the normal activity of the char, although the washed char still contains much organic matter, which can be extracted by means of caustic soda solution. Clark remarks that the behaviour of char closely resembles diffusion, the char itself acting as a dialyser, permitting the crystallisable sugar to diffuse through it more rapidly than the other substances present. Bonechar attains its maximum efficiency after being used, washed, and burnt several times. porosity is thereby reduced, as also is the percentage of organic matter other than carbon, and the percentage of calcium carbonate is reduced from about 9 to 3 p.c. The residual calcium

exists as a basic phosphate, which is partially decomposed by heating the char with dilute acids, causing an increase in decolourising power

New char exerts a slight oxidising action on colouring matters which are not absorbed by Degener and Lack state that freshly ignited bone-char, moistened with water, and exposed to light and air, produces a perceptible quantity of hydrogen peroxide, and is thus rendered more active than the untreated char If milk of lime be sprinkled over the char, calcium peroxide is produced

The high decolourising power of bone-char relative to wood charcoal was formerly supposed to be due to the presence of 5-7 p c. of nitrogen in the former, and only traces in the latter; but this view has now been abandoned in favour of a physical, or purely mechanical, action

Charcoal prepared from flesh has about the same decolourising efficiency as that made from Blood charcoal is less efficient charcoal is the subject of a patent by Adler, 1913. The finely minced fish is boiled with water, carbonised, and the resulting charcoal washed with hydrochloric acid.

# (c) 'Decolourising Carbons'

As stated under (a), very active carbons can be obtained from various woods when these are chemically treated before being carbonised The earliest patent appears to be that of R von Ostrejko, in August, 1900, for treating wood powder with calcium chloride or magnesium chloride before carbonising, and subsequently treating the carbon with acid to extract the lime In a later patent, October, 1900, he employs calcium acetate or chloride, and starch mucilage Subsequent patentees employ sulphuric acid at 200° C (Halse, 1902); earthy lignites treated with kaolin (Goldstein, carbonaceous matter of animal or vegetable origin is ignited in the presence of chlorine gas (Molenda and Wunsch, 1912); peat treated with hydroxides or carbonates of potassium, sodium, calcium, or barium (Kruszewski, 1912); wood treated with zinc chloride (Wunsch, 1913); wood treated with calcium oxide or carbonate (Bonnard, 1914)

Two very successful carbons are the Dutch

'Norit' and the German 'Eponit.'

'Norit' is a fine black powder, containing 94-96 p c carbon, and 4-6 p c mineral matters. It possesses about 30 times the decolourising power of bone-char, and about 100 times that of wood charcoal The activity increases in the presence of acids, but diminishes in the presence of alkalıs.

Eponit' is also a fine powder, containing carbon, 86 5 p c.; mineral matters, 4·1 p c; and moisture, 9.4 pc Experiments by Strohmer indicate that it possesses 10 times the decolourising power of bone-char, and is not influenced by the acidity or alkalinity of the liquid treated. From his chemical and microscopical examina-tion he concludes that 'Eponit' is a carbonised vegetable substance, probably wood.

More recently, a Committee of the Royal Society of London has investigated this carbon, and attempted to reproduce it by carbonising various kinds of wood. The conclusion arrived at was that 'Eponit' is made from a mixture of coniferous wood, such as pine or cedar, and angiospermous wood, such as poplar or willow.

Following Ostrejko's patent (see above), the Committee carried out the following experiments:—

(a) A mixture of pine and willow woods was treated with calcium acetate and staich, carbonised at a white heat, and the resulting carbon boiled with hydrochloric acid, washed with water, and heated to a red heat in a retort.

(b) Cedar wood was treated with calcium acetate alone, before carbonising, and the same

subsequent treatment

Both (a) and (b) proved superior to 'Eponit' Further experiments with cedar and willow were conducted as follows: (a) untreated, (b) treated with milk of lime; and (c) with calcium acctate before carbonising at a white heat, subsequent treatment as before. The following results were obtained (a) both charcoals were useless for decolourising purposes, (b) and (c) both woods gave very active charcoals, equal to 'Eponit,' (c) being slightly superior to (b). The Committee concluded that the type of wood has little or no influence on the result, and that probably any porous wood, after similar chemical treatment, would yield an active charcoal. Further, that the treatment with milk of lime is less costly than that with calcium acctate, and the resulting carbon is practically equal in decolourising power.

Pellet (Bull Assoc Chim Sucr 1916, 33, 220 227) has studied the relative decolourising powers of numerous carbons and charcoals relative to 'Epomit' taken as standard. He employed a dilute solution of molasses, previously clarified with basic lead acctate and the clear solution acidified with (a) hydrochloric, and (b) sulphurous acids. As some of the carbons gave slightly different values in the presence of these different acids, the two following series were obtained, in which 'Epomit' is the most

efficient —

(a) With hydrochloric acid Eponit, 1. Littoral, 2, Flandrac, 3, Flaming, 4; special carbon for wines, 5, bone-char, 6, special carbon, 7, bone-char washed with acid, 8, cherry stone carbon, 9.

(b) With sulphurous acid Eponit, 1, Flandrac, 1, Littoral, 2, special carbon, 3, special carbon for wines, 5, bone-char washed with acid, 6, Flaming, 7; bone-char, 8, cherry-stone carbon, 9

'Noist' and 'Eponit' resemble bone-char in absorbing organic and mineral matters from the solutions treated by them, and thus gradually losing their activity. This can be restored by two methods. (a) carbonising, so as to destroy the organic matter, and (b) by boiling with dilute caustic soda, which dissolves the organic matters, after which the carbon is separated in a filter-press, and washed with hot water until free from alkali

In the former method, a special type of kiln must be employed (Wijnberg's Patent, 1916). The second method was patented by Wijnberg and Sauer in 1911 and 1912, and requires no special plant, but appears to have been applied to bone-char many years previously. In another patent by Wijnberg, in 1915 Norit is employed to facilitate filtration of sugar juices through cloth-filters, owing to its power of absorbing gums and pectins.

# (d) Mineral Carbons.

Coal, or other bituminous substance, is impregnated with an alkali, or alkali carbonate, and some time later with an acid, or first with acid, and later with alkali, before ignition in retorts (Lotz, D. R. P. 1911). 'Culm,' a bituminous mineral present in the alum slate of Sweden, is dry distilled, the residue leached with acid, and washed with water. It can be regenerated by washing and re-heating (Hellsing, Eng. Pat. 1913). Coal is heated with excess of anhydrous zine chloride in an open vessel until the chloride begins to volatilise. The mass is cooled, crushed, washed in a filter press with dilute hydrochloric acid, and finally with water (Wunsch, Eng. Pat. 1914). The residue from shale-oil distillation is carbonised (Catlin, U.S. Pat. 1917).

#### (e) Carbons produced from Industrial By Product

Clacher claims that an active carbon can be prepared from 'bagasse, 'or crushed sugar cane, after the extraction of the juice (Int Sugar Journ 1914, 64 66) The Pan Chemical Co, USA, manufacture an active carbon from the by-product obtained in the manufacture of salts of tartaric acid from argol This residue contains 50 pc moisture, and 50 pc crude fibre with lime and sand It is dried and heated in retorts (U.S. Pat. 1912) Mathéus (Papierfabrikant, 1911, 9, 1435) evaporates sulphite waste lyes with milk of lime to a thick syrup, and finally in flat vessels, until it solidifies, forming a brittle mass This is powdered and heated in a closed vessel

'Black ash residue,' obtained by evaporating the alkali separated from wood pulp, consists mainly of carbon with 1–5 p.c. of ash. The percentage of ash can be reduced to about 0.8 p.c. by washing the residue with hydrochloricacid. The washed carbon has ten times the decolourising power of bone-chai (McKee, U.S. Pat. 1914).

DÉGRAS, or SOD OIL, is the waste fat obtained in the chamoising process, and is used for currying purposes, i e dressing bark-tanned or chrome-tanned leather The skins which are to be converted into chamois leather, are first 'limed,' the hair is then removed and the unhaired hides are 'drenched,' i e placed in a sour bath,' in which the free lime is neutralised through the development of an acid fermenta tion, caused by Bacillus furfuris The skins are then stretched and well rubbed with whale oil, or cod (liver) oil, in the United States with menhaden oil, and worked in 'stocks,' so as to become thoroughly saturated with the oil The skins are then exposed to the air, and the process of rubbing with oil and stamping in the stocks is repeated until enough oil has been absorbed By exposure to the atmosphere, a portion of the oil becomes changed, and is most likely converted into the glycerides of 'oxidised' acids In order to promote the oxidation of the oil, the skins are heaped together in a warm room, and covered carefully with canvas, so as to keep the generated heat in the heap whereby a large proportion of the oil is converted into oxidised 'oil The bulk of the oil is expressed from the skins by pressure, the remainder of the

oil retained by the skins being removed by one of the two following methods, known respectively as the English and German method, or the French method In the English and German method, the skins are washed with alkaline lyes; the emulsion thus obtained is acidified with sulphuric acid, when the fatty matter separates and is skimmed off This fatty substance forms the 'sod oil' of commerce. In the French method, the skins are 'stocked,' aired, and 'fermented' for a shorter period than in the English or German method, so that a large proportion of the oil can be obtained from the skins by steeping them in warm water, and wringing or pressing in hydraulic presses. The oil thus obtained is termed 'première torse moellon' The oil still retained by the skins is recovered by washing with alkaline lyes, as is done in the English and German method, and the fatty matter so recovered is usually added to the moellon An addition of other oils is also made to moellon, and for this reason the commercial product contains less fibre and mineral matter than sod oil

The most characteristic constituents of dégras

are the oxidised fatty acids

According to Jean, the characteristic oxidation product is a resin-like body melting at This substance is insoluble in petroleum spirit, but dissolves in alkaline solutions, from which it is again precipitated on the addition of acid. It has been termed dégras former by Simand, and has been shown by Fahrion to be composed of a mixture of hydroxy acids and anhydrides

Dégras is largely admixed with fish oils, blubber oils, tallow of low quality, &c ing to trade custom, such products are considered as a genuine product. On the other hand, the numerous substitutes of dégras, or artificial degras, which occur in commerce, consist of highly adulterated dégras, the adulterants being mineral oils, wool fat, or blown blubber oil, and 10sin Analyses of dégras and sod oils of different kinds are given m J Soc Chem Ind 1891, 10, 557, 1892, 11, 639, and J Amer Chem Soc 1899, 21, 291

DEHYDROTHIO-p-TOLUIDINE, DEHYDRO-THIO-p-TOLUIDINE SULPHONIC ACID, vPRIMULINE AND ITS DERIVATIVES

DEHYDROTHIO-m-XYLIDINE

$$\begin{array}{c|c} CH_3 & \\ \hline -N & \\ -S & C \\ \hline -NH_2 \\ \hline \end{array}$$

is prepared by heating m-xylidine with sulphur until hydrogen sulphide ceases to be evolved (cf. Dehydrothio-p-toluidine, Ait Primuline) The excess of m-xylidine is removed by distillation and the residue treated with hydrochloric (m p. 121°), formed simultaneously, is insoluble, m.p. 107°, b p  $283^{\circ}/14$  m.m. water, readily soluble in hot alcohol (Anschutz and Schultz, Ber. 1889, 22, 582; Paul, Zeitsch angew Chem. 1896, 9, 679).

DELPHINE BLUE v OXAZINE COLOURING

DELPHINIDIN. DELPHININ, v. ANTHO-

**DELPHININE** C<sub>31</sub>H<sub>49</sub>O<sub>7</sub>N is one of a series of ill-defined poisonous alkaloids, including delphisine, delphinoidine, staphisagroine, and staphisagroidine, found in stavesacre seeds (Delphinium Staphisagna (Linn). Official in the B. P and U.S. P. (Kora-Stojanoff, Chem. Zentr 1890, [n ] 628, and Ahrens, Ber 1899, 32, 1581, 1669) Delphinium consolida and D. ajacis, according to Keller (Aich Phaim 1910, 248, 468; 1913, 251, 207), also contain alkaloids. From various Delphinium spp Heyl has obtained 'delphocurarine,' an amorphous mixture of bases, including a crystalline substance, mp 184°-185° (Chem Soc Abstr 1903, i. 650) 'Delphocuratine' resembles curarine in

physiological action (Lohmann, Pflug. Arch

1902, 92, 398)

DELPHINIUM CONSOLIDA. Delphinium consolida is a common European plant belonging to the Larkspur family; its name refers to its powers, real or imaginary, of healing or consolidating wounds. The blue flowers were examined by Perkin and Wilkinson (Chem Soc Trans 1902, 81, 585) to determine if these yield the same colouring matters as those previously isolated from the flowers of the *D* zahl (bhd 1898, 73, 267) The presence of kaempferol only could, however, be detected For its isolation an aqueous extract of the flowers was digested at the boiling-point with addition of sulphuric acid, and the brown resinous product which separated on keeping, extracted with alcohol and the extract evaporated to a small bulk Addition of ether to this solution caused the precipitation of resinous impurity, and on evaporating the ethereal liquid a semicrystalline residue of the clude colouring matter was obtained The product was crystallised from dilute alcohol, converted into acetyl derivative, and this after purification retransformed into colouring matter in the usual manner The yield was approximately 1 p c

Kacmpferol  $C_{15}H_{10}O_6$  consists of yellow needles, mp  $276^{\circ}-277^{\circ}$ , soluble in alkaline solutions with a yellow colour. These liquids on exposure to air are slowly oxidised with

development of a brown tint

Tetra-acetylkaempferol  $C_{15}H_6O_6(C_2H_3O)_4$ , when crystallised from methyl alcohol forms colourless needles, and when heated commences to melt at 116° and becomes completely fluid at 120° On further heating, however, gradual solidification ensues and the product subsequently melts at 181°-182° This peculiarity of acetylkaempferol, which is not apparent when the substance is crystallised from ordinary alcohol, affords a convenient method for its detection

Tribromkaempferol $\rm C_{15}H_7Br_3O_6$  forms yellow needles, m p  $275^{\circ}\text{-}277^{\circ}$ ; haempferol sulphate needles, mp 275-271; https://doi.org/10.1016/html.006/hg804, orange-red needles; kaempferol hydrodude  $C_{15}H_{10}O_{8}HI$ , needles, and monopotussium kaempferol  $C_{15}H_{9}O_{8}K$ , orangeyellow pusmatic needles.

Kaempferide, a monomethyl ether of kaempferol, exists in Galanga 100t, and a monomethyl ether, apparently distinct from this latter, has been isolated from the berries of the Rhamnus catharticus The glucosides at present known of kaempferol are robinin, which occurs

in the flowers of the Robinia pseudacacia, kacmp-feritrin, found in the leaves of the Indigofera arrecta; and kaempferin, which has been isolated from senna

Fused with alkali, kaempferol gives phloro-

glucinol and p-hydroxybenzoic acid

To kaempferol v Kostanecki assigned the constitution of a trihydroxyflavonol (Ber 1901, 34, 3723) —

and its synthesis was subsequently effected by v. Kostanecki and Tamboi (Ber 1904, 37, 792)

2-Hydroxy-4·6 4'-trimethoxychalkone (1) when digested with boiling dilute alcoholic sulphuric acid gives 1 3 4'-trimethoxy flavanone (2) —

and the latter by means of amyl nitrite and hydrochloric acid is converted into iso-nitroso-1 3 4'-trimethoxyflavanone (3).

When a solution of this substance in acetic acid is boiled with 10 pc sulphuric acid 1-3-47-trimethoxyflaronol (4) is produced, from which by the action of hydriodic acid kacipperol (5) is readily prepared—

(3) 
$$CH_3O$$
  $CH_3O$   $CH_3O$ 

Kaempferol possesses well-defined dyeing properties, and gives with mordanted woollen cloth the following shades which closely resemble those given by morin:—

Chromium
Brownish-yellow
Tin
Lemon-yellow
Deep olive-brown.

It is also present in the Impatiens balsamina (Chantili Pass), the Eightrina stricta (vernacular name 'Kon kathet') (Perkin and Shulman, Chem Soc Proc 1914, 30, 177), the berries of the Rhamus catharticus and together with quercetin, both apparently as glucosides, in the flowers of the Prunus spinosa (Perkin and Phipps, Chem Soc. Trans 1904, 85, 56) For the separation of the two colouring matters a fractional crystallisation from acetic acid was

employed, kaempferol in these circumstances being the more sparingly soluble A G P

**DELPHLEGMATOR.** An apparatus used in fractional distillation. The term is also comployed in distillation for an apparatus for freeing alcohol from water (phlegma)

DELTA ACID. Disulpho acid S 1-Naph-

thylamine-4 · 8-disulphonic acid

DELTAPURPURÎN v. Azo- colouring matters.

DENATURANTS. This term is applied to substances which are added to articles usually subject to revenue imposts, and primarily intended for human consumption (as spirits, tobacco, &c) in order to render such articles unfit for human consumption, but without impairing their efficacy as raw material for use in various arts and manufactures. Articles thus denatured 'may safely (from a revenue point of view) be released from revenue control without payment of duty

The principles underlying the choice of suitable denaturants are mainly as follows—

(a) They should be inexpensive, so as not to

add materially to the cost of the denatured article,
(b) Then use should cause the minimum
amount of inconvenience to the manufacturer,
both in regard to his processes and the necessary
revenue supervision involved,

(c) The denaturant should not be incompatible with the process of manufacture or the subsequent use of the denatured article,

(d) It should be of such a nauseous and repugnant character as to remove any tempta tion to would-be consumers of the denatured article, and

(e) The denaturant should have such a relation to the original article both in quantity and character as to preclude its removal from the mixture by any process which could be profitably carried out on a commercial scale, and it should be capable of being readily detected even if present in very small quantity. In the United Kingdom the dutable articles

In the United Kingdom the dutiable articles allowed to be denatured are tea, tobacco, wine, and spirit, the last being by far the most important, both by reason of the large amount of revenue derived from it, and the great variety and extent of its applications in the arts and manufactures

Tea, before being admitted for consumption in the United Kingdom, is examined by the Customs under sect 30 of the Sale of Food and Drugs Act, 1875, and, if found satisfactory, is passed on payment of duty. but if otherwise, it is refused admission as 'tea' Since, however, it still possesses a certain commercial value as a raw product for the extraction of theme or caffeine, the Commissioners of Customs and Excise usually permit it to be admitted for this purpose duty free, after it has been effectively denatured in such a way as to make it unsuitable for use as a bevorage, but without interfering with its efficacy as a source of caffeine The same applies to those teas which have been accidentally damaged and are voluntarily withdrawn by the importers from sale as 'tea

In the case of tea, the denaturing process consists in grinding and mixing the tea with lime and asafectida in the proportions of 1 part of asafectida and 100 parts of lime to 1000 parts of tea

Tobacco is dutied on the whole leaf, of which certain portions, as the midribs or so-called 'stalks,' are by manufacturers treated as 'stalks,' are by manufacturers treated as waste or 'offal,' and the same applies to the unused portions of manufactured tobacco, known as 'horts' or 'smalls' On these the duty which has been paid is returned as 'drawback' to the manufacturer on condition, either that the tobacco offal is surrendered to the Government for destruction, or (if intended for such purposes as the manufacture of nicotine, insecticides, sheep dips, &c ), that it is denatured according to certain prescribed formulæ, and under the supervision of revenue officers. Denaturing is equally necessary in the case of offal from tobacco manufactured in bond (although no duty has been paid nor drawback given), in order to prevent its fraudulent use as a substitute for duty-paid tobacco

The following formulæ have been officially approved in the United Kingdom for denaturing certain preparations having tobacco as a basis

(a) Sheep wash To every 100 lbs. of tobacco are added 10 lbs of blue vitriol, 15 lbs. of common salt, 2 lbs of oil of turpentine.

(b) Tobacco extract manufactured in bond may be denatured by adding 30 parts of soft

soap to 70 parts of extract
(c) Hop powder, To every 75 lbs of snuff or (c) Hop powder. To every 75 lbs of snuff or tobacco are added 28 lbs of sulphur, 5 lbs of

asafætida, and 3 lbs of sago flour.

(d) Funiquet for horticultural purposes every 100 lbs of tobacco or snuff are added 10 lbs of ground hellebore, 18 lbs of saltpetre, 6 lbs of asafætida, 4 lbs of cayenne, 2 lbs of lampblack, 10 lbs of sago flour

Wine which has become unsound and sour (owing to the formation of acetic acid) so as to be no longer suitable for use as a beverage, is released from revenue custody after being denatured with a view to its conversion into wine vinegar The denaturant used in this case 18 20 p c of commercial vinegar, or an equivalent quantity of acetic acid.

(For methods of denaturing alcohol, v Methylated spirits and Industrial alcohol, art ALCOHOL.)

**DENITRIFICATION** v FERMENTATION AND

DENSIMETER v Specific gravity.

**DENTALONE.** A solution of chloretone in essential oils

DERMATOL. Bismuth subgallate BISMUTH, ORGANIC COMPOUNDS OF, also SYN-THETIC DRUGS)

DERMOGEN. A trade name for zinc peroxide.

DERMOL. Bismuth chrysophanate. yellowish - brown powder, said to have the composition Bi(C<sub>15</sub>H<sub>9</sub>O<sub>4</sub>)<sub>3</sub>Bi<sub>2</sub>O<sub>3</sub>. According to Merck, it is a mixture of impure chrysarobin and bismuth hydroxide (v Bismuth ORGANIC COMPOUNDS OF, CHRYSAROBIN and SYNTHETIC DRUGS

**DERRIS ULIGINOSA** (Benth.) The stem of this species of derris, used in the Far East as a fish poison, contains a poisonous resin (Proc Amer Pharm Assoc 1902, 50, 296).

DESAEGIN ('Colloidal chloroform'). An

albuminous substance containing chloroform.

DESCLOIZITE. A basic lead and zinc vanadate, (Pb,Zn)2(OH)VO4, crystallising in the

orthorhombic system, and isomorphous with olivenite (basic copper arsenate). A small amount of copper is sometimes present. The small crystals are deep reddish-brown in colour, and the streak is a paler yellowish-brown. It occurs in veins of lead ore in association with vanadinite, &c, and has been mined to a limited extent in New Mexico and Arizona, as a source of vanadium. It also occurs in considerable quantities in the Sierra de Cordoba in Argentina, and at Broken Hill in North-Western Rhodesia L. J. S

DESICCATION AND DRYING. The removal of mechanically admixed water from substances. The removal of chemically combined water is usually termed dehydration, but it is not always possible to draw a sharp distinction between

the two processes.

A substance may be termed 'dry,' even though it still contains mechanically admixed water, provided that this water is not apparent to the touch, the term 'desiccation' refers. strictly speaking, to the complete removal of admixed water.

The importance of drying and desiccating will be appreciated by a consideration of the numerous reasons for which these processes have to be employed, among which the following may be mentioned

1 To preserve material from undergoing physical and chemical alterations, eg leather,

tobacco, fruit

2 To remove water needed in preceding operations,  $e\,g$  drying coal after washing, woollen and cotton goods after dyeing, &c.

3 To facilitate accurate sampling, since substances are much more readily and uniformly mixed in the dry state than in the moist condition

4 To diminish the weight of an unnecessary ingredient and thereby diminish cost of packing, carriage, and freight; e.g. timber, peat, &c.

5 To retain desirable moisture in a substance by drying its surface, thereby rendering the outer layer impervious to moisture, eg. the drying of soaps and chocolates

6 To prevent injury to health or goods, as in the case of the moisture-laden air of textile

factories, evaporating rooms, &c

7 To prevent waste of heat in vapourising water when combustibles are burnt

A slight consideration of the various purposes served by drying processes is sufficient to bring out the wide range of degrees of dryness, and the various conditions to which the term 'dry' is applied This vagueness arises partly from the difficulty of stating quantitatively the amount of water present in a given instance, and partly owing to the varying capacity that substances possess for absorbing moisture. Thus it is that in ordinary conversation substances are variously described as 'soaked,' 'wet,' 'moist,' 'damp,' 'dry,' 'dried,' 'desiccated' or 'dehydrated,' in order to indicate qualitatively their degrees of dryness.

The drying processes in use may be classified under the following headings, corresponding with the degrees of drying to which they lead

A. Gravitational drying, by draining, filter-

ing, absorbing, and condensing.

B Mechanical drying, by pressure and centrifugal force.

C. Drying by evaporation.

A. Gravitational drying. The processes included under this heading are usually only preliminary to the employment of method C above.

Drainage is a natural process occasionally used for the purpose of removing suiface water, e.q. from washed coal The procedure requires

no special description.

Decantation is a process by which solid substances mixed with a large amount of water are separated from the greater portion of that liquid by allowing them to settle, and running off the liquid from above the sediment practice it is often the custom to arrange settling tanks' in series, stepwise, and gradually feed the mixture of liquid plus suspended solid into the upper vessel by means of a pipe The overflow runs into leading to the bottom the second vessel, and so on throughout the series. Arrangements are provided for emptying each tank as required China clay, chalk, and barytes are separated in this manner

Filtration is a process of accelerated drainage Thus wet pigments prepared by precipitation are drained on calico sheets stretched loosely over a skeleton framework Filtration is greatly accelerated by partially exhausting the air from the chamber into which the liquid drains vacuum filter has been designed to work con-tinuously, and consists of a hollow drum, mounted with its axis horizontal, and partly submerged in a tank containing the suspension to be filtered. The periphery is covered with filter cloth, and the water is drawn by suction, applied to the interior of the drum, through this cloth, leaving the solid matter as an outside By slowly revolving the dium, a continuous coating of solid is thus formed, and, after it reaches a certain thickness, an adjustable skimmer removes the surplus arrangement can be adapted to many drying operations, and consumes very little power

Absorption is a drying process in which the material is dried by causing it to yield its moisture to other substances which are capable of annexing it. This process is not often applied on a large scale, although it is commonly employed in the laboratory Instances are furnished, however, in the preliminary drying of large clay ware in dried plaster of Paris moulds, and in the drying of the highly water-laden atmospheres of evaporating rooms, dye houses, &c, by pumping warm, fresh air into them Warm air having a much higher capacity for holding water vapour than cold an, the result is naturally to effect a drying of the atmosphere, besides warming up the room and fittings

In the laboratory, substances are frequently dried by placing them in a desiccator This is simply a closed glass vessel containing in a suitable receptacle some chemical compound, such as anhydrous calcium chloride, concentrated sulphuric acid, or phosphoric anhydride, which has a remarkable affinity for water, so that it will, by absorption, remove water vapour from the interior even when the tension of the aqueous vapour therein is exceedingly small The substance to be dried being placed in the desiccator, in the interior of which the tension of aqueous vapour is almost nil, it gives off its moisture, and this is continuously absorbed by the desiccating agent employed. The latter must expose a large surface for rapid absorption | nected with a pump. Resting on the funnel is

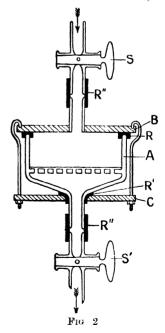

The velocity of drying in a desiccator to occur may be greatly increased by exhausting the air from the interior (vacuum desiccator), since the rate at which moisture can diffuse from the material to the absorbing agent is thereby largely augmented The degree of drying attained cannot, however, be increased, since that is limited merely by the pressure of the aqueous vapour when it has reached equilibrium with the absorbing agent. The rapidity of drying is also increased by placing the material to be dried at the bottom and suitably airanging the desiccating material above it This arises from the fact that moist air has a smaller density than dry air at the same temperature and pressure; consequently, the natural process inside the desiccator is for the moist air to rise

The error in design exhibited in most laboratory desiccators. in which the above arrangement is reversed, was pointed out by Hempel (Ber 1890, 23, 3566), to whom desiccator shown in Fig 1 is due In this desiccator, the drying agent is placed in the trough of the lid

It is usual to evacuate laboratory desiccators by means of the water-pump, but it may be easily accomplished by simple chemical means (J Amer Chem Soc 1906, 28, 834; Amer Chem J 1902, 27, 340)

A desiccator for drying by means of a current of air has been described by Pratt (J Amer. Chem. Soc 1917, 39, 271) It consists of a Buchner funnel connected below, through

cock s', to a safety flask, which in turn is con-

a heavy brass disc, B, on the lower surface of which is cemented a ring or sheet of rubber, R, to make a tight joint. Pressure is brought to bear on the disc by means of three screws acting between the disc and a metal collar, c. Heavy rubber tubing, R', prevents the collar from exerting unequal pressure on the funnel. In the centre of the disc is set a brass tube, to which is attached, by means of heavy rubber tubing, R'', the cock s'. This cock is further attached to a system of drying-bottles or towers. The material to be desiccated is either filtered into or placed in the funnel (Analyst, 1917, 156).

Condensation -This is employed as a means of drying materials which must be handled at low temperatures, and is a method adopted in cold storages. The principle of the process is, briefly, that the moist air of the rooms is drawn out and passed into chambers maintained at a very low temperature, where it is made to deposit the greater part of its moisture as a liquid The dry air is then returned to the drying rooms, either cold, when it waims itself at the expense of the materials drying, or after being previously heated This circulation of air goes on continuously The method adopted in order to maintain a low temperature in the cooling rooms is to allow liquid ammonia, carbon dioxide, or ether to evaporate at the requisite rate through long coils of metal pipes over the outer surfaces of which the moist air is drawn The latent heat of the ammonia (or other) vapour is obtained at the expense of the heat of the moist air, which is thereby cooled, the vapour condenses on the pipes and the water trickles down into troughs and flows away. The ammonia (or other) gas is repeatedly used in a cycle of operations, being successively liquefied and evaporated This process is highly efficient, but requires careful handling for economical working

B Mechanical drying. These methods are efficient when water forms a large proportion of the total weight, and when the solid material to be separated is porous in texture. They leave the solid damp or moist

Drying by pressure—There are very tew cases in which direct mechanical pressure is used for removing water from substances, the most important of which is the direct squeezing of peat in specially designed machines, in order

partly to remove the surplus water.

Filter presses are used for partly drying semi-solids, and leave them still containing about 20 pc of moisture They are efficient in removing the large bulk of the water from granular substances in a state of thick mud Essentially a filter press consists of a number of flat sections or chambers formed of iron plates covered with filtering cloths, and supported in a strong horizontal frame, in which they can be squeezed up tightly together The chambers are made either round or square, and usually each has its own outlet cock, while the washing arrangement can be made reversible The sludge to be filtered is fed in under moderate pressure, and all the outlet cocks opened After water has ceased to flow out, the solid in the press is washed, if desirable, and the press then taken to pieces to remove the moist solid cakes from its interior. This process is used for filtering, among other things, sewage sludge, gold slimes, and precipitated pigments.

Drying by centrifugal force.—This method is largely employed for drying clothes in laundries, when the centrifugal machines are termed hydro extractors. It is also used for drying wool, cotton yarns, piece goods, &c., after they have left the dye houses, and for separating and drying sugar, gun-cotton, and staich.

The process consists in placing the material to be dired in a basket containing numerous holes, and rotating it in a houzontal plane at a considerable speed. The water is thrown off from the material very effectually, much more effectually than when simple filtration or filtration under moderate pressure is adopted.

A centufugal machine consists essentially of a circular basket, rotated on a vertical central shaft and enclosed in an outer stationary casing. The circular basket is drum shaped, having an open top to introduce the material and sometimes a valve at the bottom to form an outlet The periphery is perforated for dried crystals with holes of a suitable size. These baskets are made of steel, bionze, copper, aluminium, silver, or china, as may be suitable, and are fined with rubber, cnamel, or lead when dealing with acid liquids. The outer stationary casing serves as a guard in case of accident and as a The successful working collector for the water of a centrifugal machine depends upon the skill with which the vertical shaft is mounted and driven, since the apparatus must have sufficient freedom when running for the axis to take up the position it requires, otherwise vibrations will lapidly wreck the machine

C Drying by evaporation. This is by far the most efficient method of drying, indeed, several of the preceding processes are only employed as preliminary steps to the application

of this more powerful method

Drying by evaporation is a process in which the water is removed by first converting it into vapour and then conveying the vapour away. Water always has a tendency to pass into the gaseous state, and is constantly giving off vapour from its fice surface. If this process occurs in a closed space, some of the vapour finds its way back into the liquid, and a state of equilibrium is set up when the rate at which vapour is leaving the suiface has become equal to the rate at which it is passing back into the To the state of equilibrium at any particular temperature there corresponds a definite vapour pressure, which is a measure of the tendency of water at that temperature to pass into the gaseous state, and this vapour pressure rapidly increases with rise of temperature. When evaporation takes place in free space, no condition of equilibrium is reached, since, owing to diffusion of the vapour, the rate at which it passes back into the liquid can never equal that at which vapour leaves it. Evaporation therefore goes on until no more liquid remains From these considerations, it follows that the two main practical principles in drying by evaporation are (1) to warm the material and thereby increase the tendency of its contained water to vapourise, and (ii) to remove the vapour as it is produced from the neighbourhood of the substance, in order that the evaporation shall proceed continuously.

In applying these principles it is necessary to bear in mind that the rate of drying permissible in any given instance is restricted by (a) the physical and chemical nature of the material, which put a limit to the rate at which heat may be safely applied; and (b) by the cost of drying, since the plant mechanically most sound may not be most economical in practice. It must always be remembered that the nature of the material governs the method of drying to be employed, and must be considered before the question of mechanical efficiency.

The various methods for applying heat and for removing vapour are indicated below, and in order to explain more definitely how these methods are employed in practice, bird descriptions follow of various types of drying installations in actual use, and of the purposes

for which they are used

Application of heat. In the majority of cases hot air is employed for conveying heat to the material, and its use is attended with many advantages. Air, although an extremely poor conductor, is an excellent absorber of heat, the increase in volume resulting from this process naturally tends to disperse this heat and to warm surrounding materials by convection. The mobility of the air enables it to come into intimate contact with the surfaces of materials, thereby supplying the heat necessary to vapourise the moisture. Most important of all, the heated air can be thus supplied in large or small amounts, at any desired rate and at uniform pressure, while any of these factors may be rapidly and easily altered at will

Of the various sources of heat, the cheapest Owing to its unis, of course, solar heat reliability so far as quantity and continuity are concerned, its direct use is attended by considerable risks Indirectly, however, it is of great value, in being the primary cause of natural air currents. Drying directly by furnace heat obtained by fuel combustion is economical, but the method is restricted in use to drying those substances which are not sensibly affected by high temperatures For the commonest method of drying, by means of a warm blast of an, heat is usually supplied by passing the air over the surfaces of radiators. These are simply iron vessels, built to expose as much surface as possible, and through the insides of which steam, hot water, or hot gases are passed is conducted through the non-to-the outer surface, and waims the surrounding air mainly by radiation

The dangers encountered in the application of heat result from the nature of the material, and the factors involved, which are briefly discussed below, naturally affect various

materials to very different degrees

(a) Rate of application of heat Although the amount of heat required to vapourise a definite quantity of water is fixed, yet if this heat be applied at a rate faster than that to which the material can accommodate itself, injury will result, e.g. wet bricks will crack unless the greater part of their water is first driven off at a slow and uniform rate.

(b) Change in power of absorbing heat with loss of water As a material dries, its heat

capacity usually diminishes, and hence the risk of overheating increases as drying progresses

(c) Uncertainty as to degree of dryness,

which is often unavoidable

(d) Local application of heat. This is the usual cause of distortion and cracking, since most materials shrink as they dry, and local shrinking sets up strain. This makes it advisable to keep wet material from actual contact with the source of heat, and to agitate the material to continually expose fresh surfaces, since evaporation is a purely surface phenomenon.

Methods for removal of vapour. The natural method by which vapour is removed is by means of an currents, and, excepting in the case of the vacuum process, this is the method upon which all artificial processes for vapour removal

are based

The ordinary atmospheric process for drying utilises the natural movements of the air, eg by utilising the action of the wind on floors, pans, gantries, sheds, &c It requires no motive power, but, being dependent upon varying atmospheric conditions, it is not reliable

In the exhaust process the moisture-laden and is drawn away from the wet material quicker than gravity would perform the removal. For this purpose a propeller of fan is usually employed. Since the operation is carried out under slightly reduced pressure, vapourisation proceeds quicker than it otherwise would, on the other hand, the exhaust carries away the heat-bearing medium from the material to be heated, and unless proper control is exercised, this defect may more than counterbalance the increased rate of removal of vapour.

In the racuum process the material is enclosed in an air-tight receptacle, from which the air may be exhausted to any desired extent Heat is then applied, and the vapour pumped off as fast as it is produced ('onsiderable experience is necessary in the application of this process, which, properly applied, is highly

efficient and rapid

In the plenum process the vapour is removed by supplying sufficient warm air to create an augmentation in an pressure. A fan is usually employed for this purpose, and drying must, of course, take place in an enclosed room with regulated egress for the air. This process is usually the best to employ, since it can be maintained strictly under control.

Drying installations. Drying floors. Natural floors are not often used, since serious difficulties arise as to heating, handling the material, and removing the vapour Haymaking affords a

good instance of its employment

Artificial floors warmed by the products of combustion from a furnace, by hot gases, or by steam passing in flues or pipes beneath, are a considerable improvement on natural floors. Advantage is taken in constructing them of any convenient sandy or porous ground floor; sand is put down if the natural ground is clayey

These floors are used for drying china clay, calcium phosphate, barytes, chalk, cement, and calcined quartz, materials which are not readily injured by excessive or irregular heating.

Drying gantries or racks. These are employed in order that as much surface as possible may be exposed to air currents. Their construction assumes various forms. According to

circumstances, they may be either skeleton shelves, or racks, or props, &c Occasionally hot water or steam pipes are used as supporting racks, but their use is to be avoided as uneconomical, and tending to produce uneven drying and distortion

Such substances as damp corn, peat, raw rubber, chalk, bricks, and clayware are frequently dried on open racks, while pigments in colour works are often dried in open gantries

of skeleton shelves

Drying sheds. These are merely drying floors or gantries provided with roofs to keep off rain and snow These sheds are best constructed of light open framing in order to facilitate the removal of vapour, and the more open it is on all sides the better, provided that the substance is not such that direct sunlight must be excluded from it, eg rubber Such sheds are highly efficient in producing 'air-dried' Bricks are often dried in sheds erected on drying floors, while Chile saltpetre is dried in sheds without the application of artificial heat, as also are china clay and othre in the quarry state

Drying pans and troughs. Drying pans, correctly designed and handled, are very useful appliances The oldest commercial use of such pans is in the evaporation of salt brine, which, as usually carried out, is not at all an eco-The pans are usually rectnomical process angular, and each stands in its own shed They are directly heated, three or four fires being beneath each pan

Shallow earthenware pans are of great use in the colour trade, the pigments being readily dried if the pans are carefully arranged on gantries in well-heated and ventilated chambers

Semi-cylindrical iron pans heated from below by gas or steam give good results in drying soft materials, especially powders They are most efficient when provided with revolving grids for mechanically stirring the wet material and with valve outlets at the bottom for automatically discharging their dried contents

Granulated sugar is dried in a type of troughed pan, through which passes a hollow conveyer' carrying hollow paddles. Steam is blown through the conveyer and paddles. The trough is jacketed on one side, and through this jacket air is blown into the bottom of the trough. The sugar is fed into the hot end, and automatically carried by the heated paddles to

the outlet at the cool end of the trough

Kilns. These are buildings containing a furnace, the direct heat of which is used for drying materials by allowing the products of combustion to pass through them For substances which may be strongly heated without damage, kiln-drying is an economical method of procedure, since the walls of the kiln are very effective in saving heat that would otherwise be lost; but care must be taken to provide proper exits for the vapour

A primitive type of kiln is one in which calcium phosphate is dried. It consists of a plain rectangular brick building with a wooden roof. The floor is piled with wood, and the phosphate placed upon it. Flues admit air for combustion and circulation Such a kıln wıll burn for from 2 to 5 days and dry from 1000 to 1200 tons of phosphate.

Kilns for drying clays, fuller s earth, barytes, and chalk are constructed upon the same principle, the fire being placed so as to prevent the ashes mixing with the material, the latter is sometimes supported within the kiln on iron racks.

A rotating bed dryer is in extensive use for drying materials which allow of direct firing The material is placed on a circular cast-iron bed, which slowly rotates on a vertical shaft The bed is covered by a firebrick arch, into which the exit flue leads Heating is done directly by fires, and stationary blades fixed in the arch stir the material as it is drying blades are fixed at such an angle that the material is slowly moved from the centre, above which the feed is situated, to the edge, where it is automatically discharged a common type of drying kiln for ores

Drying cylinders. This term includes those dryers in which the material to be dried is contained in a cylindrical tube, which is slowly rotated The essential feature of their construction is that the rotation of the cylinder affords the means of moving the material along. With suitable materials and the necessary power, cylinders will automatically deliver large quantities of uniformly dried product, with the minimum of labour and fuel consumption They are consequently extensively used, and many types of drying cylinders have been

devišed For materials that withstand high temperatures, the heating may be carried out by passing the hot gases from a furnace through the tube The latter is constructed of steel, and is mounted nearly horizontally (slope of 1 in 12), with the furnace at the lower end The feed is situated at the higher cold end, and the gases pass out through a flue at this end, connected with a fan or chimney As the material gravitates down the tube it is dired, and on reaching the lower end, it drops out, quite dry, into trucks A modification of this construction consists in enclosing the steel tube in a horizontal brickwork chamber and heating it externally by passing the furnace gases into this brickwork chamber, whence they pass through a series of external hooded openings into the steel cylinder itself. This arrangement allows of a more gradual and systematic heating, while dust and other objectionable parts of the products of combustion may be arrested prior to the gases entering the cylinders these two arrangements, many others have been

devised, each having its particular advantages Cylinder dryers are very suitable for heating by steam, thus meeting the requirements of such substances as sugar, salt, soda, cocoa, coffee, &c., provided they contain not more than 25-30 p.c. of moisture. The drying cylinder may be either steam-jacketed externally, or internally, or by both methods united exhaust is best taken by means of a fan at the feed end of the cylinder. In using such dryers for sugar, they are employed in conjunction with a conveyer trough dryer (v. supra), into which the sugar falls after passing through the steamheated cylinder.

Drying rollers. These are heated rotating cylinders, with the outside periphery of which the material to be dried is brought into contact. They are made of steel, cast iron, copper, or tinned iron, and are usually heated by passing steam or hot air through their Another method of heating consists in coating the cylinder externally with felt and rotating it in a polished iron bed, against the under surface of which steam is blown. The material to be dried is automatically passed between the roller and its bed, and the rollers are usually arranged in series of two to eight

The latter method is largely employed in laundry work, and the use of drying rollers is extensive in the paper and textile trades

Drying tunnels. These consist essentially of a stationary passage through which the material passes either continuously or intermittently as the drying proceeds Drying in a tunnel is progressive from one end to the other Heat may be applied either by direct firing or by heated air, which passes into the tunnel from beneath one end and travels along to the other. The warm air current usually travels in the opposite direction to that in which the material moves, but not always, as, for instance, in the drying of wool, where the pressure of the warm blast is utilised in blowing the material forward The vapour-laden air may be removed either by chimney, exhaust, or by pressure fan, while the material may be handled in a very large number of ways, according to circumstances This method of drying is economical, but the initial cost of plant is often considerable

In drying timber, the material is carried on special trucks running on a tram track air is heated by means of a heater coil fed with steam and situated under the track at the The air ascends, dries the discharging end timber, thereby becoming cooler and denser, and then, pressed forward by the incoming air, it gravitates into a large space beneath the feeding end of the tunnel and passes up the Wool is dried in a tubular tunnel, being blown along by the warm air. Soap is dried by passing it on trolleys through narrow tunnels, usually arranged in fours, through which warm air is driven by means of a propeller. In particular, bricks and clayware are dried by passing them through drying tunnels, for which purpose a very large number of types of plant have been devised

Drying rooms. These are enclosed spaces, which are warmed by means of hot air, and into which the loader or discharger has to enter When not constructed of brick or stone, the material of the walls should be chosen for its insulating qualities

The expense attached to drying by this method is due largely to the manual labour required in handling the material, which arises, in most cases, from the fact that the peculiar properties of the material render it impossible to utilise mechanical methods. Since manual labour in a heavily moisture-laden atmosphere is unhealthy, desiccation in drying rooms is restricted in practice to those materials for which the process is unavoidable. Such products as hops, confectionery, leather, paper, textile fabrics, pottery, and rubber are dealt with by this method.

The materials are supported in the most convenient manner within the chambers, and warm air circulated either through or over them. The warming of the air may be accom-

plished either within or without the compartment, by means of radiators, and, if desired, the same air can be used continuously in a circuit (compare the condensation process)

Drying ovens. These are entirely enclosed drying chambers, the necessary heat for the purpose is not generated within them, neither is it necessary to enter them in order to charge or remove the material to be dried Ovens can be adapted to suit a wide range of conditions, and some of the most scientific and economical dryers are of this type

A great variety of methods are available for the purpose of heating, since the heat is generated outside the oven Products of combustion are readily excluded from the material no necessity for the plant to cool down before the dried product is removed, and hence heat losses are greatly minimised. Heat is applied to the material either by means of hot gases, usually hot air, or by direct conduction through metallic plates, as, for instance, in steam ovens. Vapour is usually removed mechanically, either by pressure or exhaust, but it may be pumped off, as, for instance, in all vacuum machines. Ovens are more efficient than drying rooms, since the latter are frequently used for other purposes than drying, whereas the former are designed exclusively for drying. Only a few types of drying ovens can be here described

Laboratory ovens are rectangular boxes, constructed of copper, iron, or aluminium, which may be either steam- or air-jacketed, or in simple ovens not jacketed at all The substances to be died are supported on shelves inside. With air ovens heat is applied directly at the bottom of the oven or of the outer jacket. A ventilator situated at the bottom of the oven door allows air to enter, and one or more chimneys in the lid allow the warm vapour-laden air to escape. A convenient method of heating, which can be readily controlled, consists in heating electrically, by passing a current through a number of resistance coils embedded in the jacket surrounding the oven (See also Analysis, Vol I) Removable tray dryers are largely used for drying tea, coffee, cocoa, cinchona bark, &c The trays are arranged in the oven in a series of lows. Each tray has a separate slide, and is independent of the others, and each column of trays has its own regulating damper for the hot air method of working is progressive, the wet material being first placed in the top tray of the column and passed downwards stepwise to the The heat required is supplied from a multitubular furnace, which also produces the air current which aerates the material The hot air may be allowed to rise through the material, or be drawn down by two centrifugal fans on either side of the centre through the substance. The latter arrangement is more readily controlled, gives a larger output, and effects a considerable saving in height A modification giving an even larger output consists in causing each horizontal line of trays, commencing with the lowest, to automatically tilt and discharge its contents into the base of the dryer. For drying other substances than those mentioned above, many other types of tray ovens have been devised.

Sliding-panel dryers are used in laundries, and can also be adapted for drying yarns, piece goods, &c. They consist of a row of vertical sliding panels, built up with hanging rods to form rigid horses for the goods. They are readily movable on runner wheels, and each panel may be withdrawn independently of the others, with the minimum loss of heat, as the back of the panel closes the outlet and thus reshuts the oven A hot-air blast is supplied from above, and after passing through the oven it discharges into the open.

The Lennox plate-oven dryer is a type which has many advantages, is compact, and occupies a small floor space The outer vertical cylindrical casing is built up in sections to allow for extension and renewal A concentric cylindrical At each external drum slowly rotates inside section there is a horizontal metal plate within the apparatus, and each section plate contains a hole, these holes are not vertically above one The material to be dried is fed in at the top, falls on the first section plate, and is slowly stirred round by horizontal arms on the rotating centre drum till it reaches the hole in the plate It then falls through on to the next plate, is slowly stirred round till it falls on to the third plate, and so on, till it is discharged at the base Hot air is blown in at the base, and passes upwards into the central drum, from which it issues, through numerous holes in its sides, passes through the material, and thence upwards and outwards

A horizontal steam-jacketed cylindrical oven, containing a very powerful and thorough agitating gear inside, is used for drying wet pasty materials like meat, fish, &c. The material is fed in at the top, and discharged as a dry, mealy powder through a manhole in the bottom The vapour is removed from the interior through a large outlet duct operated either by a fan or pump according to circumstances In vacuum ovens the removal of vapour by means of air or other gases in motion is discarded in favour of pumping away the vapour from the warmed-up material, operating in a closed space and diminishing the pressure within it to any desired The oven must be strongly built, and all joints must fit tightly to maintain the diminished pressure. The material may be supported inside in any suitable manner, for instance, on steam-heated grids The necessary accessories are a vacuum pump, a condenser for the vapour and a receiver for the condensed The latter is provided with a sight glass in order to tell when no more water is given off by the material in the oven effective working of such a plant depends largely upon the observance of various mechanical and engineering points, the chief feature of the vacuum process is the saving of time that it offects. The oven may be designed to suit either solids or liquids, and provision may also be made for effectively stirring the material during the drying process

Desiccators. (Laboratory desiccators have

already been described)

A large-scale desiceator is any type of drying machine, which, working by evaporation, carries the degree of drying to the utmost possible extent. In some of the types previously described, it is difficult to prevent thorough desiccation, and, in fact, to avoid dehydration and calcination, but a number of machines have been devised for the effective desiccation of liquids and thin

pastes, which work upon a common principle that may be briefly explained. It consists in spreading the liquid in a thin film over a heated metallic surface kept in motion, and, when the water has been removed, skimming off the solid residue with a knife. By suitable arrangements. this process can be made continuous, and it is employed on a large scale for desiccating milk to a dry powder A modified method of removing the desiccated product is to cause the liquid to spread out on the upper part of an endless horizontal metallic belt, working over two rollers contained in a heated chamber under reduced The heated liquid, being fed on to the belt at one roller, is desiccated by the time it arrives at the other, and, on the belt passing over that roller, the dry powder falls into the delivery hopper beneath.

DEXTRAN v. Gums

**DEXTRINS**  $n(C_6H_{10}O_5)$  When diastase acts on starch paste (gelatinised starch), maltose is the final product, but, intermediate between the starch and maltose, various dextrins are formed as the reaction proceeds in successive stages These dextrins are colloidal amorphous compounds, and do not form characteristic derivatives They are soluble in water, and precipitated by alcohol Only maltodextrin, which is possibly the simplest of them, has been prepared in anything like a state of purity, and most of the other dextrins described must be regarded as mixtures

As diastatic hydrolysis proceeds, the optical rotatory power diminishes, and the cupricreducing power increases The change is rapid to a certain point, but then becomes arrested; this behaviour is interpreted as proof of an essential difference between the higher and lower dextrins The constants of this stage of hydrolysis are [a]<sub>J</sub>=1625°, K (cupric-reducing power) = 48 3, and correspond to the conversion of four-fifths of the starch into maltose remaining dextrin is hydrolysed with greater difficulty According to H. Brown, it cannot have a simpler formula than  $40(C_6H_{10}O_5)H_2O$ .

The dextrin isolated from a starch conversion stopped at a stage which gives a deep brownishred colouration with iodine is termed erythrodextrinAt a later stage indine ceases to give a colouration, and the dextrin present is termed achrodertrin. These dextrins have little or no cupric-reducing action, this point being still undecided.

Dextrins are also formed by the action of hot dilute mineral acids, or of heat alone on starch The final product in this case is dextrose instead

These methods are used for the of maltose commercial preparation of dextrin

Malfitano and Moschkoff (Compt. rend. 1912, 154, 443-446) have found that starch may be converted into dextrin merely by desiccation When kept in vacuo at 25° over phospholic oxide 28 l p c of the starch was found to have become soluble in the course of 20 days authors conclude that the starch molecule is composed of dextrin complexes linked together by water molecules

Oscar von Friedrichs (Arkiv. Kem Min Geol 1913, 5, No 3, 1-14) has studied the action of various yeasts upon the dextrins Generally speaking, dextrins with higher molecular weights are not so readily attacked as those with lower.

Yeasts which split up α-methyl glucoside are capable of fermenting dextrins to a very limited extent, while Sacchsia Suaveolens, which is known to ferment  $\beta$ -methyl glucoside, is found to ferment achroodextrins energetically results support the view that  $\beta$ -glucoside linkings are present in the starch and dextrin molecules.

Crystalline dextrins may be prepared by the action of Bacillus macerans upon starches (Schardinger, Centr. Bakt Par 1911, ii 29, 188-197) By this method two dextrins designated as  $\alpha$  and  $\beta$  have been isolated, both in crystalline form.

According to Langhans (Ber. 1912, 45, 2533-2546), both forms are acctylated by acetic anhydride in presence of zinc chloride, but seission of the molecules occurs simultaneously; under this treatment the  $\alpha$ - compound gives a hexa-acetate of a diamylose, the B- a nona-acetate of a triamylose, hydrolysis of the acetates yields a diamylose and triamylose respectively, both crystalline compounds

The properties of these crystalline dextrins have been further investigated by Pringsheim and Eissler (Ber 1913, 46, 2959-2974, see D R P 279256, 1913), in which the dextiins are produced by the action of Bacillus maccians on starch and isolated by precipitation with light petroleum

In presence of a little platinum black as catalyst, l-glucosan, heated to 180°, undergoes polymerisation, and is transformed into a white amorphous substance, which exhibits the characteristic properties of a dextrin and yields dextrose when warmed with dilute sulphuric acid (Pietet, Helv. Chim. Acta, 1918, 1, 226)

Maltodextrin  $6(C_6H_{10}O_5)H_2O$  has  $[\alpha]_J+193$  6°, [a]<sub>D</sub>+181°; cupric-reducing power, 42 These figures agree with a mixture of 1 part maltose to 2 parts dextrin; but the facts (1) that it cannot be separated into maltose and dextrin by dialysis, (2) that it is not fermentable by yeasts, (3) that it is completely converted into maltose by diastase, prove maltodextrin to be a definite chemical compound To prepare it, a starch transformation is carried out at 60°-65° until  $[\alpha]_J = +198^\circ$ The solution is boiled, concentrated to a spgr of 106, and the maltose removed by fermentation. The solution is filtered, evaporated to a syrup, and digested with alcohol first of 90 p c, and then of 85 p.c This last liquid is decarted hot, and the alcohol distilled off, when maltodextrin remains; it is purified by further treatment with alcohol.

On oxidation of maltodextrin with mercuric oxide, until the cupric - reducing power has disappeared, maltodextrinic acid is obtained This behaviour proves maltodextrin to contain an aldehydo group, but the change goes further than the oxidation of this group to carboxyl (CO,H), since it splits up the terminal C12 group into a C<sub>5</sub> acid residue, which remains attached to the rest of the molecule, and a C<sub>6</sub> residue which is eliminated

495

(For a full account of the decomposition

products of starch, v STARCH )

Manufacture - The commercial products known as solid dextiin, British gum, starch gum, &c, are mixtures containing various dextrins, together with carbohydrates (copper oxide reducing substances). They consist mainly of erythrodextrin, and accordingly give a brown iodine colouration

They are prepared (1) by the action of heat on dried starch; (2) by the action of heat on acidified dried starch

The starch is first freed as much as possible from combined water by drying in suitable ovens, and then submitted to a temperature of 212°-275° in rotating sheet-iron drums heat is supplied by hot oil, rape oil being fairly When the oilgenerally used, or by direct fire bath is used, the control over the temperature is greatest, and the colour of the product can be varied at will from white to dark brown the drums are heated by direct fire, they are made to rotate on slightly inclined axes, the dried starch being fed in at the higher end of the revolving cylinder and the product discharged at the other Sheet-non ovens are also used they are constructed singly or in sets heat is supplied by a furnace, the heated an from which is drawn over the top of the ovens The material is kept continually stirred by flat iron oars. Boxes and trays are also used as converters, and, indeed, the maker has only to consider the variety and quality of product required, and to remember that the direr the starch and the lower the temperature of conversion, the whiter will be the product, and, further, that different starches yield different products, ie behave differently when submitted to the action of heat, to enable him to construct an apparatus that will suit his require-It must also be borne in mind that the conversion takes place more slowly at a low temperature

The alternative method, in which less heat is required to yield a satisfactory product, is to spray or moisten the starch either with a mixture of dilute nitile and hydrochloric acids, or with each acid singly, or with dilute oxalic acid The paste is dired and heated at 100°-120° or to 150°, till the transformation is complete, as determined by the iodine test, it must then be arrested promptly.

Payen recommended 1000 lbs starch to be moistened with 30 gallons water containing 2 lbs nitric acid (sp gr 138), the mixture to be well kneaded, made up into balls, and dried in a hot-air chamber; then powdered, spread on brass trays to the depth of 1½-2 inches, and submitted to a temperature of from 110°-120° in a hot-air oven.

The heat method is that which was most commonly used on the Continent, whereas the

496 DEXTRINS.

use of weak nitric acid found most favour in this country.

The products thus obtained appear in commerce in the form of powders varying in colour from almost white to dark brown, through every shade of light yellow and brown. They are reduced to this state after roasting, by crushing in pans or passing through rollers, and then sifting through a rotating silk screen such as is used in flour mills.

Dextrins prepared from powdered starch are used by textile manufacturers and calico printers as vehicles for colours. They are also used for all kinds of gum, paste, sizings, and in the manufacture of paper boxes, wall paper, and for a variety of other purposes.

For a method of examination of commercial dextim and related starch products, v Babington, Tingle, and Watson, J Soc Chem Ind

1918, 37, 257 T.

On heating dry starch with formic or acetic acids, the starch nucleus is broken down and esters of dextrins are formed, which are soluble in cold water The proportion of acid fixed depends on the time of treatment After 15 hours' heating with glacial acetic acid at 90°, the product just ceases to give a blue iodine colouration, and the products of the further heating are soluble in cold water When care is When care is taken to exclude moisture, and the heating is continued for 2 or 3 hours only, using equal weights of starch and glacial acetic acid, an acceylated starch, known commercially as Feculose, is obtained. This behaves like starch towards boiling water, but the jelly does not revert on standing It forms very clear flexible films, and is said to give better results than dextrin as a textile finish (see Traquair, J Soc Chem Ind 1909, 28, 288)

Destrin symps find employment in a variety of industries. They are prepared from staich by heating it with hydrochloric or sulphuric acids in precisely the manner already described for dextrose (v. Carbonydbrates), with the exception that conversion is stopped at a much earlier stage. Thus in the modern American process of manufacture of corn syrup from maize starch, less than 10 minutes' heating is required. The product evaporated to 42°-45° B forms a colourless viscous syrup, baving the composition water, 19 pc; dextrose, 38 5 pc; dextrin, 42 0 pc., ash, 0 5 pc

In America corn syrup is used extensively in making confectionery, preserves, and table syrups, being preferable to sugar or cane syrup,

as the goods are not likely to grain

According to Yano (J Chem Ind Tokyo, 1918, 21, 865), dextrin prepared by adding 10 parts dilute nitric acid (5 parts of acid of sp.gr. 1-4 and 95 parts water) to 100 parts of sweet potato starch, drying the resulting paste at about 50°, and heating it for an hour at about 150°, is a suitable substitute for gum arabic as an adhesive

Dextrin may also be prepared by the action of malt extract on gelatinised starch. E F A.

**DEXTROFORM.** A condensation product of dextrin and formaldehyde.

DEXTROSE v. CARBOHYDRATES.

DHAK GUM v Kino.

DHAURA. A gum obtained from Anogeissus latifolia (Wall), It is extensively used in India in

calico-printing; it occurs in clean straw-coloured elongated masses, sometimes honey-coloured or even brown from impurities. As an adhesive gum it is inferior in strength to gum arabic. In India, the reputation of this gum stands high with the calico printers, especially of Lucknow, and it is probable it possesses some specific peculiarity justifying the preference, since it is used with certain dyestuffs, such as with haldi (Curcuma longa [Linn]), whilst gum arabic or 'babul' is used with madder (Rubia cordifolia [Linn]) (Watts' Economic Products of India).

DHURRIN v GLUCOSIDES.

DIABASE. This name was introduced by the French mineralogist A Brongniart, in 1807, for those varieties of basalt in which the light and dark minerals, respectively felspar and augite (or as he erroneously supposed, felspar and hornblende), are distinguishable to the unaided eye As actually defined by him, the term is therefore synonymous with the diorite of Hauy (1822), whilst with the correction of augite for hornblende it becomes a synonym of the dolerite of Hauy (1822) In the latter sense it is used by some authors at the present time (v. Dolerite) Unfortunately, the term was re-defined by German petrographers, and it came to be applied to the older, or pre-Tertiary, dolerites, which differ from those of more recent date only in showing correspondingly more alteration, with the development of secondary minerals, such as chlorite In consequence of this, the name 'diabase' is now applied by most English authors to a partially altered or weathered dolerite In this sense it has an economic bearing, since rocks of this class, being of wide distribution, are much quarried for road mend-For this purpose the fresher dolerites are somewhat brittle, whilst diabases are tougher and more durable, providing the decomposi-tion has not proceeded too far There is also a There is also a tendency to use the name 'diabase' in a loose sense, like the popular terms 'greenstone,' whinstone,' 'toadstone,' and 'trap-rock'

**DIABETIN.** A trade name for a preparation of lævulose

DIACETYL v KETONES

DIACETYLDIOXIME, DIMETHYLGLYOX-IME v Ketones

DIACETYL MORPHINE v OPIUM.

**DIAL-CIBA.** A trade name for diallyl-barbituric acid.

DIALKYL BARBITURIC ACIDS v. Pyrimi-

DIALLAGE. An important rock-forming mineral belonging to the monoclinic series of the pyrovene group. It has the same composition as diopside and hedenbergite,

# Ca(Mg, Fe)(S1O<sub>3</sub>)<sub>2</sub>

but with the addition of alumina passes into augite. It differs from the other members of the pyroxene group in possessing a fine lamellar structure, due to secondary twinning and partial alteration of the material. On the surfaces of foliation the mineral displays a shining metallic sheen, and on this account it is sometimes used as an ornamental stone. The colour is grey, brown, or green. Diallage is of common occurrence as a constituent of gabbro.

L. J. S.

**DIALOGITE.** Manganese carbonate (v. Manganese and Rhodochrosite).

DIALURIC ACID, Tartronylurea

prepared by reducing alloxan with zinc and hydrochloric acid, or with sulphuretted hydrogen at the temperature of boiling water (Liebig and Wohler, Annalen, 26, 276), or with ammonium sulphide, when ammonium dialurate is obtained and is readily converted into the acid by the action of hot dilute hydrochloric acid (Gregory, Chem. Soc. Mem. 1845, n. 11). A mixture of potassium dialurate and oxalurate is obtained by adding potassium carbonate to a solution of alloxan containing potassium cyanide (Strecker, Annalen, 113, 53), it is prepared by reducing alloxantin with sodium amalgam, or dibromobarbituric acid with sulphuretted hydrogen (Baeyer, Annalen, 127, 12; 130, 133) Magnier de la Source showed that dialuric acid is obtained by prolonged boiling of uric acid with water (Bull Soc. chim 1875, 23, 529), or it can be obtained from uric acid on gentle heating with hydrochloric acid and potassium chlorate (Biltz and Damm, Ber. 1913, 46, 3662–3665) Grimaux effected its synthesis by treating tartronic acid and urea with phosphorus oxychloride (Compt rend 1879, 88, 85)

Dialuric acid forms colourless short foursided prisms, or narrow thin leaflets with rounded ends, sparingly soluble in cold, more readily so in hot water, turns red at 180°, m p 214°-215° (corr) (Biltz and Damm, lc 3664). The moist crystals or the aqueous solution rapidly absorbs oxygen from the air to form alloxan, which combines with the dialuric acid, forming alloxantin The rate at which the change takes place is illustrated by the results obtained by Hartley (Chem Soc Trans. 1905, 87, 1804), in an unsuccessful attempt to obtain the absorption spectra of dialuric acid; 0 144 gram of pure dialuric acid was dissolved by agitation and warming in 100 cc of water, and immediately afterwards the solution yielded the same series of absorption spectra as a solution of 0 322 gram of alloxantin, dissolved in 250 cc of water Alloxantin is also formed by mixing solutions of equivalent quantities of dialuric acid and of alloxan (cf Richter, Ber 1911, 44, 2155-2158). Dialuric acid is monobasic, and, contrary to the statements of Menschutkin (Ber. 1875, 8, 760; Annalen, 1876, 182, 70), forms only one series of salts of the type  $C_4H_3O_4N_2M'$  The sodium, polassium, ammonium, and barium salts are crystalline (Koech, Annalen, 1901, 315; Behrend and Friederich, Annalen, 1906, 344, 1)

crystallises in white prisms or leaflets; m.p.  $210^{\circ}-212^{\circ}$ ; gives a violet precipitate with barium hydroxide; forms the potassium salt  $C_6H_5O_5N_2K,H_2O$ , and combines with alloxan to form acetylalloxantin  $C_{10}H_8O_9N_4,H_2O$ , m.p.  $263^{\circ}-265^{\circ}$ ; benzoyldialuric acid  $C_{11}H_8O_5N_2$ , crystallises in prisms, m.p.  $209^{\circ}-210^{\circ}$ , yields with barium hydroxide a white precipitate, turning violet, and combines with alloxan to form benzoylalloxantin  $C_{16}H_{10}O_9N_4,H_2O$ , or  $1\frac{1}{2}H_2O$ , m.p.  $253^{\circ}-255^{\circ}$  (Behrend and Friederich, Annalen, 1906, 344, 1-18)

Substituted dialuric acids of the type  $CO \stackrel{\text{NH CO}}{\sim} C(OH)R$  are obtained by the condensation of alloxan with (1) aromatic ketones, eg phenacyldialuric acid, where  $R = C_6H_5$  CO  $CH_2 -$ ; (2) aromatic amines, eg. p-aminophenyltartronylurea, where

$$R = NH_2 C_6 H_4 - ;$$

(3) pyrazolone bases, eg phenylmethylpyrazolonetartronylurea, where R = | C - |

(4) phenols, e.q p-hydroxyphenyltartronylurea, where R=OH C<sub>6</sub>H<sub>4</sub>-. For the preparation and technical application of these compounds, see art ALLOXAN.

Methyl dialune and C<sub>5</sub>H<sub>6</sub>O<sub>4</sub>N, H<sub>2</sub>O may be prepared by reducing dimethyl alloxantin with sodium amalgam, crystallises in round clusters of silky needles or narrow lancet-shaped leaflets, in p. 167°-168° (corr.), or directly from theobromine on careful treatment with finely divided potassium chlorate in presence of hydrochloric and crystallises in bundles of colourless glistening filaments, many of which widen to slender narrow leaflets. The molecule of water is driven off at 110°-120° From alcohol the and crystallises in anhydrous, stout, lustrous rhombohedra, in p. 184°-185° (Biltz and Damm, Bei, 1913, 46, 3665-3667)

Dimethyldialuric acid
CO NMe CO CH OH

obtained by reducing amalic acid (tetramethylallovantin) with sulphuretted hydrogen (Maly and Andreasch, Monatsh 1882, 3, 92), or with sodium amalgam (Techow, Ber 1894, 27, 3082), forms colourless compact crystals which become red at 100° and decompose at 170° (cf Biltz and Damm, thid 3667–3668), the acid crystallises with one molecule of water, which is partly lost in vacuum and completely at 110°. The hydrated acid has mp just under 100°, and decomposes about 210°. The anhydrous acid begins to discolour at 190°, and has mp 218° (corr) with decomposition. It forms crystalline alkali salts, and reduces cold solutions of silver and copper salts.

180-Dialuric acid

the action of bromme water on 150-barbitume acid CO NH CH CO C(OH) or aminouracil or hy-

droxyxanthine (Behrend and Roosen, Ber 1888, 21, 999), crystallises in trimetric prisms sometimes a centimetre long (Weinschenk, Annalen, 1889, 251, 243), is readily soluble in water, less so in alcohol, it loses one molecule of water of crystallisation at 100°. The other molecule, which is regarded as water of constitution, is lost at 140°-150°, at which temperature the compound decomposes Isodialuric acid is converted into dialuric and by the action of bases (Koech, Annalen, 1901, 315, 246). It yields unclaim of silver salts, and combines with hydroxylamine to form two isomeric oximino- compounds. The

a- oxime forms shining plates or prisms, becomes red and decomposes at 100°; the \$\beta\$- oxime crystallises in needles which do not become red at 110° (Behrend and Roosen, Annalen, 251, 244).

Methylisodialuric acid C5H8O5N2, prepared by oxidising methylisobarbituric acid (Lehmann, Annalen, 1889, 253, 80) with bromine water, crystallises in rosette-like aggregates from water, and in contradistinction to isodialune acid, contains only I molecule of water, which 13 regarded as water of constitution M A. may be prepared by adding zine dust to sodium p-nitrotoluene sulphonate in a hot solution of caustic soda, until the liquid is decolourised, filtering and acidifying with hydrochloric acid The precipitated diaminostilbenedisulphonic acid may be purified by re-solution in sodium carbonate, and reprecipitation with acid (Leonhardt and Co D R P 38735, cf Bender and Schultz, Ber 1886, 19, 3234) May also be obtained by reducing dinitrostilbenedisulphonic acid with ferrous hydroxide and ammonia (Green and Wahl, Eng Pat 5351, 1897, Ber 1897, 30, 3100)

**DIAMOND.** Carbon crystallised in the cubic The contrast presented by the physical system characters of the two forms of crystallised carbon—diamond and graphite—is very striking Diamond is the hardest of minerals, and, indeed, of all known substances, but at the same time it is very brittle, on the other hand, graphite is one of the softest of minerals, and it is flexible and inclastic The one is colourless and transparent and a bad conductor of electricity, whilst the other is black and opaque and a good conductor. There is also a considerable difference in density, diamond, 3 52; graphite, 2 25 "I'he name diamond, in French and German Diamant, and similar in most other European

languages, is a corruption of the Latin Adamas, which was used for this mineral by Manilius (A.D. 16) and Plmy (A D 100) This came from 'Aδάμας, meaning invincible, a word applied by the Greeks to hard metals and stones similar name adamantine-spar was used by the chemist Joseph Black for coundum. Although diamond and colundum are numbered respectively 10 and 9 in the mineralogist's scale of hardness, and with no other mineral falling between the two, yet, as shown by abrasive tests, diamond is 140 times harder than corundum, and more than a thousand times harder than quartz (No 7 on the scale) It is on this high degree of hardness that all the technical applications of diamond depend, and a faceted gem never shows any signs of wear. Lapidanes assert that stones from Borneo and New South Wales are harder than those from other localities.

Crystalline Form -Crystals of diamond are almost always found singly and with faces developed on all sides, thus indicating that they grew freely from individual centies in some surrounding medium. By far the commonest form is the regular octahedron, the faces of which are often delicately marked with minute triangular pits or 'etched figures,' whilst the edges are nearly always rounded and often marked with a pronounced furrow Other forms are a hexakis-octahedron (six-faced octahedron), and less often the rhombic-dodecahedron and the cube, while crystals of distinctly tetrahedral habit are rare Nevertheless, it is probable that crystals of diamond are really hemihedral (tetrahedral-cubic), the apparent octahedron consisting of two tetrahedra interpenetrating in twinned position Distinctly formed twinned crystals are not uncommon. These are contact-twins with a face of the octahedron as twin-plane, and the two individuals flattened parallel to this plane, giving a triangular plate with re-entrant angles at the three corners These are known to the Dutch cutters as 'naadsteenen' (suture-stones). In addition to the rounded edges, noted above, the faces themselves are often curved, sometimes to such an extent that the crystals are almost spherical in form. This rounding, as well as the etched figures, indicate that the crystals have been corroded subsequent to their growth An important crystallographic character of diamond is the existence of perfect cleavages in four directions parallel to the faces of the (On the crystallography of diaoctahedion Fersmann and V Goldschmidt, mond, v ADer Diamant, Heidelberg, 1911)

Physical Characters - In its optical characters, diamond is remarkable for its very high refractive and dispersive powers, the indices being for red light (B) 2 40735, yellow (D) 2 41734, violet (H) 2 46476, and the dispersive value (H-B) 0 05741 The critical angles of total reflection corresponding with these indices are 24° 33′, 24° 26′, and 23° 56′, respectively. The angles between the facets of the brilliant form of cutting adopted for the diamond are so arranged that a ray of light entering the gem by the front facet will meet the back facets at a greater angle than the critical angle, and will be internally totally reflected, passing out again from the front of the stone, and with a chance that rays of different colours will be separately

DIAMOND 499

ected A cut stone, therefore, shows much illiancy or 'fire,' together with flashes of ismatic colours Corresponding with the high ractive index, diamond displays a high degree lustre, which is of the quality known as damantine 'lustre Uncut stones, especially ien not quite clear, and with rough rounded rfaces, present a peculiar and very characteramond is without colour and perfectly transrent The best stones are described as of the ust water' or 'blue-whites.' More often ere is a tinge of colour ('off-coloured' stones), ually pale yellow, brownish, grey, or greenish. ones of a good canary-yellow, coffee-brown, black colour are not uncommon, but those of h shades of green, blue, or red are very rare, no nature of the colouring matter is uncertain, it it is probably inorganic (eg iron and anium in the brown stones) (hanges in lour may be effected by the action of heat or / exposure to radium emanations ('rystals diamond being cubic, they should be optically otropie, but when examined under the polarisg microscope they are frequently seen to possess iomalous double refraction, especially around iclosures in the stone This is due to a state strain, which in some stones is so great that ey burst Phosphorescence is readily produced diamond by the action of sunlight, ultraolet, Rontgen, cathode, and radium rays, or mply by rubbing (triboluminescence) Diaand becomes positively electrified by friction is very transparent to the Rontgen rays; hilst glass imitations are opaque – Bem∉ a ood conductor of heat, it can be distinguished om a glass mutation by touching with the tip the tongue, diamond feeling much colder an glass. The specific heat is less than that f graphite, and it increases rapidly with the emperature

Chemical Characters — The combustibility of iamond was first proved experimentally by the lorentine Academicians in 1694 Lavoisier, in 772, found that the presence of an was necesirv, and that 'fixed air' iesulted, but it was mithson Tennant, in 1797, who first proved hat equal weights of diamond and carbon ielded equal weights of carbon dioxide onvincing experiments in this direction have een made by Davy, Dumas and Stas, A Crause (1890), and H. Moissan (1893). Powdered hamond burns readily in air at a red heat 101ssan determined the temperature of ignition n oxygen to be 690°-790°, according to Joly, t is 850° in air It burns with a small paledue flame, and in oxygen is able to support ts own combustion It is infusible even in the lectric arc; and it can be heated at high emperatures (1500°) without alteration in various gases (hydrogen, nitrogen, sulphur lioxide and trioxide, and nitrous oxide) earbon dioxide, however, at 1200° the crystals ire corroded, with formation of carbon monoxide t is unattacked by acids, caustic alkalis, iodic inhydride, hydrogen potassium sulphate, or a nixture of sedium chlorate and nitric acid, but s oxidised when heated to 180°-230° in a mixture of potassium bichromate and sulphuric acid In fused potassium nitrate or sodium carbonate at about 900° small etched figures are slowly produced; at 1200° the action is more rapid

carbon dioxide being liberated. It is acted upon by sulphur vapour at 900°, and it combines with iron, yielding steel ('iystals are etched by molten olivine (magnesium silicate) The fact that diamond gives with oxidising agents only carbon dioxide, whilst graphite yields graphitic oxide has led to the suggestion that these two forms of carbon are chemical isomerides Observations at high temperatures are somewhat contradictory; a mere blackening of the surface has often been observed, but not always confirmed C Doelter (1911), with crystals packed in charcoal or thorium oxide and heated to 2500°, obtained only a superficial blackening without any alteration in the physical characters of the material Moissan (1893), however, records the conversion into graphite at the temperature of the electric arc (about 3600°); and Parsons and Swinton (1907) found that a diamond placed in the focus of cathode rays un vacuó swelled up into a coke-like mass when the temperature reached 1890° In this connection the occurrence of cubes of graphite (cliftonite) in meteorie irons is significant, these have been supposed to be paramorphs after diamond

The ash remaining when diamond is buint amounts, for colourless crystals, to 0.02–0.05 p.c., but in the less pure carbonado it may reach 4.8 p.c.. It consists mainly of non-oxide and silica, with some lime, magnesia, and titanium. The non-and titanium may represent the colouring matter present in the stone, but the frequent presence of minute enclosures in diamond is not to be overlooked. In addition to liquid enclosures (carbon dioxide and water), the following materials have been recorded, black carbonaceous matter, ilmenite or hematite, quartz, juitle, non-pyrites, gold, chlorite (1), apophyllite, &c

Varieties—Differing in certain points from the general characters enumerated above, there are two varieties of diamond—bort and carbonado—which, for technical purposes, are more important than the puricity stals used for gens. These are crystalline aggregates, as distinct from single well-developed crystals.

Bort (boart or boort) consists of a number of individual crystals with a radial grouping around a common centre, giving rise to rounded extenor forms These are sometimes quite spherical ('shot-bort'). They are usually rough on the exterior, it being only here that the fibres, or individual crystals, have been free to develop crystal faces—in the interior these have interfered with each other's growth. Although each individual possesses the cleavage characteristic of diamond, yet for the whole mass there is no continuous cleavage. For this reason, bort is tougher than the single crystals, which readily split along the cleavage directions, and is thus better adapted for boiling, turning, and cutting tools This, no doubt, is the explanation of the common statement that bort is harder than diamond; further, since in ciystals the degree of hardness varies with the direction, a chance section of bort will present both maximum and minimum values. The rounded pieces of bort are translucent to cloudy and opaque. They are grey or black with a gleasy to metallic lustre, and, usually, a peculiar leaden appearance; sp.gr. 3.50. In the trade

DIAMOND. 500

the term bort also includes fragments (such as those obtained by bruting), and all crystals and stones that are useless for gem purposes. Such material is of value as an abrasive, but not for tools.

Carbonado, or 'black diamond' (known in the trade as 'carbon' or 'carbonate'), is a finely granular crystalline material, dull, black, and opaque, and often more or less porous, with somewhat the appearance of coke. It forms irregularly-shaped masses, and consists of a confused aggregate of minute crystal grains of diamond. It therefore presents no cleavage as a whole, and is consequently tougher and less frangible than crystals It is less pure than ordinary diamond, yielding more ash (up to 48 pc) when burnt. An analysis of the ash gave Fe<sub>2</sub>O<sub>3</sub>, 53 3, SiO<sub>2</sub> 33 1, CaO 13 2 pc, MgO trace The sp gr is less, 3 15-3 34 (the value for crystals being between the limits 3 516-3 525) The largest known piece of carbonado was found in Bahia, Brazil, in 1895 It weighed 631 9 grams, that is, slightly more than the famous 'Cullinan' diamond (which weighed 6212 grams) Both carbonado and bort show considerable variations in texture, and with increasing coarseness of grain they may pass insensibly into ordinary diamond

Occurrence -India, from very remote times until the middle of the eighteenth century, was the only source of diamond (with the unimportant exception of Borneo) Since the discovery of the Brazilian and South African deposits the output has gradually fallen off, amounting in 1916 to only 20 carats. The amounting in 1916 to only 20 carats secondary deposits have, however, only been worked by native methods, and the original deposits have not been discovered. Indian diamonds, being of the best gem-quality, there is thus a possibility of further developments. They occur associated with pebbles of jasper and vein-quartz in thin beds of conglomerate in the ancient sedimentary rocks (sandstones and shales) of the Vindhyan system (probably pre-Cambrian), which rest directly on the crystalline rocks With the weathering of these strata, the diamonds are left on the surface or are accumulated in the alluvial deposits of the The districts where mining present rivers has been done fall into three main groups: a southern group in the basins of the Pennar, Kistna, and Godavaii rivers, an eastern group in the Mahandi valley, and a northern group near Panna in Bundelkhand A doubtful occurrence of diamond in pegmatite has been described from Wajra Karur near Bellary, and, unfortunately, nothing is known as to whence the diamonds found in the ancient sedimentary rocks were derived (On Indian diamonds, v Manual of the Geol of India, vol 3, Economic Geology, 1881, by V. Ball, vol. 4, Mineralogy, 1887, by F. R. Mallet)
In Brazil, diamonds were discovered about

1725 in the alluvial gold-washings at Tejuco (now Diamantina) in Minas Geraaes, and, although they have been since found in several other districts, notably in Bahia, this has remained the principal diamond-mining centre. Here, as in India, the diamond-bearing alluvial deposits have been derived from conglomerates and sandstones (including the flexible sandstone known as itacolumite) of considerable geological Finally, the stones are cleaned by boiling in a

age, and the original rock from which these were derived is not known. The Brazilian deposits are, however, remarkable for the variety of minerals found as well-worn pebbles ('favas') in association with the diamond; and the nature of these minerals, or indicators, has led to the suggestion that they, together with the diamonds, originally came from quartz-veins. (On Brazilian diamonds, see Mineralogical Papers by O. A Derby and by E Hussak, also E Hussak, Os Satellites do Diamante, Rio de Janeiro, 1917, H. Preston, J. Soc. Arts, 1909, lvm 101.)

In South Africa, diamonds were first discovered in 1867 near Hopetown on the Orange River. In 1868 the important workings ('river diggings') on the Vaal River were commenced; and in 1870-1871 the diamonds were traced to deposits of an unique type, in the neighbourhood of which the town of Kimberley in Griqualand West, Cape Province, very quickly sprung up. Here are situated the famous mines De Beers, Kimberley, Dutoitspan, Bultfontein, and Wes-Other mines of the same type are the Jagersfontein and Koffyfontein mines in Orange Free State, and the great Premier mine (discovered in 1902) near Pretoria in the Transvaal. The diamond-bearing rock of these mines fills volcanic pipes, 200-300 yards (in the case of the Premier mine half a mile) across, penetrating vertically the surrounding beds of basalt, shale, diabase, and quartzite, and extending to un-known depths The rock, known as kimberlite, or locally as 'blue ground,' consists mainly of a hydrated magnesium silicate with much the same composition as serpentine It contains boulders and broken fragments of various rocks (basalt, shale, sandstone, quartzite, granite, mica-schist, eclogite, &c ) and minerals (ilmenite, pyrope, enstatite, chrome-diposide, iron-pyrites, &c), and is of the nature of a volcanic agglomerate. Diamond is present in this rock on an average of one part in forty millions, and in the richest part of the Kimberley mine one part in two millions Numerous pipes of a similar character, but containing few or no diamonds, are scattered over a wide area in South Africa The diamond was brought from below up with the igneous material, which must have been derived from a basic magma rich in olivine. Although the origin of diamond has been the subject of much discussion, there seems no reason to doubt but that it crystallised from this basic magma The rare presence of diamonds embedded in boulders of eclogite (a garnetpyroxene rock) found in the blue ground has led to the suggestion that this is the motherrock; but it is quite conceivable that the mineral crystallised from more than one kind of basic magma

The early open workings ('dry diggings') at the Kimberley mines were soon replaced by a regular system of underground mining. The blue ground, when brought to the surface, is either directly crushed or is spread on floors and exposed to the action of the weather for about a year, when it is crumbly enough to enable the heavy minerals to be separated by washing. From this concentrate the diamonds are separated by means of a mechanical sorting table coated with grease, to which the diamonds adhere, whilst the other minerals pass over. DIAMOND. 501

solution of caustic soda and in aqua regia or hydrofluoric acid Diamonds also occur in gravels in the Somabula Forest in Southern Rhodesia, and kimberlite pipes have been described as present in this region. In 1908 large numbers of small diamonds were found in the sand-dunes on Luderitz Bay in South-West Africa; in this case the source of the diamonds have not yet been traced. The output of South African diamonds amounted in 1913 to over five million carats (approximately one ton), valued at 11,389,807l (On South African diamonds, v. G. F. Williams, The Diamond Mines of South Africa, 2nd edit. New York, 1907, P. A. Wagner, The Diamond Fields of Southern Africa, Johannesburg, 1914.)

Other diamond-producing countries of less importance are Borneo, New South Wales, and British Guiana. Finds have been reported from many of the states of North America, in British Columbia, Mexico, Dutch Guiana, Russian Lapland, the Ural Mountains, Siberia, China, Western Australia, South Australia, Queensland, Tasmania, Belgian Congo, Gold Coast, and Liberia. In most of these cases the mineral has been found as a few scattered stones in alluvial gold washings. But in Arkansas and British Columbia it has been found in an altered (scrpentinised) peridotite of much the same character as the South African' blue ground'

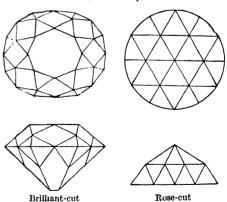

The presence of diamond in certain meteorites is of special interest. It was first observed in the stone which fell on September 4, 1886, near the village of Novo-Urei on the Alatyr river in Govt Pensa, Russia This stone is composed of olivine (675 pc) and augite (238 pc), together with nickel-iron, troilite, chromite, black carbonaceous matter, and about 1 pc of diamond, the last as minute greyish grains As dull black grains it has also been found in the meteoric stone of Carcote, Chili In several, though not in all, of the masses of meteoric iron from Cañon Diablo in Arizona, it has been found as colourless crystals, and as black and colourless grains, the largest 1 mm across It is also recorded from the meteoric iron of The cubic form of graphite Magura, Hungary (cliftonite), probably a pseudomorph after diamond, has been found in the meteoric irons of Youndegin (Western Australia), Smithville (Tennessee), Crosby's Creek (Tennessee), and Magura (Hungary)

Origin and Artificial Production —The occurrence of diamond in acid igneous rocks and in quartz-veins is very doubtful. On the other hand, its presence in basic igneous rocks is well established; eg in kimberlite and eclogite in South Africa, in serpentinised peridotite in Arkansas and British Columbia, and in diabase in New South Wales; whilst in meteoric stones the matrix is also of the same general character In these cases the diamond is very probably present as a primary mineral, and one of the first constituents to crystallise out from the In addition, we have basic silicate magma the occurrence of diamond in the nickel-iron of meteorites This may be regarded as a magma of a still more basic type, and it is thus probable that diamond may crystallise from basic magmas of widely varying composition

Many attempts have naturally been made to constrain the abundant element carbon to

crystallise as the rare and valuable diamond. but, as yet, with no great measure of success. The results have in many cases been doubtful, and have often not been confirmed. The products are always microscopic and their identification a matter of difficulty In some cases the very hard carbides of silicon, &c , have probably been mistaken for diamond The experiments of I Friedlander (1898), and of R. von Hasslinger (1902-1903), in which carbon was dissolved in molten magnesium silicate (olivine or kimberlite), bear some relation to the natural occurrences, but doubts have been expressed as to whether the microscopic crystals so obtained were really diamond E de Boismenn (Fabrication synthétique du diamant, Paris, 1913) states that he obtained crystals up to 2 mm across by the electrolysis of fused calcium carbide The only method, however, that has been amply confirmed is that first used by R S Marsden (Proc R. Soc. Edinburgh, 1881, x1 20) and elaborated by Moissan (1893-1896, Le Four électrique, Paris, 1897, and The Electric Furnace, London, 1904), in which carbon is dissolved in silver or iron at a high temperature and the mass suddenly cooled by immersion in water or lead A contracting crust is so formed and the molten interior subjected to great pressure Sir C A Parsons (Bakerian Lecture, Phil Trans 1919, A 220, 67, and J Inst Metals, 1918, xx) from a long series of experiments, however, concludes that pressure is not a necessary condition, and that the diamond has been formed from gases, probably carbon monoxide, occluded in the iron. O. Ruff (Zeitsch. anorg Chem 1917, 99, 73), in a systematic repetition of the various methods, also obtained negative results except by Moissan's method The presence of microscopic diamonds in certain kinds of hard steel should finally be noted.

Applications—The value of diamond as a gem depends on its high degree of hardness, enabling it to resist wear, and its high refractive and dispersive power. These optical characters are, however, only brought into full play when the stone is faceted in a particular manner;

and for this reason, old stones cut by Indian lapidaries have often been re-out. The form most suited for this purpose is the brilliant-cut, and stones so cut are known as brilliants. The rose-cut, or rosette, is only used for quite small stones usually mounted in number as a surround. The accompanying figures show a brilliant

502 DIAMOND.

viewed on the large front facet, or table, and a side-view, and the rose-cut, viewed from above and the side. Being the hardest known material, diamond can only be worked very slowly and tediously with its own powder. The groundform of the brilliant is approximately an octahedron, and this can be obtained, if necessary, by cleavage, or more safely by the modern method of sawing with a thin metal disc chaiged with diamond dust. The brilliant is then roughly shaped out by jubbing two diamonds to other—a process known as bruting. The final grinding and polishing of the facets is performed on a rapidly revolving cast-iron disc fed with diamond dust and olive-oil.

The large historical diamonds with their associations of mystery and romance are mostly of Indian origin, but these are now eclipsed by the numerous, much larger stones found in The largest Indian stone still South Africa preserved is the 'Koh-i-noor,' which was re-cut in England in 1852 as a brilliant of 106 to carats 1 (=21 786 grams). The largest Brazilian stone, the 'Star of the South,' found in 1853, weighed in the rough 254½ 'carats,' and when cut 125 'carats' The largest known crystal of diamond is the 'Cullinan,' which was found in 1905 in the Premier mine, Transvaal This showed a large cleavage surface, and was only a portion, probably about half, of the complete crystal The portion as found weighed 6212 grams (3106 metric carats, or nearly 1 lb 6 ozs avoirdupois) Being too large to cut as a single stone, it was cleaved and cut as mine larger gems (weighing from 106 04 to 0 88 grams) and ninety-six small brilliants, the yield of cut material amounting to 34½ p.c. The 'Cullman,' although the largest crystal, is not the largest piece of diamond that has hitherto been dis-A mass of carbonado weighing 631 9 grams was found in 1895 in Bahia, Biazil

As an abrasive, diamond powder is the most effective agent available It is the only material with which diamond itself can be worked, and it is much used by lapidaries for cutting other hard stones A thin disc of soft iron charged on the edge with diamond powder is used for sawing stones, both for ornamental purposes and in the preparation of thin microscopic sections of rocks. The small steel tools used by engravers of cameos and intaglios, and also the steel points used for boring precious stones, &c, are charged with diamond dust. The material used for abrasive purposes, though included in the trade under the term bort, consists largely of the waste material from shaping the better stones as brilliants, and also the less clear and spotted crystals not suitable for cutting as gems It is crushed in a diamond-mortar, splinters suitable for other purposes being picked out under a magnifying-glass, and the remainder reduced to a fine powder

The glazier's diamond is a crystal or fragment bounded by two rounded crystal-faces meeting in a curved, or cusped, cutting edge For writing, drawing, and engraving (e.g. fine scales and rulings) on glass, metal, stones, ivory, &c) fine splinters are used, or the diamond may be cut to a rounded point or chisel-edge. Diamond points are also used for drilling hard stones, glass, porcelain, teeth &c.

drilling hard stones, glass, porcelain, teeth, &c Carbonado and bort, by reason of their absence of cleavage, are much more suitable than ordinary diamond for mounting as small fragments (2-3 carats in weight) as cutting tools which may be subjected to shocks These are mounted in the crowns of rock-drills, used in tunnelling, mining, and sinking bore-holes for artesian wells, &c , and on the edges of blade, band, circular, or wire saws for sawing large blocks of marble, granite, &c Fragments, either in a rough form, or fashioned to a suitable shape, are mounted as lathe tools for working stone, metal, &c For example, for turning electric-light carbons, the edges of watch-glasses, finishing accurate turning work of the hard steel axles of instruments and machines of precision, boring cannon, forming the sharp-edged furrows on the gunding surfaces of millstones, for dressing emery wheels, &c

Small cleavage plates or flat crystals of diamond drilled from each side with fine conical holes are used for drawing fine wire, down to 0.01 mm in diameter. For the tantalum, tungsten, and osmium filaments of electric lamps the metal is forced by pressure through the hole. Bored diamonds are also used for the pivot-supports of delicate instruments, such as chronometers, electric meters, &c.

The application of diamond for optical purposes is limited by the high cost and difficulty of working Diamond lenses would need to have a much slighter curvature than those of glass, and they would be immune from scratching Microscope objectives with such lenses were constructed by Pritchard under the direction of C. R. Goring, in 1824–1826. A hemisphere of diamond would also increase considerably the range and durability of refractometers.

DIANTHINE v AZO- COLOURING MATTERS DIAPHTHERIN, DIAPHTHOL, DIASPIRIN, SYNTHETIC DRUGS

DIARSENAL. Canadian name for salvarsan DIASPIRIN. Trade name for succinyl salicylic acid.

DIASPORE. A native hydrated alumina, Al<sub>2</sub>O<sub>3</sub> H<sub>2</sub>O or AlO(OH), crystallising in the orthorhombic system and isomorphous with goethite and manganite. It is usually found as scales or foliated masses with a perfect cleavage in one direction on which the lustre is pearly but it is readily distinguished from other tohated minerals (mica, &c) by its much greater hardness  $(H = 6\frac{1}{2} - 7)$ . Sp gr 34 When heated before the blowpipe it decrepitates violently, breaking up into pearly white scales (hence the name diaspore, from  $\delta i\alpha\sigma\pi\epsilon i\rho\epsilon\nu$ , to scatter) In colour, it is usually grey or yellowish-brown, but pale-violet crystals are also found usually found as an alteration product of corundum and emery, but occurs also as a mineral of contact-metamorphic origin in crystalline limestones It is of importance as a constituent of bauxite, and in a particular type of bauxite, called diasporite, occurring in crystalline limestone in the Bihar Mountains, Hungary, it constitutes the bulk of the material

DIASTASE or Amylase is the name given to the enzyme or mixture of enzymes which converts starch and glycogen into maltose. In France, the word 'diastase' is used as a general term for all enzymes, a custom which causes considerable confusion, and which it is to be hoped will lapse.

Diastase is very widely distributed in plants and in animals—it is found in blood serum, in muscle, liver and panereas, and particularly in the saliva, this latter enzyme being long known under the name ptyulin

The power of genminated bailey to hydrolyse starch was discovered by Kirchoff in 1814, and the enzyme preparation was first made by Payen and Persoz in 1833. Diastase is found very generally in the leaves and twigs, in the germinating seeds, in the bark, in the pollen grains, and in the latex of plants. It occurs in yeast and in most of the mould fung, the enzyme of Aspergillus orizæ, the so-called Taka duastase being well known on account of its industrial use in the manufacture of the Japanese beverage, koji.

Diastase, like all other enzymes, has not been prepared in anything approaching a pure state. Considerable uncertainty exists also as to whether it is a single enzyme or a mixture of enzymes acting in turn to convert starch into dextrin and dextrin into maltose. Modern evidence favours the view that it consists of a starch-liquefying enzyme or amilopectase, and a saccharifying enzyme able to hydrolyse soluble starch, but without much action on raw starch until this has been rendered soluble by the amylopectase. The two enzymes are found together, but in unequal proportions. Wheaten flour, for example, frequently has a deficiency of liquefying enzyme

There are well-marked differences between the enzymes present in resting barley and in malt (cf. Lintner and Eckhardt, Zeitsch. Ges. Brauw. 1899, 389; J. L. Baker, Chem. Soc. Trans. 1902, 81, 1177), one of the chief of these being that the disatase of raw grain possesses little if any starch-liquefying power. Baker has shown that the products of hydrolysis of starch by alcohol-precipitated enzymes from the two sources, are not the same. Brown and Morris have termed the enzyme of resting barley 'translocation disatase,' that of malt 'secretion disatase' (Chem Soc Trans 1890, 58, 458. 1893, 63, 604) They regarded these as not only different in their actions, but as formed from different materials. This latter assumption has been disputed (cf. Ling, J. Inst. Brewing, 1908, 14, 494, Ford and Guthrie, Ic., 1908, 14, 61)

Some authors consider the saccharifying enzyme to be a mixture, attributing a different enzyme to each stage in the simplification of the starch molecule. It is impossible at present to make any definite statement on this point. In support of it, it appears that exposure to a temperature of 68° acts more injuriously on the conversion of dextrin to maltose than on that of starch into dextrin. Heating diastase does not affect the liquiditying power, though the saccharifying action largely disappears

The quantity of diastase contained in the bailey grain increases gradually in the course of germination—it is said to reach a maximum in about 8 or 9 days, when the plumules are twice as long as the grains.

Diastase as it exists in cereals is partly present as an insoluble zymogen in combination with protein substances which are capable of attack by pepsin; in solution the enzyme is free and unaltered by pepsin. The dissolved enzyme is more active as the amount of nitrogen in solution increases

Preparation —A great variety of methods have been proposed for the preparation of diastase, the majority of these starting from malt According to O'Sullivan (Chem Soc Trans 1884, 45, 2), finely ground pale barley malt is saturated with water, adding enough to slightly cover it and after 3-4 hours as much of the solution as possible is expressed by means of a filter press. After filtering, alcohol (sp gr. 0 83) is added, as long as a flocculent precipitate forms, the addition being discontinued as soon as the liquid becomes opalescent or milky. The precipitate is collected, washed with alcohol of increasing strength until dehydrated, pressed between cloth and dried in vació over sulphuric acid.

Lintner (J pr Chem 34, 378) treats 1 part of green barley malt or flour of air-dried malt with 2 to 4 parts of 20 pc alcohol for 24 hours, and precipitates the extract with 2 the volumes of absolute alcohol. The precipitate is washed with alcohol and ether to dehydrate it, and dried in ració

Loew extracts germinated barley with 4 p c. alcohol, and precipitates the extract with basic lead acctate. The precipitate is suspended in water, lead removed with hydrogen sulphide, and the enzyme precipitated with a mixture of alcohol and ether.

Wroblewsky extracts finely powdered malt, first with 70 pc and then twice with 45 pc alcohol Alcohol is added to the two last extracts until 70 pc is present, the precipitate formed is collected, washed with alcohol and ether, and dried.

For further purification, both Wroblewsky

504 DIASTASE.

and Osborne and Campbell dissolve the enzyme in water, and precipitate it with ammonium sulphate, which is added drop by drop, until the liquid contains 50 p.c. On standing, a very active yellowish flaky precipitate is obtained

Green barley malt may also be extracted with glycerol, and the diastase precipitated by alcohol Effront extracts with water and induces alcoholic fermentation in the extract so as to remove carbohydrate and protein matter. It is then filtered and the diastase precipitated by alcohol

Animal diastase is best obtained from saliva Cohnheim uses freshly prepared calcium phosphate as precipitant, extracts this precipitate with water, and adds alcohol to obtain the enzyme. Alcohol is also used for direct precipitation, likewise ammonium sulphate. Von Wittich extracts pancreas diastase with glycerol.

For the preparation of an active diastatic extract for laboratory use, ground malt should be extracted with twenty times its weight of distilled water at 21° for 3 hours and filtered bright.

The diastase of Aspergillus origae is sold in commerce as Taka-diastase. A pure form can be prepared from the commercial article by extracting with water, precipitating with ammonium sulphate, dissolving the precipitate in water, dialysing and finally precipitating fractionally with alcohol

Preparations of diastase obtained as described above are colourless, amorphous, and friable, readily dissolving in water, but if allowed to dry without being dehydrated, they are horny and not easily penetrated by water. They invariably contain ash, which consists of potassium, calcium, and magnesium phosphates, with a trace of sulphate. They give a deep blue colour with a 1 pc alcoholic solution of gum guaiacum and hydrogen peroxide.

Linther's diastase gave the reactions of the proteins, and was found to contain C, 46 66 pc; H, 7 35 pc; N, 10 42 pc; S, 1 12 pc, calculated on the ash-free product. Osborne (Ber. 1898, 31, 254) found for his most active preparation, which had a diastatic power of 600 and contained 0 66 pc of ash, C=52 5 pc, H=672 pc, N=161 pc, S=19 pc; and Wroblewsky gives N=165 pc for his purest diastase. Both authors regarded diastase as a protein combined, according to Osborne, with a proteose

The most recent work of Frankel and Hamburg (Betr Chem Physiol n. Path, 1906, 8, 389) leads to the conclusion that diastase contains neither protein groups nor reducing carbohydrates in its molecule. Impurities were removed from the enzyme solution with lead acetate, the solution sterilised by filtration, and further purified by fermentation with a yeast which had been rendered nitrogen-hungry. This preparation could be divided by dialysis into two distinct enzymes, one of which—the saccharifying—passed through the paper, while the other—the liquefying—was left behind. It showed absence of typical protein reactions, but contained a pentose in small amount.

The purified diastase preparations obtained by Pribram (Biochem Zeitsch 1912, 44, 293) from malt extract contained 77 p c of nitrogen and 15 p c of ash; one-sixth of the nitrogenous matter separated as a coagulum on heating. The filtrate on hydrolysis with sulphuric acid

yielded a reducing substance which was considered to be a polycarbohydrate acid which existed in the enzyme in combination with a simple polypeptide. The purified diastase was inactive, but is activated by the addition of traces of lactic acid.

Particularly active preparations have been obtained by Sherman and Schlesinger (J. Amer. Chem Soc 1913, 35, 1617) by extracting ground malt with two and a half times its weight of water or very dilute acid phosphate solutions at as low a temperature as possible, with subsequent dialysis, followed by fractional precipitation with alcohol or acetone. The products obtained had a diastatic power of 1800–2200 on the Lintner scale

The most active preparations contained most nitrogen—about 14 pc in maximum. When tested by the Van Slyke method they contained combined nitrogen in all the usual eight forms, the proportions being within the range of variation shown by typical protein substances. The optimum hydrogen ion concentration expressed by Sorensen's exponent was between  $p_{\rm H}^+$  4 2 and 4·6 (J Amer. Chem. Soc. 1915, 37, 623) The purified amylases obtained from the pancreas and from malt are similar in physical properties, show the same qualitative reactions

the pancreas and from malt are similar in physical properties, show the same qualitative reactions and have the same percentage of nitrogen distributed in the same way among the different types of amino acid radicals (J. Amer. Chem. Soc. 1915, 37, 1305)

The activity of diastase is very greatly influenced by the nature of the substrate on which it acts, more particularly as to whether this is alkaline or acid Certain substances. such as the amphoteric amino- acids and asparagine, also ammonium and calcium phosphate, increase the activity, asparagine being especially effective in some instances. Vegetable diastase exhibits the maximum activity in presence of traces of weak organic acids. The very smallest quantities of alkali stop action, though this begins again as soon as the alkali is neutralised. In reality, the above accelerating substances are all of acid nature, and the apparently favourable effect of acid is due not to the acid per se, but to its neutralising alkaline impurities present. Maximum activity is attained in neutral (in the sense that water is neutral) solution. Minute traces of metallic impurities have an adverse influence. The temperature of maximum activity of diastase is about 55°; heated above this, it begins to show decomposition.

Estimation of diastatic power - Since it has not been obtained in a pure state, the absolute estimation of diastase is an impossibility; moreover, the very great influence of external conditions on diastatic activity, to which allusion has been already made, makes it difficult to do more than compare the relative activities of a number of materials under precisely similar As this is an important operation conditions in brewery control, the methods of analysis have been accurately laid down. The diastatic power is often termed the Lintner value, and expressed in degrees Lintner. The standard is 100° when 0 1 c.c. of a 5 p.c. solution of malt, acting on a 2 p.c solution of soluble starch for 1 hour at 70°F, produces reducing sugar equivalent to 5 c.c. of Fehling's (Barreswil's) solution. To obtain accurate results, great stress must be laid on the purity of the distilled water and soluble starch used: commercial starches are frequently alkaline. All work must be carried out in hard-glass apparatus (cf. Ford, J. Soc.

Chem Ind 1904, 23, 8)

The method adopted by the Malt Analysis Committee of the Institute of Brewing (J Inst Brewing, 1906) for malt, is as follows: 25 grams ground malt are extracted with 500 cc, of distilled water for 30 hours at 70°F, and filtered bright 3 cc. is allowed to act on 100 cc of 2 pc. soluble starch at 70°F for 1 hour Diastatic action is then stopped by the addition of 10 cc N/10-sodium hydroxide, and the liquid made up to 200 cc. Sugar is then determined either volumetrically or gravimetrically. The results are calculated by the formula

### Diastatic power=1000/xy

where x=the number of c.c of malt extract contained in 100 c c. of the fully diluted starch-conversion liquid, and y=the number of cc. of the same liquid required to reduce 5 c c. of Fehling's solution. When the diastatic capacity exceeds 50°, 2 c c or less of malt extract are taken, particularly for the malts over 80° used by distillers and vinegar makers. The diastatic power of English brewing malt ranges between 35° and 40°, that of green malt from 110°-125°, showing that a large proportion of the enzyme is destroyed during the kilning

Lintner tests solid preparations of the purified enzyme by dissolving 0.2 to 0.5 gram in 50 c c water and adding to a series of test-tubes, each containing 10 c c of 2 p c soluble starch solution, 0.1, 0.2, &c, up to 1 c c of the enzyme solution. After an hour, each tube is boiled in the water-bath with 5 c c of Fehling's solution, and that determined in which the copper solution is just completely reduced. A second series enables this point to be ascertained with

greater accuracy.

Similar methods have been based on the colourations with iodine, shown by starch and dextrin solutions. Wohlgemuth sets increasing quantities of enzyme in a series of tubes with 5 c c of a 1 p c starch solution under precisely similar conditions. After 30 to 60 minutes at 40°, the tubes are cooled in ice and a drop of N/10 iodine solution added. Colours varying from dark-blue, blue-violet, reddish-yellow, and yellow are obtained. Wohlgemuth selects the tube in which the violet shows as indicating complete conversion to dextrin.

Diastase, like other enzymes which act on carbohydrates, is much affected by the products of its activity with which it forms adsorption compounds—hence the peculiarities exhibited in a starch conversion. Provided that the temperature and other conditions selected are such that the enzyme is not destroyed, the diastase recovered at the end of a reaction is just as active towards a second quantity of starch as an equal portion of fresh enzyme. Diastase is thus a true catalyst (cf. Van Laer, Bull Soc. chim. Belg. 1912, 26, 223).

Uses —Diastase plays a most important part in the brewing, distilling, and baking industries Malt extracts, concentrated in vacus at a low

temperature to viscid syrups, are largely used by bread bakers and in some food preparations. Considerable quantities of such active preparations, made from malts of high diastatic power, also find employment in laundries for the purpose of removing starch from stiff collars, shirts, &c. (See also articles STARCH. FERMENTATION; HYDROLYSIS)

E. F. A.

DIATOMITE (Diatomaceous Earth, Infusorial Earth, Tripolite or Tripoli; Ger Kieselguhr, Bergmehl) A form of opaline silica consisting of the siliceous remains of diatoms (Diatomaceæ) These are unicellular, free-swimming plants belonging to the large group of Algæ. The cell-wall, or frustule, of each minute individual consists of two shields or valves of siliceous material with elaborate and beautiful ornamentation More than 10,000 species of diatoms have been described, they vary considerably in form—fusiform elliptical, discoidal, globular, and accoular Material composed of individuals of the acicular form, the length of which varies from 0 093 to 0 156 mm and the thickness 0 00156-0 00468 mm, is best suited for technical purposes Diatoms multiply extremely rapidly and inhabit both fresh and salt water, being more abundant in cold latitudes On death, their remains accumulate, under certain conditions, at the bottom of swamps, lakes, or the open ocean Besides being formed at the present day, such deposits are also met with in strata of Pleistocene and Tertiary age

Diatomite is a loose, pulverulent material with a mealy or earthy texture, resembling soft chalk or dried clay in appearance. It is friable between the fingers with a harsh feel, and grates between the teeth In colour it is white, grey, yellowish, brownish, or greenish. It is very light, floating on water, sp gr of air-dried material 0.24 and of calcined 0.34. Its high degree of porosity depends on the fact that the shells of the diatoms are hollow material absorbs four or five times its weight of water Further, it is a bad conductor of heat, electricity, and sound, and is resistant to heat and most chemicals. Of acids, only hydrofluoric attacks it, but it is slowly dissolved by a hot solution of caustic alkali Chemically it consists of hydrated silica, mixed with various impurities, such as sand, hydroxides of iron, clayey, calcareous, and organic matter p c. of SiO2 may be present

Analysis I, is of white material (dried at 105°) from Auxillac, Cantal, Auvergne; II, of green material from Auxillac; III, from Loch Cuthir (or Quire), Skye, Scotland; IV, from Richmond, Virginia, and V, of Tripolite from Bilin, Bohemia (including also SO<sub>3</sub> 0 12, P<sub>2</sub>O<sub>5</sub>

0.24, NH<sub>4</sub> 0 03).

506 DIATOMITE.

Tripolite (Ger. Tripel, Polierschiefer=polishing shale) differs from diatomite in being more compact with a laminated structure and consequently less light (sp gr 186) and porous merely represents the same material of a greater

geological (Tertiary) age

The most extensively worked deposits of typical diatomite (Kieselguhr) are those on the Luneburger-Heide (heath) in Hanover beds with a thickness of 10-15 metres occur in The uppermost basins in Pleistocene sands layers are white, below they are grey, and at the bottom of the deposit green. The green material contains from 15 to 30 p.c. of organic matter, sufficient for calcination without A bed of 5-7 metres covered addition of fuel by Tertiary clay and basalt is worked at Vogels-berg near Altenschluf in Hesse Similar deposits of recent to Miocene age are also widely distributed in the volcanic region of central France (Departments of Cantal and Puy-de-Dôme) the material is known as randannite and ceyssatite, from Randanne and Coyssat respectively, and it is worked commercially under the name tellurine (On the French and German deposits, see C Schmidt, Ann des Mines, Paris, 1910, xvii. 370) Deposits are met with in peat-bogs at several places in Scotland, and beds up to 40 feet in thickness of good quality material are now worked at Loch Curthin (or Quire) in the parish of Kilmuir in Skye (W. I. Macadam, Min Mag 1884, vi 87, 1886, vii 30, 35, 1889, viii 135 Special Reports on the Mineral Resources of Great Britain, Mem Geol Survey, 1916, vol v) Similar deposits also occur in Co. Antrim (J H Pollok, Sei Proc R Dublin Sec 1899, ix 33) Extensive deposits, many of them of Tertiary age, are of wide distribution in the United States, especially in California, (H. Ries, Economic Geology, New York, 1916). Other localities are Monte Amiata in Tuscany, Victoria, 1 Norway, Denmark, Hungary, Algeria Chili, &c The typical tripolite forms yellowishwhite bands 0.5-1.5 m thick in beds of clay, gypsum, and 'Saugschiefer' (absorbentshale) in a Tertiary basin near Bilin in Bohemia

In the preparation of the material for the market, that of the purer white quality, after being dug out from open pits, is simply air dried in the open or in sheds Organic matter is removed by calcination. Less pure material containing sand, &c, is treated by washing and sedimentation Iron is removed by the action of acids

The varied uses of diatomite depend on its peculiar properties of porosity, lightness, nonconductivity, resistance to heat and acids It was used by the Greeks and Romans for making light fire-proof tiles, and in the middle ages was mixed with meal for bread, under the impression that it had a medicinal value an absorbent it has been much used with nitroglycerine for the manufacture of dynamite. The so-called dry sulphuric acid is prepared by saturating calcined diatomite with three or four times its weight of acid Such material can be transported with little risk Diatomite packed around carboys of acid will soak up leakage in case the vessels become cracked It has also been used as an absorbent of bromine, dis-

On Australian deposits, see Bull Imp Inst., London, 1916, xiv 40.

infectants, and liquid manures. On account of its non-conductive properties it is used, sometimes with asbestos, as a light packing material for boilers, steam-pipes, cookingstoves, safes, refrigerators and refrigerating apparatus, fire-proof and sound-proof floors and partitions of buildings, bulkheads of ships. Mixed with clay, lime, sawdust, &c, it can be used in the manufacture of fire-proof bricks and tiles, and having a low coefficient of expansion such material is specially adapted for making tubes, models, &c. It is used in the manufacture of various cements and artificial stones. Mixed with magnesia cement it gives a fire-proof cement for stoves, with shellac, scaling-wax and gramophone records are made It is also used as a filtering material for liquids and gases, and various liquids (wine, beer, acids, oil, syrups) can be clarified by stirring with 1 p c of diatomite and allowing to settle. As a filler it is employed in the manufacture of rubber, cotton fabrics, paints, safety matches, paper, papier-mâché, soap, scouring-powders, tooth-powders, &c Fused with calcium and magnesium borates it yields a non-cracking glass for glazes and enamels, which can also be used for painting on glass. As a source of silica, it is used in the preparation of sodium silicate, ultramarine, smalt, &c Finally, as an abrasive (qv) it, particularly the tripolite variety, is used for polishing metals and stoves (Ref. B. Dammer and O. Tietze, Die Nutzbaren Mineralien, Stuttgart, 1913, vol 1, Diatomaceous Earths (Kieselguhr) and their Utilisation, Bull. Imp. Inst London, 1905, m 88-103 L J S

DIAZINE BLACK, -BLUE, -GREEN v Azo-COLOURING MATTERS

DIAZO- COMPOUNDS. These organic substances, like the azo- compounds, contain the characteristic group  $-N_2$ -, but whereas, in the latter series, this bivalent radical is invariably attached to two carbon atoms, CN, C, in the former it is generally, although not invariably combined with only one carbon atom, the other valency being satisfied by (1) an electro-negative 100  $\overline{A}c$  in the diazonium salls  $CN_2\overline{A}c$ , (2) an oxygen atom in the diazohydroxides ('diazohydrates')  $CN_2$  OH and diazo-oxides ('diazotates')  $CN_2$  OR, (3) a nitrogen atom in diazoamines (diazoamino- compounds)

CN, NHR

C·N.·NH·C;

and diazoimines (azimino-compounds)

(4) a sulphur atom in diazosulphonates

CN2 SO3K

and diazosulphides C  $N_2$  S  $N_2$  C The diazocyanides C  $N_2$  CN contain the azogroup attached to two carbon atoms, one of which belongs to a cyanogen group, and these compounds which, in general, are distinctly coloured, form an intermediate group between the foregoing diazo- derivatives and the azo- compounds

Certain aliphatic diazo- compounds (v infra) contain the group -N2- attached by two active valencies to the same carbon atom.

# I. DIAZONIUM SALTS.

These diazo- derivatives are generally, but not exclusively, prepared from aromatic amines, and the process, which is termed diazotisation, is carried out with the undissociated salt of the amine, and not with the free base. In a hydrolysing solvent like water, it is therefore customary to diazotise aniline and its derivatives with sodium nitrite (1 molecule) and excess (2½ to 3 equivalents) of mineral acid.

#### AROMATIC DIAZONIUM SALTS.

The diazotisation of the benzenoid and naphthalenoid amines is frequently carried out on a manufacturing scale owing to the employment of aromatic diazonium salts in the production of azo-colouring matters. More than 1000 tons of para-intrandine are diazotised annually in the production of 'para-intrandine red'.

The aromatic base is dissolved in dilute hydrochloric or sulphune acid (3 equivalents in 10-20 p.c. aqueous solution) and the solution treated with an equivalent quantity (1 molecule) of sodium nitrite in 10-20 p.c. solution. The diazotisation is completed when the liquid contains a slight excess of nitrous acid as indicated by starch and rodide paper.

With anilme and its homologues, the temperature of the diazosolution is generally maintained at 0° 5° to prevent, so far as possible, the decomposition of the unstable diazonium salt, but in other cases, eg the intrainlines, naphthylamines, benzidine, and other diphenyl bases, the diazotisation is carried out most readily at 10°. The amino anthraquinones are diazotised at 30°-40° (Schaarschmidt, Bei 1916, 49, 2678)

In the manufacture of soluble azo- dyes, the diazonium safts are generally employed in aqueous solution, but solid diazo- compounds, in dry or paste form, have been introduced to enable dyers to prepare 'ingrain' azo- colours which are developed on the textile fibres (v. Eng. Pat. 18429, 21227, 1894, 8989, 11757, 1895, 1645, 1896, 15353, 1897, D. R. PP. 85387, 88949, 94280, 1894, 89437, 1896)

In alcoholic or acetic acid solution, diazotisation can be effected on the salt of the amine without using an excess of acid, and ethyl or amyl nitrite may, with advantage, be substituted for sodium intrite. Gaseous methyl nitrite, which has been employed in certain diazotisation (Chem. Soc. Trans. 1913, 103, 1398), is very readily prepared and is a cleaner reagent than amyl nitrite.

Benzenediazonium chloride  $C_gH_g$  N<sub>2</sub>Cl, the simplest example of an aromatic diazonium salt, is prepared by adding the calculated quantity of amyl nitrite to aniline hydrochloride suspended in glacial acetic acid at  $10^\circ$ , it is precipitated from the clear solution thus obtained by the addition of ether

Benzenediazonium sulphate C<sub>6</sub>H<sub>5</sub> N<sub>2</sub> HSO<sub>4</sub> is prepared in a similar manner from aniline sulphate suspended in glacial acetic acid, the precipitation being effected with alcohol and other

Benzenediazonium nitrate C<sub>6</sub>H<sub>5</sub> N<sub>2</sub>·NO<sub>3</sub>, which was first precipitated from aqueous solution by ether and alcohol (Griess, Annalen, 1866, 137, 39), can also be produced in alcoholic or glacial acetic acid solution (Knoevenagel, Ber 1890, 23, 2995; Bamberger, *ibid* 1896, 29, 446, Hirsch, *ibid*, 1897, 30, 92, Hantzsch and Jochem, *ibid* 1901, 34, 3337).

Diazonium salts have been obtained with a large variety of amons—platinichlorides, aurichlorides, stannichlorides, ferrit yanides, nitropriestates (Ber 1879, 12, 2119, 1885, 18, 965), chromates (Jahresberichte, 1867, 915), Chem Soc Trans 1905-87, 1), carbonates and nitrites (ibid, 1906, 87, 921), fluorides (Ber. 1903, 36, 2059), prichlorides (ibid 1906, 39, 2713, 3146), picrates (Chem Soc Trans 1907, 91, 1316), azides (ibid 1910, 97, 1697), Ber 1903, 36, 2056), thioxidiphates, tungstates (J. Soc. Dyers, 1901, 17, 279), thioacetates (Monatsh. 1907, 28,247), benofluorides (D. R. P. 281055), phospho molyblates and tungstates (Chem Soc. Trans. 1909, 95, 1319), arylsulphinates (Ber. 1911, 44, 1415), zinichlorides, Rev. Gén. Mat. Col. 1914, 18, 4, \$\beta\$ naphthol-1-sulphonates, Eng. Pat. 8989, 11757, of. 1895, D. R. P. 93305

All diazonium salts are hable to explode in the dry state, for they are endothermic compounds (Berthelot and Vieille, Compt. rend. 1881, 92, 1076. Sventoslavsky, Ber. 1910, 43, 1479) and in some cases the explosion point has been determined (Ber. 1899, 32, 1691., 1900, 33, 527). The diazonium chromates and perchlorates decompose with considerable violence, so that the former have been suggested as explosives (Bull. Soc. chim. 1867, [2], 7, 270., Fr. Pat. 73286).

Bisdiazonium salts (Tetrazo- salts) These compounds are produced from aromatic diamines which do not contain their aminogroups in ortho- or peri- positions (v. Cyclic diazo- compounds)

When the two amino- groups are in the same aromatic nucleus, complete diazotisation is effected only with some difficulty Metaphenylenediamine hydrochloride and sodium nitute furnish the azo- colouring matters included under the term 'Bismarck brown' (Bei 1897, 30, 2111, 2899, 1900, 33, 2116), but when a solution of the base in excess of hydrochloric acid is added quickly to a large excess of well-cooled aqueous nitious acid, complete diazotisation takes place and benzene-m bisdiazonium chlorede Calla N, Cl. 18 produced When the nitrite is added suddenly to the diamine hydrochloride, nitroso m phenylenediamine results Para-phenylenediamine hydrochloride, when diazotised in the usual way, gives a mixture of diazonium and bisdiazonium chlorides, but when the hydrochloride is added to excess of nitrous acid, benzene-p-bisdiazonium chloride is obtained

In the naphthalene series, 14-naphthylenediamine is diazotised with difficulty, owing to its oxidisability, but in producing its azo- derivatives, this difficulty is surmounted by working with its monoacyl-derivatives and diazotising in two stages with an intervening hydrolysis The heteronucleal (Eng. Pat. 18783, 1891) naphthylenediamines, excepting the 18-compound, can be completely diazotised, yielding naphthalenchisdiazonium salts (Ewer and Pick, D R PP 45549, 45788, Badische Anilin und Soda Fabrik D R P 130475, Morgan and Micklethwait, Chem Soc Trans 1910, 97, 2558) Benzidine, tolidine, dianisidine, and other similar heleronuclear diamines of the diphenyl and ditolyl series are readily diazotised, furnishing bisdiazonium salts (e.g. diphenylbisdiazonium chlorude Cl N2 C4H4 C4H4 N2 Cl), which are employed in the manufacture of substantive azo- dyes (v. Congo red and Benzopurpurin; art. Azo-colouring matters) There are certain substituted para-diamines in the benzene diphenyl and naphthalene series which have hitherto resisted all attempts at complete diazotisation (Ber 1884, 17, 603; 1896, 29, 2285, 1905, 38, 3769; Eng Pat 2946 of 1896)

### VELOCITY OF DIAZOTISATION

Under the usual experimental conditions, diazotisation proceeds with great rapidity, but in N/1000 solutions, the velocity of this reaction has been determined by a colorimetric method for estimating the free nitrous acid The reaction is of the second order, and the values of the constant  $C = \frac{x}{t(a-x)}$  are 0.036 for aniline, 0 038 for p-toluidine, and 0 041 for m-xylidine, with one molecular proportion of free acid at 0°. At higher temperatures, the rate is increased (Hantzsch and Schumann, Ber 1899, 32, 1691; 1900, 33, 527; Tassilly, Compt rend 1913, 157, 1148; 1914, 158, 335, 489) Both colorimetric and electrolytic determinations of the velocity of diazotisation show that, in the absence of disturbing influences, all the aromatic amines are diazotised at the same rate.

# ALTERNATIVE METHODS OF PRODUCING AROMATIC DIAZONIUM SALTS

Nitrosyl chloride or bromide has been suggested as a diazotising agent (Tilden and Millar, Chem Soc Proc 1894, 59; Kastle and Keiser, Amer Chem J 1895, 17, 91) Nitrosyl sulphate has been used with advantage (Pabst and Girard, D R P 6034; Ber 1879, 12, 365, Morgan and Micklethwait, Chem Soc Trans 1910, 97, 2558) This reagent or sodium nitrite dissolved in concentrated sulphuric acid is employed in diazotising slightly basic amines (Morgan and Evens, Chem. Soc. Trans. 1919, 116, 1130, cf. J. pr. Chem. 1906, [ii.] 74, 275) Barium nitrite, when employed in conjunction with sulphuric acid, furnishes diazo- solutions free from inorganic salts (Witt, Ber 1903, 36, The last-named investigator has brought forward an interesting process which consists in dissolving the base in cold concentrated nitric acid and adding the calculated amount of potassium metabisulphite required to produce sufficient nitrous acid for the diazotisation (Ber 1909, 42, 2953)

Diazonium bromides are formed by the inter action of hydrazines and diazonium perbromides

$$2R N_2Br_3+RN_2H_3=3R N_v Br+3HBr$$

(Chattaway, Chem Soc Trans 1908, 93, 958) An electrolytic process for the production of diazonium salts has been patented (Boehringer & Sons, D. R. P. 152926, and Eng. Pat. 2608 of 1904)

Diazonium salts can also be prepared from compounds not containing amino- groups; mercury diphenyl and nitrous fumes give benzenediazonium nitrate (Ber 1897, 30, 509), and the same salt is produced from nitrosobenzene and nitric oxide in chloroform solution (*ibid* 1898, 31, 1528) Fuming ritric acid reverses the coupling process and regenerates the diazonium salt from its azo- derivatives (Meldola, Chem. Soc Trans 1889, 55, 608; 1894, 65, 841; and O. Schmidt, Ber. 1905, 38, 3201).

Diazonium chlorides are regenerated from azo-dyes by decomposing the latter with chlorine or hypochlorous acid (J. pr. Chem. 1912, [n.] 85, 235.

Certain complex or highly substituted amines resist diazotisation unless treated under pressure (D R P. 143450) or with excess of nitrous and mineral acids (Annalen, 1873, 165, 187; 1891, 260, 224; Ber 1900, 33, 520)

(For indirect methods of forming diazonium salts, v Annalen, 1879, 199, 320; 1888, 243, 282; 1892, 270, 116; Ber. 1893, 26, 2190, 1899, 32, 1809; 1900, 33, 1718; J pr. Chem. 1896, [Ii.] 54, 496; Gazz chim. ital. 1900, 30, 1526; Bull. Soc. ehim. 1891, [Iii.] 6, 94)

#### REACTIONS OF AROMATIC DIAZONIUM SALTS.

In addition to their power of coupling with phenols, aromatic amines, and their sulphonic acids to form the technically important azocolouring matters, the diazonium salts are synthetical agents of the greatest value, and the following is a synopsis of the principal reactions in which they take part:—

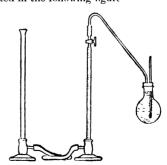

l Decomposition of Diazonium Salts by Water.

(Cf Rer 1874, 7, 1061; 1894, 17, 2704; 1899, 32, 1773; 1890, 23, 3635; 1902, 35, 89, J pr Chem 1881, [n | 24, 476, Chem Soc Trans, 1902, 81, 77; 1903, 83, 688; 1905, 87, 5; 1906, 89, 19.)

The decomposition of soluble diazonium salts by water is a unimolecular reaction, and is represented by the well-known equation.

$$C = \frac{1}{t} \log_{A-x}^{A}$$

The relative stability of the diazonium salts is ascertained by comparing the values of the constant C for a given temperature. The most successful method of making this determination consists in heating solutions of the diazo-compounds at a fixed temperature, and measuring the rate at which nitrogen is evolved. A convenient apparatus, which can be used in this determination and also for studying the decomposition of diazo-compounds in general, is indicated in the following figure.

These quantitative decompositions show that the diazonium salts from aniline and orthoand meta-toluidine are among the least stable of the series, whereas considerably greater stability is exhibited by the diazonium sulphonates derived from the benzenoid and naphthalenoid aminesulphonic acids.

The rate of decomposition of diazo- comunds increases with the temperature and in cordance with Arrhenius's formula for the nperature coefficient

$$\mathbf{C}t_1\!=\!\mathbf{C}t_0\epsilon^{\mathbf{A}(\mathbf{T}_1-\mathbf{T}_0)/\mathbf{T}_1\mathbf{T}_0}$$

The rate of decomposition is independent of e quantity of mineral acid present, and equivait solutions of benzenediazonium chloride, omide, sulphate, nitrate, and oxalate decomse with the same velocity; this change is, wever, accelerated by colloidal platinum or ver, owing to catalytic action (Hantzsch, Ber. 00, 33, 2517; Hausser and Muller, Bull Soc. m. 1892, [m] 7, 721; 1893, 9, 353; Compt. d. 1892, 114, 549, 669, 760, 1438; Schwalbe, itsch. Farb. Ind 1905, 4, 433; Ber 1905, 38, 96, 3071; 1909, 42, 196; Cam, Chem. Soc. ans 1902, 81, 1412; 1903, 83, 206, 470, 1905, 2511; Euler, Annalen, 1902, 325, 292; Voley d Cam, Trans. Faraday Soc. 1909, 5, 1)

In general, the decomposition of a diazonium It by water leads to the formation of a phenol

$$R N_2 \cdot HSO_4 + H_2O = R OH + H_2SO_4 + N_2$$

The sulphate is the best salt to employ in is reaction, because the chloride and nitrate e apt to lead respectively to alternative or condary changes. Benzenediazonium sulate and its homologues furnish phenol and e cresols and xylenols; diphenyl-4 4'-bisazonium sulphate gives rise to 4 4'-dihydroxyphenyl Aurin is similarly obtained from azotised rosaniline (Annalen, 1878, 194, 306)

In certain cases, more especially in the phthalene series, the product is contaminated azo- compounds, resulting from the coupling the hydroxy- derivative with a portion of the ill undecomposed diazonium salt (Chem Soc ans 1903, 83, 221) To obviate this difficulty, far as possible, excess of acid is used in the

composition The manufacture of the aphtholsulphonic acids (e.g. OH SO<sub>3</sub>H=1 4 id 1.8) from the corresponding a-naphthylninesulphonic acids furnishes typical examples the technical application of the process

Secondary reactions occur even in the simest cases (Ber 1890, 23, 3705), and in many stances, where the boiling is protracted owing the great stability of the diazo- compound, t a trace of the hydroxy- derivative can be olated (Amer Chem J. 1889, 11, 319, Cam, iem Soc Trans 1903, 83, 688) When the ienolic product is volatile in steam, the normal ange is facilitated by operating with solutions uling above 100° A good yield of guaracol is stained by adding the diazo- salt of orthousidine to a mixture of sodium sulphate and lute sulphuric acid boiling at 135°-145°, the

olatile product being removed at the moment formation (Kalle & Co, Eng. Pat 7233 1897; cf. Annalen, 1889, 253, 281; Ber 1874, 1008; D. R. P 167211, Chem Soc Trans. 06, 87, 19; cf. Willstatter and Schudel, Ber. 118, 51, 782.

(For other exceptional decompositions of azo- compounds, v. Ber. 1874, 7, 1061; 1884, , 2704, 1899, 32, 1773; 1902, 35, 89; Chem. oc Trans 1896, 69, 1327; 1902, 81, 77, 1905; , 5; 1906, 89, 19).
The diazo- compounds are very sensitive to

tht, which induces the phenolic decomposition

even in certain cases where the action of hot water or acids is very slight (Chem Soc Trans 1907, 91, 35; cf. Compt. rend. 1881, 92, 1074; Ber. 1890, 23, 3131; 1901, 34, 1668; D. R. PP 53455, 56606; J. Soc. Chem Ind. 1890, 9, 1001) 2. Decomposition of Diazonium Salts by Alcohols.

The reaction between diazonium salts and alcohols may proceed in two different ways. 1 R N<sub>2</sub> X+C<sub>2</sub>H<sub>5</sub> OH=R H+C<sub>2</sub>H<sub>4</sub>O+N<sub>2</sub>+HX 2 R·N<sub>2</sub>·X+C<sub>2</sub>H<sub>5</sub>OH=R O C<sub>2</sub>H<sub>5</sub>+N<sub>2</sub>+HX

The former of these changes was originally regarded as the general reaction, but more recent researches have shown that the second is the The factors determining the normal change course of the reaction are, however, numerous and complicated, involving (1) the nature of the alcohol; (2) the influence of substituents in the diazonium salt, (3) the pressure and temperature at which the decomposition is affected.

The tendency to replace the diazo- group by hydrogen increases with the molecular weight of the alcohol employed. Benzenediazonium chloride or sulphate and methyl alcohol give anisole exclusively With ethyl alcohol, these salts yield chiefly phenetole, but benzene is also pro The diazonium sulphates from p-chloroduced and p-bromo-aniline furnish only p-chloro- and p-bromo benzene with ethyl alcohol, but with methyl alcohol they give use mainly to the methyl ethers of p-chloro- and p-bromo-phenol (Amer Chem J 1898, 20, 229, cf Annalen, (Amer Chem J 1898, 20, 229, cf Annalen, 1871, 159, 191, Ber 1901, 34, 3337, 1903, 36, 2061, Amer Chem J 1893, 15, 518; 1897, 19, 531, 547, 561)

The diazo- salts of the simpler amines (aniline and its homologues) react chiefly in the direction indicated by the second of the foregoing equations, and yield mixed ethers, but the presence of acid substituents

# (Cl, Br, NO<sub>2</sub>, CO<sub>2</sub>H, NH SO<sub>2</sub>R)

favours the predominance of the first change. The intramlines (ortho-, meta-, and para-) give respectively 87, 51, and 40 pc of introbenzene the 1 2-, 2.1-, and 1 4-intronaphthylamines furnish the corresponding nitronaphthalenes, whereas  $\alpha$ - and  $\beta$ - naphthylamines yield  $\alpha$ - and β-ethoxynaphthalenes (Remsen and others, Ber 1885, 18, 65, Amer Chem J 1886, 8, 243, 1887, 9, 587, 1891, 13, 153, 1892, 14, 15)

The yield of alkyl ether increases with rise of pressure, but the addition of zinc-dust or an alkalı (sodium hydroxide or ethoxide, potassium carbonate) inhibits almost entirely the formation of mixed ether and leads to the substitution of the diazo- group by hydrogen (Amer. Chem J 1893, 15, 105, 301, 320, 379; 1894, 16, 235, 1895, 17, 454; 1897, 19, 163, 531; 1898, 20, 298; 1904, 31, 119)

3. Replacement of the Diazo- Group by

Hydrogen.

In addition to the action of alcohol, the diazo- group can be eliminated by the use of a variety of reducing agents

(1.) The diazonium salt is reduced to the corresponding hydrazine and the hydrazino- group NH NH, removed by boiling with copper sulphate (Baeyer and Pfitzinger, Bei 1885, 18, 90, 786)

(ii) Reduction of the diazo- compound with alkuline sodium stannite (Friedlander, Ber. 1889, 22, 587).

(iii) By various other reducing agents, stannous formate (Pci 1885, 18, 357, J pi Chem 1889, [ii ] 40, 97), hypophosphorous acid (Ber 1902, 35, 162), sodium hyposulphite (ibid 1907, 40, 858), formic and and copper powder (ibid 1890, 23, 1632), aluminium powder in

alcohol (Morgan and Evens, lc).

4 Replacement of the Diazo- Group by Halogen, Cyanide, Cyanate, and Thiocyanate Radicals

Fluorine may be introduced into the atomatic nucleus in place of the diazo- group by treating the diazonium salt with hydro-fluoric acid Diazoamino- compounds (v. infra) are also employed in bringing about this replacement, and when treated with concentrated hydrofluoric acid they yield the corresponding fluoro- derivative, fluorobenzene is thus produced from diazoaminobenzene or diazobenzenepiperidide (J. pr. Chem. 1870, [n. ] 1, 395., Ber. 1875, 8, 893, 1879, 12, 581, 1889, 22, 1846)

The first really successful process for replacing the diazo- group by chlorine (or bromine) was discovered by Sandmeyer, it consists in adding the diazotised solution to cuprous chloride (or bromide) dissolved in warm hydrochloric (or hydrobromic) acid, when nitrogen is evolved and the corresponding chloro- or bromoderivative is produced (Bct 1884, 17, 1633, 2650, 1885, 18, 1492, 1496, 1886, 19, 810, 1890, 23, 1628, 1880, Annalen, 1893, 273,

The first stage in the Sandmeyer reaction is considered to be the formation of an additive compound of diazonium salt and cuprous chloride, the decomposition of this intermediate product proceeds readily only above a certain temperature, which is different for each diazonium salt (Eidmann, Annalen, 1893, 272, 141, of Votoček, Chem Zeit Rep. 1896, 20, 70, Hantzsch and Blagden, Ber. 1900, 33, 2544) The substitution of biomine for diazonitrogen follows a similar course (Phil Trans 1864, 154, 673, Annalen, 1866, 137, 49, Amer Chem J 1891, 13, 486, Gazz chim ital 1890, 20, 631)

The foregoing substitutions are also effected by the addition to solutions of diazonium chlorides or bromides of finely divided copper or the copper bronze of commerce (Gattermann, Bei 1890, 23, 1218, 1892, 25, 1071, Ullmann, ibid 1896, 29, 1878, if Angeli, ibid 1891, 24,

Iodine is readily substituted for the diazo complex by treating the acid diazo- solutions with potassium iodide even in the absence of

copper or cuprous salts

The Sandmeyer reaction includes the important synthetical operation of replacing the diazo- group by a cyande radical, the diazo-nium salt being added to a warm solution of potassium cuprocyanide The Gattermann process is also applicable to this synthesis, the addition of copper powder to a mixture of diazonium salt and potassium cyanide inducing a similar replacement (Ber 1890, 23, 1218) The cyanate radical is introduced in the place of the diazo- group by adding successively to a solution of diazonium salt, potassium, cyanate, and copper powder (Ber 1890, 23, 1220, 1892, 25, 1086). The thiocyanate group is introduced by adding potassium thiocyanate and cuprous throcyanate to a solution of diazonium sulphate (1814 1890, 23, 738, 770) , 5 Replacement of the Diazo- Group by Sul-

phur and Sulphur-containing Radicals.

These reactions are of importance as furmshing methods for the synthetical production of sulphonic acids

Throphenols or disulphides are obtained by treating diazonium salts with potassium xanthate and then hydrolysing the resulting aromatic vanthate (Leuckart, J. pr Chem. 1890, [n | 41, 179], cf. Ber 1887, 20, 349, Chem Soc Proc 1895, 11, 141). Phenyl sulphide is produced by treating benzenediazonium salts with hydrogen sulphide or ammonium sulphide (Ber. 1882, 15, Benzenoid diazonium salts yield sul-1683)phides on treatment with sodium cupious thiosulphate, but diazotised α-naphthylamine only gives a-azonaphthalene (Bei 1901, 34, 3968)

The replacement of a diazonium by a sulphinic group is effected by saturating with sulphur dioxide an acid solution of diazonium sulphate and adding copper powder, introgen is evolved and the resulting sulphinic acid extracted with other (Gattermann, Ber 1899, 32, 1136, Eng Pat 26139 of 1896, D R P 95830)

The foregoing thiophenols, disulphides and sulphinic acids yield the corresponding sulphonic acids on oxidation (D. R. P. 70286). Eng. Pat. 11865 of 1892)

6 Replacement of the Diazo- Group by Nitro-, Nitroso-, and Amino- Radicals.

The introduction of a nitro- group is brought about either by heating the diazonium salt with nitious acid and cuprous oxide or by mixing the diazonium sulphate with cupro-cupric sulphite and adding excess of alkali nitrite latter process, 2.4.6-tribromobenzenediazonium sulphate gives 65 p c of 1-nitro 2.4 6-tribromobenzene and diazotised β-naphthylamine gives 25 p.c. of \(\beta\)-nitronaphthalene, a substance prepared with considerable difficulty by other processes (Ber 1887, 20, 1497, 1900, 33, 2544). The introduction of a nitroso- group is effected by treating a diazonium chloride with alkaline potassium ferrocyanide (Ber. 1893, 26, 471) The addition of hydroxylamine to a solution of diazonium salt results in the regeneration of the original amine (Ber 1892, 25, 372; 1902, 35, 2593, 3920)

#### 7 Formation of Azoimides.

The introduction of the azimino- group  $N_3$ into the aromatic nucleus is effected by the following reactions: (1) action of hydroxylamino on diazonium sulphates (Bei 1892, 25, 372, 1893, 26, 1271, Forster and Fierz, Chem Soc Trans 1907, 91, 855, 1350); (2) interaction of ammonia and diazonium perbromides; (3) direct action of sodium azide on diazonium salts in excess of sulphuric acid (Nolting and Michael, Ber 1893, 26, 86, Forster and Fierz, Chem. Soc Trans 1907, 91, 1942). The last of these processes is carried out so readily that the production of an azimino- compound may be used to estimate the number of diazo- groups in a diazonium salt (Meldola and Hawkins, Chem Soc Proc 1892, 8, 133, Morgan and Micklethwait, Chem Soc. Trans. 1910, 97, 2560). Aromatic azoimides are ilso produced by the interaction of chloroamine, NH<sub>2</sub>Cl, and diazonium chlorides (Forster, Chem. Soc. Trans. 1915, 107, 260), and by removing water from the nitrosoarylhydroxylamines

These aryl azomides can be employed synthetically as a means of transforming an amine into the corresponding aminophenol when warmed with moderately concentrated sulphuric acid, two-thirds of the introduced into the nucleus (Ber. 1894, 27, 192; Morgan and Porter, Chem Soc Trans 1915, 107, 651).

Miscellancous substitutions, v Chem Soc Trans 1888, 53, 460; Amer. Chem J 1888, 10, 368, Bei 1902, 35, 1964.

For the replacement of the diazo- group by assinic and stibinic complexes consult Organic Arsenicals and Organic Antimonials.

#### CONDENSATIONS EFFECTED BY MEANS OF AROMATIC DIAZONIUM SALTS

Azo- compounds are formed, to a slight extent, during the Sandmeyer reaction, and this condensation takes place to a greater extent when the usual order of mixing is reversed and the cuprous chloride added to the cold solution of diazonium salt Aniline, o-chloraniline, and o- and p-toluidine give considerable quantities of azo- derivatives, but the nitianilines and their homologues furnish diphenyl compounds (Niementowski, Ber 1901, 34, 3325, Ullmann and Forgan, *ibid* 3802, D R P 126961) Cuprous oxide dissolved in ammonia or hydroxylamine also promotes the diphenyl condensation (Annalen, 1902, 320, 122), diphenyl itself being readily prepared by adding copper, zinc, or non powder to benzenediazonium sulphate in dilute alcohol (Ber 1890, 23, 1226), ββ-dinaphthyl is produced from B-diazonaphthalene similarly sulphate (Chem Soc. Trans 1895, 67, 653) 2 2'-Dimethyl-1 1'-dianthraquinonyl results from the condensation of 2 mols of 2-methylanthraquinone-1-diazonium sulphate when stirred with acetic anhydride and copper bronze powder (Scholl and Kunz, Ber 1907, 40, 1697, Eng. Pat 14578 of 1905)

# INTERCHANGE OF GROUPS IN DIAZONIUM SALTS.

The diazonium salts of the more highly substituted amines frequently undergo remarkable transformations, some of which have been suggested for use in the technical production of azo- compounds.

The dinitroanisidines, containing nitrogroups either in ortho- or para- positions with regard to the amino- group, exchange these radicals for hydroxyl during the process of diazotisation. In certain instances, the methoxyl group present in these compounds undergoes demethylation, &c, with the production of internal diazo- oxides (quinonediazides) The nitro- group is set free in the form of nitious acid, which continues the diazotisation process on further quantities of the base (Meldola and others, Chem Soc Trans 1900, 77, 1172, 1901, 79, 1076; 1902, 81, 988, 1905, 87, 1205) Methoxyl or chlorine radicals in para-positions with respect to the diazo-complex are rendered labile by contiguous nitro- groups so that paradiazo-oxides are produced (Klemenc, Ber. 1914, 47, 1407; Morgan and Porter, Chem Soc. Trans 1915, 107, 653), but an accumulation of acidic (nitro) groups favours the removal of adjacent nitro- groups and the formation of oitho-diazo oxides (Meldola and Reverdin, Chem Soc Trans, 1910, 97, 1204). A sulphonic group is replaced by hydroxyl in the diazotisation of m-phenylenediammedisulphonic acid (Eng Pat 18283 of 1903), and certain of the dimitronaphthylamines, when diazotised, yield internal diazo-oxides, owing to the initial replacement of a intro-group by hydroxyl (Bei 1894, 27, 2211, 1895, 28, 1951, of Chem Soc Trans 1895, 67, 908)

The replacement of an acidic (electronegative) substituent by hydroxyl frequently occurs on treating the diazonium salt with alkalis

$$\begin{array}{c} \cdot \\ \cdot \\ \text{CIN}_2 \\ \\ \cdot \\ \text{SO}_3 \\ \text{H} \end{array} \rightarrow \begin{array}{c} \text{OH} \\ \\ \cdot \\ \text{OH}_2 \\ \\ \cdot \\ \text{SO}_3 \\ \text{H} \end{array} \rightarrow \begin{array}{c} \text{O} \\ \\ \cdot \\ \cdot \\ \text{N}_2 \\ \\ \cdot \\ \text{SO}_3 \\ \text{H} \end{array}$$

A sulphonic acid group may be similarly eliminated as in  $\beta$ -naphthylamine-1 5 7-trisulphonic acid which, when diazotised and treated with weak alkali, yields naphthylene 2-diazo-1-oxide-5 7-disulphonic acid (D. R. P. 141750), Eng. Pats. 16811, 20551, of 1901, 1561, 6615, 23993, of 1902, 16995, 27372, of 1903, 4997, of 1904).

These replacements sometimes take place even when the diazo-solutions are diluted with water, or spontaneously when the diazonium base is present as the salt of a weak and (acctate, oxalate, carbonate, &c) (v. Orton, Proc. Roy. Soc. 1902, 71, 153., Chem. Soc. Trans. 1903, 83, 796., 1907, 91, 1554., Nolting and Battegay. Ber. 1906, 39, 79)

 $p\hbox{-}{\rm Chlorobenzene diazonium}\quad {\rm thioeyanato}$ 

undergoes a remarkable molecular transformation when dissolved in alcohol containing a trace of hydrochloric acid. The thiocyanate and chlorine radicals change places, and on adding other to the solution, p-thiocyanobenic ne diazonium chloride is precipitated (Hantzsch, Ber 1896, 29, 947) Similarly, 2 4 6-tribromobenzenediazonium sulphate in presence of excess of potassium thiocyanate is converted into 2.4.6-trithiocyanobenzenediazonium thiocyanate and many brominated diazonium chlorides pass into chlorimated diazonium bromides (Bei 1897, 30, 2334, 1898, 31, 1253, 1900, 33, 505, cf Chem Soc Trans 1902, 81, 1376) The last of these transformations has been studied quantitatively, and the following generalisations have been established -

- (1) Bromine atoms are replaced by chlorine only when present in the ortho- or para- position with respect to the diazonium group, those in ortho- positions being most readily removed. A bromine atom in the meta- position is not affected
- $(\pi)$  The ease of transformation increases with the number of bromine atoms present
- (iii) The transformation constant, calculated from the equation for a unimolecular reaction  $K=1/t(\log A/A-x)$ , increases with the temperature and is also influenced by the solvent, having its minimum value in water, and becoming greater as the series of alcohols is ascended.

(iv) Diazonium salts containing two bromine atoms are stable when dry, but are rapidly transformed in ethyl alcohol; 2 4.6-tribromobenzenediazonium chloride becomes transformed in the dry state

These changes do not occur either with iodinated diazonium chlorides or with brominated diazonium fluorides (Hantzsch, Ber. 1903, 36,

zuoe).

CONSTITUTION OF AROMATIC DIAZONIUM SALTS.

Aromatic diazonium salts are generally soluble in water to a neutral solution, thus showing, by an absence of hydrolytic dissociation, that the diazonium base is a stronger base than the aromatic amine from which it was derived. The strength of the diazonium base has been confirmed by physico-chemical measurements.

Determinations of the electrical conductivity of solutions of benzenediazonium chloride and mirate show that the benzenediazonium radical is strictly comparable with other quaternary ammonium ions. The rate of migration of the benzenediazonium ion at 25° is 457, the corresponding constants for the methylpyridinium and tetramethylammonium ions being 443 and 436 respectively. The molecular electrical conductivity of solutions of diazonium salts increases with dilution, just as in the case of the corresponding potassium and ammonium compounds.

The affinity constant of benzenediazonium hydroxide at 0° is 70 times greater than that of ammonium hydroxides, and somewhat exceeds that of piperidine. The affinity constants of p-methoxybenzenediazonium and \(\psi\)-cumidine-diazonium hydroxides are even greater, and approximate closely to those of the alkali hydroxides A comparison of the electrical conductivity experiments, with the results obtained in the hydrolysis of ethyl acetate by benzenediazonium hydroxide, shows that in N/128 solutions at 0°, approximately 33 p.c. of the base exists in the ionised condition (Ber. 1890, 23, 3220; 1895, 28, 1737, 1898, 31, 1612)

Benzenediazonium (Diazobenzene) behaves like an alkali or a complex ammonium cation

Benzenediazonium hydroxide (Diazobenzene hydrate or hydroxide) is only known in solution, and is produced by treating aqueous benzene-diazonium chloride with the calculated amount of silver oxide, or by adding barium hydroxide to a solution of benzenediazonium sulphate (Hantzsch, Ber 1898, 31, 340) The solution is strongly alkaline, and gives at once an azocompound with \$\beta\$-naphthol, the dissolved base decomposes, however, fairly rapidly even at 0°

The striking similarity in the physical and chemical properties of the diazonium and quaternary ammonium salts suggests the existence of quinquevalent introgen in the former compounds, and on these grounds the following formula, formerly proposed by Blomstrand (1869), Strecker (1871), and Erlenmeyer (1874), has now been generally adopted for benzenediazonium chloride and its homologues:

$$C_6H_5$$
— $N^V$ — $Cl$ 

although, for many years, the alternative configuration,  $C_6H_6$ : N=N CI, suggested by Kekulé, was usually employed.

The close analogy existing between the diazonium and alkali salts is shown further by the facility with which the former yield double salts with cobaltic nitrite and with the chlorides of platinum, gold, and mercury. Diazonium perhalides are also known, corresponding with the perhalides of potassium, rubidium, cæsium, and quaternary ammonium bases (Ber. 1895, 28, 1736, 2754).

The benzenoid diazonium salts with colourless anions (nitrates, sulphates, chlorides) are generally colourless, but the corresponding bromides, iodides, and thiocyanates are coloured, and the deeper the colour the more explosive the salt. When cooled in liquid air, these coloured salts become less coloured; moreover,

their aqueous solutions are colourless

The development of colour and increase in explosibility are considered by Hantzsch to indicate a change in constitution, the coloured substance being regarded as an equilibrium mixture of diazonium salt and syn-diazocompound (v infra). This equilibrium is disturbed in the sense of forming more colourless diazonium salt by lowering the temperature or by dissolving the substance in water (Hantzsch, Ber 1897, 33, 2179, 1900, 33, 2179, Euler, Ber. 1895, 31, 4168) But although in the benzeno series the diazonium chlorides, nitrates, and sulphates are colourless, yet in the diphenyl and naphthalene series, many diazonium salts with these amons are coloured and comparatively stable. Moreover, this colour (yellow or orange) is retained either in aqueous solution or at the temperature of liquid air. Apart from their colour, these salts have all the properties of the simpler diazonium salts (neutral solutions, &c). These facts coupling with phenols, indicate that increase in the complexity of the organic portion of the diazonium cation leads to the development of colour in normal diazonium

(Coloured diazonium salts, v. Hantzsch, Ber 1900, 33, 3183, 1901, 34, 4168, Annalen, 1900, 312, 126, Cain, Chem. Soc. Trans. 1905, 87, 5; Morgan and others, ibid. 1907, 91, 1311, 1505; 1908, 93, 614, 1909, 95, 1319)

The idea embodied in Blomstrand's diazonium formula (v. supra) fails to express one important point, namely, the dependence of the stability of the diazo-complex on the presence of an unsaturated group. Yet this is a matter of fundamental importance, for hitherto no amine in which the basic nitiogen is attached to a fully saturated ring or complex has yielded a diazonium salt.

Cain has suggested an alternative formula, (2), giving expression to this circumstance (Chem Soc Trans 1907, 91, 1051), in which the diazonium salt is represented as having a parahemiquinonoid constitution, and this conception has been extended by Morgan (*ibid.* 1908, 93, 617; 1910, 97, 2563) so as to include the equally admissible ortho-hemiquinonoid configurations (1) and (3):

$$\begin{array}{c|c} X & & H \\ H & & H \\ H & & H \\ \end{array} \xrightarrow[N]{H} H \end{array} \rightleftharpoons \begin{array}{c} X & & H \\ H & & H \\ H & & H \\ \end{array} \xrightarrow[N]{H} H$$

Euler has also advocated a para-hemiquinonoid structure for diazonium salts (Ber 1908, 41, 3979).

#### Non-aromatic Diazonium Salts.

The foregoing hypotheses of the constitution of aromatic diazonium salts, which bases their existence on the unsaturated nature of the aromatic complex, accord with the fact that certain non-aromatic primary amines containing unsaturated organic groups manifest, in some degree, the property of diazotisability. Among those bases are aminotriazole (1) and its derivatives, and aminoantipyrine (II):

(Thiele and Manchot, Annalen, 1898, 303, 33: Knorr and Stolz, *ibid*. 1896, 293, 67, *cf* Ber 1900, 33, 1158, 1906, 39, 2925, Annalen, 1900, 312, 133). In addition to amino derivatives of the pyrazoline group (Michaelis, Annalen, 1906, 350, 288), the 4- and 5-amino derivatives of the pyrazole group give rise to remarkably stable diazonium salts (Morgan and Reilly, Chem Soc. Trans 1914, 105, 436; Michaelis and others, Annalen, 1911, 385, 1; 1915, 407, 229, 274; Mohr, J. pr Chem. 1914, [11] 90, 509) 2 Aminothiazole, a heterocyclic base containing sulphur and nitrogen in the ring, furnishes diazonium salts of the oxyacids (Morgan and Morrow, Chem Soc Trans 1915, 107 1291). Distinct evidence of diazotisability has been adduced in the indole and pyrrole series (Angeli and d'Angelo, Atti. R. Accad Lincei, 1904, [v.] 13, 1. 258; Angelico, Ic 1905, 14, 11 167) It has also been shown (K. A. Hofmann, Hock and Roth, Ber 1910, 43, 682, 1087) that aminoguanidine gives rise to diazonium salts, derived, however, not from the salts of aminoguanidine itself, but from a more complex molecule containing two guanidine residues, and having a greater degree of unsaturation. The diazonium greater degree of unsaturation nitrate, for example, is represented by the formula ·

$$NH \underbrace{\begin{array}{c} NO_2 \cdot N_2 \ NH \ C(\ NH) \\ C(NH_2) \ NH - NH \ N \end{array}}_{} N$$

containing a diazo- complex associated with an open chain having three unsaturated linkings

#### II. CYCLIC DIAZO- COMPOUNDS.

In certain instances, the action of nitrous acid on substituted aromatic amines leads to the formation of compounds having their diazonitrogen in a cyclic complex, this result being due to the subsequent interaction of a substituent group.

#### 1. INTERNAL DIAZONIUM SALTS.

Sulphonated ammes of the benzene and naphthalene series furnish diazo- derivatives which are generally misnamed diazo-sulphonic acids. These compounds, however, do not contain ionic hydrogen, and are really internal diazonium salts; No 1, the so-called 'diazobenzenesulphonic acid,' being benzenediazonium-p-sulphonate, whilst No. 2 is naphthalene-1-diazonium-5-sulphonate

These internal diazonium sulphonates are of great technical importance in the manufacture of azo-dyes (r. Azo-colouring matters). They are prepared either by adding sodium nitrite to an acid suspension of the amino sulphonic acid or by acidifying a solution containing nitrite and the alkali salt of the aminosulphonic acid (Rev. prod. chim. 1917, 20, 21).

Of a similar nature are the cyclic diazo-

Of a similar nature are the cyclic diazoderivatives obtained by diazotising aromatic aminocarboxylic acids (cf. Bulow and Haas, Ber, 1911, 44, 601), e.g. 'diazo-anthranilic acid' or benzeneduzonium-o-carboxylate

#### 2. Cyclic Dia7o- Compounds due to Internal Condensation

Aromatic ortho- and pen-diamines do not yield diazonium salts, masmuch as their interaction with introus acid leads at once to the formation of cyclic diazonimes (Arimino-compounds)

Phenylene-o-diazoimine (1) (Aziminobenzene) and naphthylene-1 8-diazoimine (2) (1 8-Azimino-naphthalene) are typical members of this series of diazo-compounds

The triazole rings thus set up are remarkably stable, and in the case of the ortho-derivatives (No 1) are not opened by mineral acids without complete rupture of the molecule. The peridiazonimes (No 2) occupy a position intermediate between the ortho-diazonimes (No. 1) and the para-diazonimes (v infra)

The 12- and 23-naphthylene-diamines furnish respectively 12- and 23-naphthylene-diazomines (12- and 23-aziminonaphthalenes). (Constitution of ortho-diazomines and their acyl- derivatives, Griess, Ber. 1882, 15, 2195; Kekulé, Lehrbuch, 11739, Morgan and Godden, Chem. Soc Trans 1910, 97, 2557; cf Ber 1874, 7, 316; 1876, 9, 221, 1887, 20, 2999, 1894, 27, 874; Annalen, 1889, 255, 344. Chem. Soc Trans 1906, 89, 4) Although Griess's formulation for the azimino-compounds

$$C_6H_4$$
 $N$ 
 $NH$  still persists in chemical litera-

ture, it has been disproved completely, and that of Kekulé substantiated by the preparation of three pairs of isomerides having respectively the following formulæ, where R=acetyl, benzovl, or benzenesulphonyl

This form of isomerism could not exist with Guess's symmetrical configuration (Morgan, Micklethwait and Schaiff, Chem Soc Trans 1913, 103, 1394, 1914, 105, 117). Although these diazoimines do not couple with phenols and aromatic bases to form azo-dyes, yet a synthetic employment has been found for them in the production of carbazole derivatives which are obtained on heating these cyclic dia/o-compounds (Ullmann, Ber 1898, 31, 1697, 1914, 47, 380).

Similar stable cyclic diazo- compounds are obtained by diazotising the ortho-aminothiophonols, o-phenylenediazosulphide being a colourless crystalline substance with a sweetish odour and feebly basic properties

$$C_0H_4{<}_N^S{>}N$$

 $^{\text{Cl}_{0}}\text{H}_{4}{<}_{N}^{\text{S}}{>}N$  (Jacobsen, Annalen, 1893, 277, 209, 218, 232, 237)

3 CYCLIC DIAZO-COMPOUNDS DUE TO COMBINED INTERNAL CONDENSATION AND SALT FORMA-

In this group are found certain diazoderivatives of amines containing slightly acidic substituents in ortho- or para-, but not metapositions with respect to the aminic nitrogen

(1) Internal diazo- oxides are produced from ortho- and para- aminophenois and their derivatives În some cases, an intermediate diazonium salt is formed which condenses to the diazo-oxide on treatment with silver oxide or an alkalı (Schmitt, Ber 1868, 1, 67, Hantzsch and Davidson, *ibid* 1896, 29, 1522, Cameron, Amer Chem J 1898, 20, 229) The first diazocompound prepared by Griess (Annalen, 1858, 106, 123), namely, dinitrobenzenediazo-oxide

$$(NO_2)_2C_6H_2$$
  $\bigcup_{N_2}^{O}$  belongs to this class; it is

produced by diazotising pieramic acid, and has been utilised in the production of azo-colours (D R. P 151332). The 12-, 2.1-, 23-, and 1.8 aminonaphthols and their sulphonic acids similarly give rise to internal diazo-oxides which are so stable that they can be nitrated. These internal diazo-oxides are readily transformed into diazonuim salts by mineral acids, and are therefore available in the production of azo-dyes (Eng Pat 28107, of 1897; 10235, 15025, of 1904; Fr Pat 353786 of 1905; D R. PP 155083, 164665, 171024, 172446, 175593, 176618, 176619, 176620).

Internal diazo-oxides can also be produced by leaving the diazonium salts of highly substituted amines (eq 246-trichloroaniline) in aqueous solutions containing no free mineral acid (Orton, Proc Roy Soc 1903, 71, 153; Chem. Soc Trans. 1903, 83, 796)

Thes, diazo- derivatives have been formulated either as cyclic diazo-oxides (1) or as quinonediazides (II.):

$$\begin{array}{ccc}
O \cdot C_6 H_4 \cdot N_2 & O \cdot C_6 H_4 < N \\
I & II.
\end{array}$$

(cf. Wolff, Annalen, 1900, 312, 126, Morgan and Micklethwait, Chem. Soc. Trans 1908, 93, 607)

Repeated attempts to prepare internal diazooxides from m-aminophenol and its nitroderivatives, which have been quite unsuccessful, strengthen the view that these diazo-derivatives are to be regarded as quinonediazooxides (II), with the reservation that similar compounds are producible from 18-aminonaphthol, 'H acid,' and other peri-derivatives (Morgan and Porter, lc). In the case of aminophenolsulphonic acids the NH: OH=1.2 compounds give these coloured o-quinonediazides, the NH<sub>2</sub>OH=14 compounds yield diazonium sulphonates changing to p quinonediazides on partial neutralisation, the NH<sub>3</sub>:OH=13 compounds give rise only to diazonium sulphonates which lose diazo-nitrogen and furnish complex azo derivatives on treatment with alkali (Morgan and Tomlins, Chem. Soc Trans. 1917, 111, 497).

(11) Para diazoimines and diazoimides.

The simplest example of the para-diazomines is obtained by the action of alkalis on the diazonium salts of p-aminodiphenylamine (Annalen, 1888, 243, 282; Ber 1902, 35, 895) The following alternative formulæ (III and IV) have been given to this product -

corresponding respectively with the foregoing formula (1 and II) for the internal diazo-oxides. Successive nitration of the phenyl group gradually increases the stability of these pdiazoimines (Chem Soc Trans 1908, 93, 604).

The para-diazomides are produced from the acyl- and arylsulphonyl- derivatives of the para-diamines, and similar products are obtained the arylsulphonyl-I · 8-naphthylenediamines. The production of these diazoimides takes place in two stages, the diazonium salt first produced being decomposed by sodium acetate or mild alkali, yielding the internal condensation product

These para-diazoimides (VI.) are yellow sparingly soluble substances readily reconverted by strong acids into the corresponding diazonium They combine additively with phenols, naphthols, naphthylamines, and their sulphonic naphonous, naphonylamines, and their sulphonic acids, yielding azo-colouring matters (Morgan and Micklethwait, J. Soc. Dyers and Colourists, 1909, 25, 107, cf. Chem. Soc. Trans. 1905, 87, 74, 921, 1302, 1906, 89, 1162; 1907, 91, 1509, 1908, 93, 615. Badische Anilin- und Soda-Fabrik D. R. P. 205037)

The foregoing general reaction has been extended further by the device of diazotising with liquid nitrogen trioxide in an anhydrous solvent such as acetone. In this way the simplest members of the series Ac N.C. H.: N2 have been obtained containing formyl, acetyl, and benzoyl groups (Morgan, Upton and Cleaze, Chem. Soc. Trans. 1917, 111, 187; 1918,

#### III. DIAZOAMINES.

The diazoamines or diazoamino- compounds have the general formula XN<sub>2</sub> NHY, and may be either aromatic, mixed aromatic-aliphatic, or aliphatic in character, according as to whether X and Y are aromatic or aliphatic hydrocarbon radicals.

#### 1 AROMATIC DIAZOAMINES.

The aromatic diazonmines are produced (1) by the action of nitrous acid (1 molecule) on two molecular proportions of a primary benzenoid amine, (2) by coupling a diazonium salt with a primary or secondary benzenoid amine.

Diazoaminobenzene C<sub>6</sub>H<sub>5</sub>·N<sub>2</sub> NH C<sub>6</sub>H<sub>5</sub>, yellow crystals, mp 98°, is produced in quantitative yield by dissolving 10 parts of aniline in two parts of water containing 12 parts of hydrogen chloride, diazotising with 8 parts of sodium nitrite, and adding the diazo-solution to a solution of 10 parts of aniline in the calculated amount of hydrochloric acid. The diazoamine is precipitated on the addition of sodium acetate. (Absorption spectrum of diazoaminobenzene, Purvis, Chem. Soc. Trans. 1914, 105, 590.)

When warmed with aniline containing aniline hydrochloride, diazoaminobenzene is transformed into p-aminoazobenzene (v Azocolouring matters), the velocity of transformation obeying the law of unimolecular reactions. When the transformation occurs below 40° a small proportion (about 4 pc) of o-aminoazobenzene is produced (F H Witt, Ber 1912, 45, 2380, 1913, 46, 2557)

Diazoamino p-toluene C<sub>7</sub>H<sub>7</sub> N<sub>2</sub> NH C<sub>7</sub>H<sub>7</sub> is prepared in a similar manner, and undergoes transformation into an ortho-azo-compound, but the velocity of this change is only about one-ninth of that of the preceding transformation to para-azo-derivative

The coupling of diazonium salts with metaphenylenediamine, diphenylamine, the naphthylamines and their alkyl derivatives, leads directly to the production of azo-derivatives, in these cases, intermediate diazoamines have not been isolated, except when the reactive ortho- or para-positions are already substituted (Morgan, Chem Soc Trans, 1902, 81, 91; 1907, 91, 370)

Chem Soc Trans. 1902, 81, 91; 1907, 91, 370)

When an aromatic base, XNH<sub>2</sub>, is coupled with a diazonium salt YN<sub>2</sub>Cl, the resulting diazoamine is identical with that produced from XN<sub>2</sub>Cl and YNH<sub>2</sub>, and is generally regarded as being an equilibrium mixture of the two isomerides XNH·N<sub>2</sub>Y and XN<sub>2</sub>·NHY This explanation assumes the migration of the diazogroup which has been observed to occur in several instances (Ber 1882, 15, 2190; 1896, 29, 287; 1897, 30, 1412).

(For the constitution of the unsymmetrical aromatic diazoamines, XNH·N<sub>2</sub>Y, v McIdola and Streatfelld, Chem Soc Trans 1886, 49, 624; 1887, 57, 102, 434; 1886, 53, 664; 1889, 55, 412; 1890, 57, 785; cf. Forster and Garland will 1909, 95. 2051)

## 2. ALIPHATIC-AROMATIC DIAZOAMINES.

The diazoamines containing one aliphatic and one aromatic group can be produced by (1) coupling a diazonium salt with an aliphatic amine (Ber. 1888, 21, 1016, 1112; 1889, 22, 938,

1302); (2) by treating an azide with Grignard reagent:

R N
$$\stackrel{N}{\downarrow}$$
 +R' MgBr=R N(MgBr) N NR'  
H<sub>2</sub>O  $\Rightarrow$  R NH N NR'+MgBr OH

(Dimroth, Ber 1903, 36, 909; 1905, 38, 670, 2328; 1907, 40, 2390). Diazoamines present the possibility of stereoisomerism, but their relative stability and the fact that they couple only slowly with  $\beta$ -naphthol, confirm the view that they are generally anti-diazo-compounds.

that they are generally anti-diazo- compounds. (For stereoisomeric diazoamines, v J Russ Phys. Chem Soc 1906, 38, 578; Zeitsch angew Chem 1900, 13, 762; 1902, 15, 1209)

Aromatic bisdiazoamino- compounds, e.g. (C<sub>6</sub>H<sub>5</sub> N.), N. C<sub>6</sub>H<sub>5</sub>, have been obtained by the action of 2 molecular proportions of a diazonium salt on one of an aromatic amine (Ber. 1894, 27, 1863, 2597, 1895, 28, 170)

Mixed aliphatic-aromatic bisdiazoamino- derivatives (v. Ber. 1888, 21, 1016, 1889, 22, 933; 1907, 40, 2390)

Diazo- $\psi$ -semicarbazines (v. Forster, Chem. Soc. Trans. 1906, 89, 223)

#### 3. ALIPHATIC DIAZOAMINES.

Dimroth's general method may be applied to the production of purely aliphatic diazo-amino-compounds. In this way, the simplest member of the series, diazoaminomethane (dimethyltriazene) CH<sub>3</sub>N·N NH CH<sub>3</sub>, has been prepared from methyl azide and magnesium methyl iodide. This substance, which is isolated by distilling its copper derivative with diazoaminobenzene under reduced pressure, is a colourless liquid, solidifying at --12° and boiling at 92° (Dimroth, Ber. 1905, 38, 1575, 1906, 39, 3905)

#### IV DIAZO- OXIDES

When a diazonium salt couples with a phenol the product is generally an ortho or a parahydroxyazo- compound (the C-azo- derivative), but in all probability, the O-azo- derivative is first produced, for in a few instances, when the velocity of transformation has been lessened by substitution, the intermediate O-azo- compound or diazo-oxide has been isolated p-Bromobenzenediazonium chloride and p-introphenol give p-bromobenzenediazo-4 oxynitobenzene

#### CaHaBr N N O CaHa NO,

which, at 80°, becomes transformed into its isomeride, p-bromobenzene-2-azo-4-nitrophenol

C<sub>6</sub>H<sub>4</sub>BrN N C<sub>6</sub>H<sub>4</sub>(NO<sub>2</sub>)OH

(Ber 1908, 41, 4027, 4304)

Occasionally traces of these intermediate diazonmines and diazo-oxides can be detected in the commercial azo-colouring matters (Vaubel, Zeitsch Farben Textil Ind 1902, 1, 3).

# V. METALLIC DERIVATIVES OF DIAZO-COMPOUNDS.

In 1894 Schraube and Schmidt (Ber 27, 514) found that on adding a 10 p.c. solution of p-nitrober zenediazonium chloride to 18 pc aqueous sodium hydroxide at 50°-60°, a sodium diazo-derivative separated in yellow bronzy leafiets, to which they gave the formula

NO2 C6H4 NNa NO, H2O

regarding the compound as the sodium derivative of p-nitrophenylnitrosamine. This view of the constitution of the product was confirmed by the action on the compound of methyl iodide when p-nitrophenylmethylnitrosamine.

was obtained

This sodium salt, which was regarded by Hantzsch as having the constitution of an antidiazo-compound, sodium p-nitrobenzenediazo-nxide (v infra), has been manufactured for use in the production of 'introsamine red' (Badische Anilin- und Soda-Fabrik D. R. PP. 78874, 80263, 81134, 81202). The addition of excess of mineral acid to this metallic diazo-derivative, determines the regeneration of the original diazonium salt, but treatment with dilute acetic acid leads to the formation of a yellow product, p-nitrophenylnitrosamine. NO<sub>2</sub> C<sub>6</sub>H<sub>4</sub> NH NO, a substance showing little tendency to couple with β-naphthol

The silver derivative obtained from the foregoing sodium salt yields on methylation an oxygen ether NO<sub>2</sub> C<sub>6</sub>H<sub>4</sub> N N O CH<sub>3</sub>, a reaction suggesting the possibility of tautomeric change in many instances, two isomeric modifications of these metallic diazo-deit-

vatives have been isolated

Benzenediazonium chloride and cold concentrated potassium hydroxide yield the normal labile form of potassium benzenediazo-oxide (I), which readily couples with β-naphthol. The stable modification of potassium benzenediazo-oxide (II) is produced by heating the strongly alkaline solution of the normal or labile salt at 130°–140°; this isomeride couples only very slowly with β-naphthol

According to Hantzsch, these isomerides have respectively the following formula —

$$\begin{array}{cccc} C_8H_8 & N & C_8H_8 & N \\ & \parallel & & \parallel \\ & KO & N & N & OK \\ I & \textit{Syn-} & (labile form) & II & \textit{Anti-} & (stable form) \end{array}$$

Dobbie and Tinkler (Chem. Soc. Trans. 1905, 87, 273) have found, however, that these isomeric potassium salts have totally different ultra-violet absorption spectra But as stereo-isomerides, like the benzaldoximes, have identical absorption spectra, it seems probable that the above isomeric salts are structurally dissimilar. Confirmation of the stereochemical theory would be obtained by isolating the antidiazohydroxide from the stable (anti-) potassium salt, but on treating this with an acid, the nitro-Moreover, the product supsamine separates posed by Hantzsch and Pohl to be an antidiazohydroxide (Ber. 1902, 35, 2964) was shown by Orton to be a mixture of quinonediazide and a hydroxyazo- compound (Proc Roy Soc 1903, 71, 153; Chem Soc Trans 1903, 83, 796)

The existence of the syn-diazohydroxides is doubtful, and diazonium hydroxides (v. supra) are only known in solution.

Diazo-anhydrides RNNON·NR or R·N·ON.NR are very unstable explosive com-N

pounds produced by the action of acetic acid on the metallic sym-diazo-oxides. The anti-diazooxides, when thus treated, give nitro samines.

Aromatic diazoic acids Ar N<sub>2</sub>O<sub>2</sub>H. Benzene-

diazoic acid, produced by oxidising potassium benzenesyndiazo-oxide or -isodiazo-oxide with potassium ferricyanide in alkaline solution, is obtained in sparingly soluble white leaflets (mp 46°) dissolving readily in organic solvents or alkalis. With mineral acids it is transformed into o- and p-introamline, and with hypochlorites it yields 4-chloro-2-introamline lits sodium salt gives the  $\alpha$ - or N-ester C<sub>6</sub>H<sub>5</sub>, N(CH<sub>2</sub>) NO<sub>2</sub>, the silver salt furnishes the  $\beta$ - or O-ester, C<sub>6</sub>H<sub>5</sub> N NOO CH<sub>3</sub>. Since the acid is also obtained by the action of introgen pentoxide on aniline it is probably a tautomeric substance C<sub>6</sub>H<sub>5</sub> N N NO<sub>2</sub>=C<sub>6</sub>H<sub>5</sub> N NO<sub>2</sub>H (Bamberger, Ber 1893, 26, 471; 1894, 27, 359, 914, 584, 1273, Hantzsch, Ber. 1902, 35, 258)

#### VI DIAZO- CYANIDES.

The addition of the calculated amount of potassium cyanide to a cold acid solution of a diazonium salt determines the formation of a sparingly soluble diazo-cyanide. In many instances, two modifications of the diazocyanides can be distinguished, and these varieties are regarded by Hantzsch as being stereoisomeric forms p-Chlorobenzenediazonium chloride, from p-chloraniline, yields first the yellow labile syn-p-chlorobenzenediazoeyanide (1.), which readily evolves nitrogen, yields

$$\begin{array}{cccc} C_6H_4CIN & C_6H_4CIN \\ \parallel & & \parallel \\ CN\cdot N & & N\cdot CN \end{array}$$

I. Syn-diazocyanide II. Anti-diazocyanide p-chlorobenzontrile on treatment with copper powder, and passes into the stable anti-p-chlorobenzenediazocyanide (II) The latter substance, which is not affected by copper powder, may be distilled in steam without decomposition.

Confirmation of this stereochemical theory of the constitution of the diazo-cyanides has been obtained by a study of the cyanides derived from p-methoxybenzenediazonium chloride. This salt with potassium cyanide in alcoholic solution yields the syn-diazocyanide (III), an orange-red insoluble substance (mp. 51°), which couples with \(\beta\)-naphthol and slowly changes into the non-coupling anti-diazocyanide (IV), a brownish - red compound, melting at 121°.

The existence of a third isomeric cyanide is indicated by evaporating at the ordinary temperature in the presence of excess of hydrocyanic acid, an aqueous solution of p-methoxy-benzenediazonium hydroxide. The colourless crystalline product has the composition:

CH<sub>3</sub>O C<sub>6</sub>H<sub>4</sub>·N<sub>2</sub>·CN,HCN,2H<sub>2</sub>O

and possesses all the properties of a true metallic salt; it is very soluble, and its solution is an electrolyte. Moreover, this double salt couples with  $\beta$ -naphthol, and is converted by alkalis into the yellow syn-diazo cyanide. These properties correspond with those of the normal diazonium salts, and the foregoing soluble cyanide is regarded as having the following constitution:

N (Hantzsch, Ber. 1900, 33, 2161; 1904, 34, 4166).

The two pairs of diazo- cyanides from pchlorandine and p-anisidine were examined spectroscopically by Dobbie and Tinkler, who found that each pair gave almost identical ultra-violet absorption spectra, whereas the above soluble diazonium cyanide gave an entirely different spectrum These results are in accordance with Hantzsch's view of the configuration of the diazo- and diazonium cyanides (Chem Soc. Trans. 1905, 87, 273)

It has, however, been suggested by several workers in this field that the isomerism of the diazo- cyanides is structural, the syn- compounds being iso-cyanides R N N NC and their antiisomerides, cyanides R N N CN (Ber 1895, 28

861; Chem Soc. Trans 1903, 83, 805)

#### VII DIAZO- SULPHONATES.

Although the stereochemical theory of the constitution of diazo- cyanides is supported by physical as well as chemical evidence, yet it is significant that the only other series of salts in which this isomerism has been detected is one derived from sulphurous acid, a substance resembling hydrocyanic acid in giving rise to organic isomeric derivatives which are structurally dissimilar

The diazo-sulphonates, prepared by adding potassium sulphite to aqueous solutions of benzenoid diazonium chlorides, frequently exist in two differently coloured modifications, but in most cases the syn- isomeride is too unstable to be isolated in a pure state

Potassium syn-2 4-diiodobenzenediazosulphonate (I.) is an orange substance, whilst the antisalt (II) is yellow:

The diazotised naphthylamines behave exceptionally, yielding only syn-diazosulphonates, which, on warming pass, not into their antiisomerides, but into the corresponding azonaphthalenes (Ber 1897, 30, 71).

The syn- and anti- modifications of potassium benzenediazosulphonate  $C_0H_5$  N N  $SO_3K$ , were found by Dobbie and Tinkler (lc) to have identical ultra-violet absorption spectia fact supports the stereochemical theory of their structures (cf. Ber 1894, 27, 1726, 2099, 2586, 2930, 3527; 1895, 28, 242, 447, 834, 861, J pt. Chem 1894, [n] 50, 239; Meyer and Jacobsen, Lehrbuch der Org Chem 11 303)

# VIII. ALIPHATIC DIAZO- COMPOUNDS.

The amines of the aliphatic series, when treated with nitrous acid, generally lose their basic nitrogen, the amino- group becoming replaced by hydroxyl In some cases, however, the nitrogen is retained and an aliphatic diazocompound is produced, having the general

formula RH C  $\stackrel{\cdot}{\underset{N}{\bigcup}}$  with the azo- group attached

entirely to the same carbon atom

An alternative formulation has been suggested for the aliphatic diazo- compounds in the general formula becomes >('N' N (Thicle, Ber. 1911, 44, 2522; Forster and Cardwell, Chem Soc. Trans. 1913, 103, 861; cf Ber 1912, 45, 1654; 1916, 49, 1884

Although glycine is converted by nitious acid or alkyl nitrites into glycollic acid, yet its ethyl ester gives 1180 to ethyl diazoacetate  $N_2$  CH CO<sub>2</sub> C<sub>2</sub>H<sub>5</sub>, a yellow liquid freezing at 24 and boiling at  $143^{\circ}-144^{\circ}/72$  mm (Curtius,

Ber 1883, 16, 2230)

One kilogram of ethyl aminoacetate hydrochloride and 750 grams of sodium nitrite are added successively to 2 lities of water containing 5 grams of sodium acetate. The mixture is shaken until the temperature falls to 0°, 5 cc. of 10 p c sulphuric acid and 500 c c of ether are added and the liquids thoroughly agitated The ethereal layer is separated and the treatment with dilute acid and ether repeated until red fumes are evolved The ethereal extracts are washed with dilute aqueous sodium carbonate till alkaline, dried with calcium chloride, and the solvent removed on the water-bath. The yield of ethyl diazoacetate is 94 7 p c of the calculated quantity (Silberrad, Chem Soc Trans 1902, 81, 600)

With iodine, ethyl diazoacetate yields duodoacetic acid, and with aldehydes it condenses to form ketonic esters

$$\begin{array}{c} {\rm R\cdot CHO + N_2\ CH\ CO_2\ C_2H_5} \\ \longrightarrow \\ {\rm R\ CO\ CH_2\ CO_2\ C_2H_5} \end{array}$$

One of the most remarkable reactions of this diazo- ester is its condensation with benzene and its homologues, giving rise to a series of esters containing seven-membered hydrocarbon rings (Bucherer, Ber 1896-1903, 29, 106, 30, 632, 1949, 31, 399, 402, 2004, 2241, 2247, 32, 705, 33, 184, 36, 3509; Annalen, 1908, 358, 1)

Ethyl diazoacetate, when heated with alkalis undergoes a series of complex polymetic changes (Curtius, Ber. 1885, 18, 1283, 1906, 39, 1383, 3398, 4140, 1907, 40, 84, 815, 1176, 1194, 1470, 1908, 41, 3116, 3140, 3161, J pr Chem. 1888, [2] 38, 408, Hantzsch, Ber 1900, 33, 58, cf Chem Soc Trans 1902, 81, 598)

Diazo- derivatives are not obtained from free a-amino-carboxylic acids, and only from those amino-esters of aliphatic acids containing the amino- group in the a-position with respect to alkylated carboxyl group. The esters of those polypeptides which contain the aminogroup in the α-position to a carboxyl- group can also be transformed into diazo- derivatives.

$$\begin{array}{c} \mathrm{NH_2\,CH_2\,CO\,NH\,CH_2\,CO_2Et} \\ \quad \boldsymbol{\to} \quad \mathrm{N_2\,CH\,CO\,NH\,CH_2\,CO_2Et} \end{array}$$

The  $\alpha$ -aminoketones (e.g.  $\alpha$ -aminoacetophenone  $C_6H_5$  CO  $CH_2$   $NH_2$ ) give diazo- compounds (Ber 1904, 37, 2080), and so also do certain urie acid compounds, eg ammomethyluracil.

Diazomethane 
$$CH_2 \stackrel{N}{\swarrow}_N$$
, or  $CH_2 \cdot N : N$ , the

simplest aliphatic diazo- compound, is prepared by adding methyl-alcoholic potassium hydroxide to an ethereal solution of nitrosomethylurethane

and distilling the mixture on the water-bath, when the distillate consists of an ethereal soluwhich one nitrogen is quinquevalent, so that tion of the diazo- compound, the yield being 50 p.c. of the calculated quantity. This substance is also produced by the action of hydroxylamine on dichloromethylamine

 $CH_3 NCl_2 + H_2NOH = CH_2 N_2 + H_2O + 2HCl$ 

Diazomethane is a poisonous yellow gas condensing in snow and calcium chloride to a yellow liquid boiling below 0° It is a powerful methylating agent, converting hydroxyl groups into methoxyl, and alkylating primary and secondary bases. With iodine, diazomethane gives nitiogen and methylene iodide, and aldehydes are converted into methyl ketones (cf Monatsh 1905, 26, 1295, 1311, Ber 1907, 40, 479, 1908, 41, 3199, 1909, 42, 2559; Chem. Soc. Trans. 1908, 93, 242).

Diazomethane combines additively with unsaturated compounds; with acetylene it gives pyrazole (Ber 1898, 31, 2910), and with ethyl fumaiate it furnishes ethyl pyrazolinecar-

boxylate

Diazoethane CH3 CH . N2 and phenyldiazomethane C6H8 CH N2 have both been prepared (Ber. 1902, 35, 897) The former closely resembles diazomethane, the latter is a dark-red

Substitution increases considerably colour of these diazo- derivatives dimethyldiazomethane  $C(CH_3)_2$   $N_2$  is red and diphenyl-diazomethane is obtained in bluish red needles melting at 20' (Staudinger, Ber 1916, 49, 1884)

Diazomethane should not be confused with azoniethane CH<sub>3</sub> N H CH<sub>3</sub>, the simplest azocompound which is produced by oxidising symmetrical dimethyllightazine (hydrazomethane) with chromic acid (Thiele, Bei 1909, 42, 2575) Azomethane is a colourless gas condensing to a pale yellow liquid (b p 15°).

Diazomethanedisulphonic acid, noteworthy example of an aliphatic diazo-compound, results from the interaction of potassium cyanide and potassium bisulphite in presence of caustic potash. The solution, acidified and treated with nitrous acid, yields successively aminomethanedisulphonic acid and the diazo- compound Sulphurous acid and diazomethanedisulphonic acid yield an additive compound which, on boiling, furnishes hydrazine (V. Pechmann, Ber · 1895, 28, 2374, 1896, 29, 2161)

Diazoacetone CH<sub>3</sub> COCH N<sub>2</sub>, a pale yellow liquid, is obtained from aminoacetylacetone by converting this base into diazoacetylacetone anhydride and treating this product with aqueous caustic alkalı (Wolff, Annalen, 1912,

394, 23)

Metallic diazo- derivatives of the aliphatic series are produced by treating nitrosoalkyl urethanes with concentrated caustic potash solution or ethereal potassium ethoxide Potassium methyldiazo-oxide CH3 N B OK, H2O separates in white crystals, when nitrosomethylurethane is added to concentrated aqueous caustic potash at 0°. Potassium benzyldiazo-oxide

C<sub>6</sub>H<sub>5</sub> CH<sub>2</sub> N N OK,H<sub>2</sub>O

is similarly prepared from nitrosobenzyluiethane These metallic derivatives are very unstable, they are decomposed by water with explosive violence, yielding respectively diazomethane and phenyldiazomethane (Hantzsch and Lehmann, Ber 1902, 35, 897)

DIAZOMETHANE v Diazo- compounds

**DIAZURINE** r Azo- colouring matters. DIBASIC ACIDS. Oxalic acid series numerous and important group of acids, having the general formula  $(nH_{2n-2}O_4)$  The lowest member of the series is oxalic acid C2H2O4, and the highest member at present known, dicetyladipu acid C38H74O4 As the radical CnH2n is capable of existing in a variety of ways, it follows that these acids may exist in many isomeric forms. Unlike the fatty acids, the lowest members of the oxalic acid series are solids

The naturally occurring acids exist partly free and partly as salts or esters. Thus oxalic acid occurs chiefly as the potassium salt in different varieties of Oxalis and Rumex, malonic acid, as the calcium salt, is found in the sugar beet, succinic acid in amber, certain varieties of lignite, resins, turpentine oils, and animal fluids, rocellie acid in Rocella tinctoria (D. C.) Other members of this series are obtained by the oxidation of naturally occurring substances suberic acid is obtained by boiling cork with mitie acid, azelaic acid by the oxidation of castor oil, adipic acid by the oxidation of suct or. tallow, whilst homologues of succinic, glutaric and adipic acids are frequently obtained in the oxidation of derivatives of the terpene compounds. The higher members of the series are prepared by the oxidation of members of the fatty acid series

General methods of preparation

(1) By the oxidation of the diprimary glycols, primary hydroxyaldchydes, dialdehydes, primary hydroxy- acids, or aldehydeeg glycol, glycollic acid, glyoxal, or glyoxylic acid -> oxalic acid

(2) By the oxidation of the fatty acids or of acids of the oleic acid series, e.g. erucic acid

→ brassylic acid

(3) By the reduction of unsaturated diearboxylic acids, eg fumanic acid  $\rightarrow$  succinic

(4) By the action of silver (powder) on monoiodo- (or bromo)- fatty acids;  $e.g. \beta$ -iodopropionic acid -> adipic acid

Exception —The reaction is abnormal when a-bromisobutyric acid is used, di- and tri- alkyl-

glutaric acids being produced.

(5) By the conversion of monohalogen. substituted fatty acids or of the halogen addition products of the alkylenes  $C_nH_n$  into cyanderivatives and saponification of the latter, e.g. cyanacetic acid -> malonic acid; ethylene dicyanide -> adipic acid.

(6) By the replacement of the hydrogen atoms of the CH<sub>2</sub> group in the malonic esters by various alkyl-groups; e g sodium malonic ester and methyl iodide  $\rightarrow$  180-succinic ester.

(7) By the blectrolysis of concentrated solutions of potassium alkyl salts of the dicarboxylic acids, eg potassium ethyl malonate  $\rightarrow$ diethyl succinate

(8) By the introduction of acid residues into the acctoacetic esters, and decomposition of the product with alkali,  $\epsilon g$ , acctosuccime ester  $\Rightarrow$  succime acid

(9) By the decomposition of tricarboxylic acids containing two carboxyl- groups attached to the same carbon atom,  $e\,g$ , ethanetri-

earboxylic acid  $\Longrightarrow$  succinic acid

The acids of this series behave differently on the application of heat, depending upon the position of the carboxylic groups Oxalic acid, the first member of the series, breaks down on heating mostly into carbon dioxide, carbon monoxide, and water, and partly into carbon dioxide and formic acid. This latter decomposition is typical of those homologues of oxalic acid in which the two carboxyl- groups are attached to the same carbon atom, they are the \$-dicarboxylic acids, and of these malonic acid is the type On application of heat, malonic acid splits into acetic acid and carbon The next class, the γ-dicarboxylic acids, in which the two carboxyl- groups are attached to adjacent carbon atoms, when heated, lose a molecule of water and pass into anhydrides Succinic acid is the type of these acids. Acids, such as glutaric acid, in which the earboxyl- groups are attached to two carbon atoms separated by a third, behave similarly to the  $\gamma$ -dicarboxylic acids, but form anhydrides less readily When the carbon atoms to which the carboxyl- groups are attached are separated by two carbon atoms, eq adipic acid, they do not influence one another on the application of heat For these reasons, the paraffin dicar-boxylic acids are arranged in different groups, the general properties of which will be discussed under Malonic Acid, Succinic Acid, and Glu-TARIC ACID, which are types of the several groups mentioned above

(For melting-points of the dibasic acids, v Massol, Bull Soc chim [3] 21, 578, melting-points of their esters, v. Schneider, Zeitsch physikal Chem. 22, 228, electrical conductivity of the acids, v Walden, ibid 8, 448, volatility in steam, v. Auwers, Annalen, 292, 159)

DIBENZIL v. KETONES.

DI-150-BUTYLACETIC ACID v DECATOIC ACIDS.

#### 2 6 DI 150-BUTYLPIMELIC ACID

 $CH_2[CH_2 CH(C_4H_9) CO_2H]_2$ 

Prepared by heating 1.5 di-180-butylpentanetetracarboxylic acid at 200°-220° (Perkin and Prentice, Chem. Soc Trans 1891, 842); mp 82°-84°.

**DICENTRINE**  $C_{20}H_{21}O_4N$  occurs with protopine in *Dicentra pusilla* (Sieb and Zucc) and possibly in *D. formosa* (Walp.). Prismatic crystals, m r  $168^{\circ}-169^{\circ}$ ,  $\lceil \alpha \rceil_D+62^{\circ}$  in chloroform Salts crystalline (Heyl. Arch. Pharm. 1903, 241

313; Asahina, tbid. 1909, 247, 201). Produces slight narcosis (lwakawa, Arch expt. Path Pharm. 1911, 64, 369) Gadamer has stated (Arch. Pharm. 1911, 249, 680) that dicentine resembles glaucine in its properties, and suggests that it is glaucine in which the two—OMe groups in positions 5 and 6 are replaced by a dioxymethylene group

by a dioxymethylene group

DICETYLADIPIC ACID C<sub>38</sub>H<sub>74</sub>O<sub>4</sub>. Propared by heating dicetylbutanetetracarboxyle acid to 205° (Lean, Chem Soc. Trans. 1894, 1016) Two isomerides are thus produced, which may be separated by crystallisation from alcohol, α acid, m p 42°-43°, β-acid, m.p 32°-34°

**DICETYLIC ACID** ('H(('1<sub>8</sub>H<sub>32</sub>)<sub>2</sub>COOH is obtained by heating dicetylmalome acid; m.p. 69°-70° (Guthzeit, Annalen, 206, 365)

#### DICETYLMALONIC ACID

The ethyl ester is formed by treating diethyl-malome ester with sodium methoxide and cetyl rodide, the ester is decomposed with a concentrated solution of caustic potash, mp 86°-87° (Guthzeit, Annalen, 206, 362)

**DICHLORAMINET.** Toluene-p-sulphone di-

chloramme.

# 2 5-DICHLOROANILINE

Prepared by reducing 2–5-dichloronitiobenzene with non-and hydrochloric acid; mp 50°, b p 246°/744 mm. Used in making the chloramine dyes

# 2.5-DICHLOROANILINE-4-SULPHONIC

2 5-dichloroaniline Soluble in hot water. Solum salt with 5 molecules H<sub>2</sub>O readily soluble (Noclting and Kopp, Ber 1905, 38, 3513)

# 1.5-DICHLOROANTHRAQUINONE

is obtained by boiling an aqueous solution of alkali anthraquinone-1 5-disulphonate with hydrochloric acid and sodium chlorate (Ullmann and Knecht, Ber 1911, 44, 3125, Farbenfab. vorm F Bayer & Co, D R P 205195) Also by suspending 1 5-diaminoanthraquinone in hydrochloric acid, diazotising at 5°-10°, and treating the solution with cuprous chloride dissolved in hydrochloric acid (idem D R. P. 131538) Citron-yellow needles, readily soluble in hot toluene, sparingly soluble in alcohol, mp 251° Used in making indanthrene violet (q v art Indanthrene).

#### 3 3'-DICHLOROBENZIDINE

$$NH_2$$
 $Cl$ 
 $NH_2$ 
 $NH_2$ 

Prepared by chlorinating a sulphuric acid solution of diacetyl benzidine (made by boiling benzidine with glacial acetic acid) with bleaching powder or sodium hypochlorite solution, filtering, adding hydrochloric acid, and hydrolysing the product (Levinstein, Eng. Pat. 25725, 1896) May also be obtained by reducing o-chloronitrobenzene in an alkaline solution by means of zinc dust (cf. Cohn, Ber. 1900, 33, 3551).

DICHLOROCARBAMIDE v HYDRAZINES. DICHLOROPHTHALIC ACIDS v. PHTHALIC

2' . 5'-DICHLORO-4'-SULPHO-1-PHENYL-3-METHYL-5-PYRAZOLONE. Prepared by condensing ethyl acetoacetate with 2 5-dichlorophenylhydrazine 4-sulphonic acid (D. R. P. 222405). Used in making Xylene yellow (see PYRAZOLONE COLOURING MATTERS)

DICHROITE v IOLITE.

DICYANDIAMIDE, Cyanoquanidine

# NH2(NH )C NH C+N

Obtained by the polymerisation of cyanamide in aqueous solution on long standing or on warming, especially after addition of a drop of ammonia (Belstein and Geuther, Annalen, 108, 99, 123, 241, Haag, ibid 122, 22), by treating thiourea with mercuire and ine (Montecchi, Gazz chim ital 28, ii 434) Prepared by heating ammonium sulphate and sodium cyanamide on the water-bath, cyanamide separates as a vellow oil, which, after some hours, with frequent shaking, changes into dicyandiamide (Hermann, Monatsh 1905, 1025) Soll and Stutzer (Ber 1908, 4534) make crude calcium nitride into a paste with water and heat to boiling The hot liquid is filtered by suction, and dicyandiamide separates out from the filtrate Crystallises in needles; mp 205° (Pohl, J pr Chem 77, [2] 533) By warming with dilute acids, it is transformed into dicyandiamidine (quanyl urca) NH<sub>2</sub>(NH )C NH CO NH<sub>2</sub> It is used in quantitative analysis to separate nickel from cobalt The solution containing mickel and cobalt is made alkaline, and to it is added a small quantity To this is added dicyandiof sugar solution amidine sulphate (prepared by dissolving di-cyandiamide in dilute sulphure acid), whereby the nickel salt of dicyandiamidine is precipitated, the cobalt remaining in solution. The precipitate is filtered through a Gooch crucible, dued at  $115^{\circ}$ – $160^{\circ}$ , and weighed as anhydrous mekel dicyandiamidine Ni(C<sub>2</sub>H<sub>5</sub>N<sub>4</sub>O)<sub>2</sub> (Grossmann and Schuck, Analyst, 1910, 247, 1909, 455 . 1907, 273, 394) Dievandiamide is reduced by zine and dilute hydrochloric acid at the ordinary temperatures to methylamine and guanidine, the methylamine being formed by the reduction of the prussic acid first produced (Bamberger and Seeberger, Ber 1893, 1583), a mixture of nitric and sulphuric acids converts it into nitrodicyanodiamidine (Thiele and Uhlfelder, Annalen, 303, 107); it condenses with dialkyleyanacetic or malonic esters yielding pyrimidine derivatives, thus with diethylevanacetic ester a condensation product is obtained which yields diethylbarbituric acid on treatment with sulphuric acid (Bayer & Co, D R P 165223; Chem Zentr 1906, 1 514) All manures containing calcium cyanamide contain also dicyandiamide, formed by the spontaneous polymerisation of the calcium cyanamide; it is not poisonous to plants if not used in too large quantities (Perotti, Atti R. Accad. Lincei, 15, 48; Chem Zentr. 1909, 1 1497; Inouye, J. Soc.

Chem Ind. 1909, 1054; Aso, ibid.). The Cyanide-Gesellschaft (Chem. Zentr. 1904, u. 1079; D.R P. 154505) treat calcium carbide or a carbideforming mixture with nitrogen, lixiviate the mass with water, and use the product, which contains calcium cyanamide, dicyandiamide, &c, as a manure (v. also Frahk, Zeitsch angew Chem 19, 835) The constitution of dicyandi-Chem 19, 835) amide is regarded as NH<sub>2</sub>(NH.)C·NH·C·N or the tautomeride (NH<sub>2</sub>)<sub>2</sub>C N C·N (Bamberger, Ber 1883, 1459, 1891, 899; Biltz, J pr. Chem 77, In 1533, Prianichnikov, J. Soc Chem. Ind 1909, 724)

DIDYMIN v SYNTHETIC DRUGS

DIDYMIUM v Praseodymium and Neo-DYMIUM

DIETHYLACETIC ACID. Pseudo-ca proic acid (v CAPROIC ACID)

DIETHYLALLOXAN v ALLOXAN.

**DIETHYLAMINE** v. under Ethylamines, art ETHYL

p-DIETHYLAMINOBENZOIC ACID

$$CO_2H$$
  $N(C_2H_5)_2$ 

Prepared by the action of carbonyl chloride on diethylaniline or by ethylating p-aminobenzoic acid, mp 188°.

DIETHYL-m-AMINOPHENOL

$$\underbrace{OH}_{N(C_2H_{5})_2}$$

Formed by heating m-aminophenol hydrochloride with ethyl alcohol under pressure (Bad Aml und Soda Fabrik, D. R. P. 44002), by heating resorcinol with diethylamine (Leonhardt & Co, D R P 49060), by alkalı fusion of diethylaniline-m-sulphonic acid (Soc Chem Ind Basle, D R P. 44792) For details of the last-named process as used on the large scale, see Cain, Intermediate Products for Dyes, mp 78° bp 201°/25 mm Used in the manufacture of rhodamine B

DIETHYLANILINE  $\langle N(C_2H_5)_2 \rangle$ Ob-

tamed by heating aniline hydrochloride with ethyl alcohol under pressure, or, better, by heating aniline hydrobromide with (thyl alcohol at 145°-150° (Stadel, D. R. P. 21241), or by ticating aniline with ethyl alcohol in presence of iodine at 235° (Knoll & Co, D. R. P 250236), m p -381°, b p 2165°, spgr 0930 at 18°. DIETHYLANILINE-m-SULPHONIC ACID

$$\underbrace{\begin{array}{c} \mathrm{SO_3H} \\ \mathrm{N}(\mathrm{C_2H_5})_2 \end{array}}$$

Is prepared by acting on diethylaniline with fuming sulphuric acid

DIETHYLDIACETOSUCCINATE v KETONES. DIETHYL OXALACETATE v KETONES DIETHYLSAFRANIN v. AZINES

**DIETZEITE.** A double rodate and chromate of calcium crystallising in the monoclinic system, discovered in 1891 in the sodium nitrate deposits of Atacama, Chile Analyses lead to the formula  $7\text{Ca}(\text{IO}_3)_2$ ·8CaCrO<sub>4</sub>, but the simple double salt formula  $\text{Ca}(\text{IO}_3)_2$ ·CaCrO<sub>4</sub> appears more probable Distinct crystals are rare, the mineral usually forming crystalline fibrous aggregates of a dark gold-yellow colour. Sp gr. DIFFUSION. 521

3.698 It is soluble in hot water; on cooling crystals of hydrated calcium iodate  $(Ca(IO_3)_2 + 6H_2O)$  separate, leaving the calcium chromate in solution. The simple calcium iodate  $(Ca(IO_3)_2)$  called lautarite occurs in the same deposits.

L. J S DIFFUSION. In any gaseous mixture of liquid solution, even when protected from mechanical disturbances and kept at a uniform temperature throughout, the composition ultimately becomes the same at all points, whatever the original distribution of the gaseous or dissolved substances may have been The process by which this condition is reached is termed 'diffusion,' and it depends, not on the circulation of the unequally distributed substances as a whole, but on molecular movement According to the kinetic theory, a mass of gas which, as a whole, is at rest, is yet the scene of great activity on the part of the constituent molecules are endowed with a high velocity, and alter the direction of their motion only when they collide with one another or with the walls of the containing vessel If this point of view is adopted, then the occurrence of diffusion in a mixture of irregularly distributed gases becomes intelligible There are, moreover, many experimental grounds for extending the kinetic theory to the liquid state, and for the view that the molecules of a liquid also are in a state of constant motion With this conception the phenomenon of diffusion of a dissolved substance is obviously in harmony

#### Diffusion of Gases.

When two vessels containing different gases at the same temperature and pressure are put into free communication, each gas penetrates the other until its partial pressure is uniform in both vessels. The experimental investigation of this phenomenon on quantitative lines is not easy, but it appears to be well established that the diffusion coefficient of each gas varies from point to point of the diffusion system (see Loschmidt, Sitzungsbei. Akad Wiss Wien, 1870, 61, 367, 1870, 62, 468, von Obermayer, 500 dt 1880, 81, 1102, 1882, 85, 147, 748, 1883, 87, 188; 1887, 96, 546, Waitz, Ann Physik, 1882, 17, 201, 351, Lomus, 1001, 1909, 29, 664)

When the concentration of a gas is maintained constant at one point of a gas system and zero at another point, a static condition of affairs is established analogous to what is observed when one end of a metal bar is kept at a high temperature and the other end at a low temperature. If, for instance, a tall cylinder, communicating freely with the atmosphere, contains at the bottom a layer of caustic alkali, there is a regular concentration gradient from the top downwards, the carbon dioxide being completely absorbed at the surface of the alkali Provided the concentration difference between the top and bottom of the cylinder is maintained constant, a steady condition of diffusion is attained, and the rate of flow of the carbon dioxide, as deduced from the amount absorbed by the alkalı, is inversely proportional to the length of the diffusion column (see Brown and Escombe, Phil. Trans B, 1900, 193, 223, also Winkelmann, Ann Phyrik, 1884, 22, 1, 152)

Much attention has been devoted to the phenomenon of diffusion across porous dia-

phragms, through capillary tubes, and from Graham showed (see Cheminarrow apertures cal and Physical Researches, p 44) that the exchange of two gases across a perous diaphragm, the pressure on the two sides remaining the same, takes place in such a way that the volumes of the gases diffused in a given time are inversely proportional to the square roots of their densities. This observation is of very great interest in connection with the kinetic theory, from the assumptions of which it follows that the mean velocity of the molecules of a gas is inversely proportional to the square root of its Giaham's law is not accurate except when the diaphragm is extremely thin, but it is nevertheless the basis of a method for separating Thus, for two gases of different densities instance, when a mixture of hydrogen and oxygen in the proportion of 2 1 by volume is passed at a suitable rate through a train of claypipe stems, the gas collected at the further end will ignite a glowing splint By experiments of this kind it was shown that atmospheric nitrogen is a mixture of at least two gases of different density (see Rayleigh and Ramsay, Phil Trans 1895, 186, 206). The operation of separating gases by this method is termed 'atmolysis'

In the passage of a gas through a capillary tube—' transpiration,' as it is sometimes called—friction generally plays a considerable part, but it has been found that if the diameter of the tube is small in comparison with its length and with the mean free path of the gas molecules, then the quantity of gas passing through a given tube in unit time is inversely proportional to the square root of the density (Knudsen, Ann. Physik, 1999, 28, 75)

The time required for the escape or 'effusion' of a given volume of gas through a fine aperture in a thin plate into a vacuum is approximately proportional to the square root of the density of the gas. The thinner the plate and the smaller the aperture, the more nearly is this relationship fulfilled (see Graham, Chemical and Physical Researches, p. 88., Bunsen, Gasometry, p. 121, Timofécif, Zeitsch physikal Chem. 1890, 6, 586, Donnan, Phil. Mag. 1900, 49, 423, Emich, Monatsh. 1903, 24, 747, Knudsen, Ann. Physik, 1909, 28, 999). An apparatus for determining the relative density of two gases, based on this principle, has been described by Bunsen (lee) (v. Specific gravity)

The passage of a gas across a diaphiagm takes place, not only when the diaphragm is porous in the ordinary sense, but also when it has the power of dissolving or absorbing the gas Thus, at high temperatures, platinum and palladium absorb considerable quantities of hydrogen, and this gas readily diffuses through the walls of a vessel made of other metal Winkelmann (Ann Physik, 1901, 6, 104, 1902, Nicol & Parnell, Phil Mag, 1901, 6, 104, 1902, Nicol & Parnell, Phil Mag, 1901, 8, 1, Schmidt, Ann Physik, 1904, 13, 747) has shown that the rate of diffusion of hydrogen through glowing platinum or palladium is not, as might be expected, proportional to the pressure of the hydrogen, at lower pressures diffuses relatively more rapidly. the gas The experimental data seem to indicate that it is the atoms, not the molecules, of hydrogen which can pass through the metal

522 DIFFUSION.

On the ability of hydrogen and the inability of other gases to diffuse through heated palladium, there is based the osmotic cell described by

Ramsay (Phil Mag 1894, 38, 206)

The rate of diffusion of gases across a layer of water or aqueous solution depends mainly on the solubility and the density of the gas. According to Exner, who made experiments on the diffusion of gases across a film of soap solution, the velocity is, cateris paribus, directly proportional to the absorption coefficient of the gas, and inversely proportional to the square root of its density (Exner, Sitzungsber. Akad. Wiss Wien, 1874, 70, ii. 465, cf. Muller, Ann Physik, 1891, 43, 554). Other workers, who have studied the diffusion of gases through a jelly, through a layer of water supported by a plate of hydrophane, or through a rubber membrane, find that Exner's law is only an approximate statement of the facts (see Wichelbewsky, Pogg. Ann. 1876, 158, 545, Ann Physik, 1879, 8, 29, Hufner, Zeitsch physikal Chem. 1898, 27, 227, Hagenbach, Ann. Physik, 1898, 65, 673). Except for oxygen, the diffusion soefficients of gases are smaller in gelatine solution than in pure water.

#### Diffusion of Dissolved Substances.

The foundation of our knowledge of this subject was laid by the classical experiments of Thomas Graham (see Chemical and Physical Researches, pp. 444-600). In his experiments, 700 cub cm of water were placed in a cylindrical jar, and then 100 cub cm of the solution to be diffused were carefully conveyed to the bottom of the jar by a pipette. After a suitable time, portions of 50 cub cm were successively drawn off, these portions were evaporated, and the amount of substance that had diffused into each layer was thus ascertained Graham's comparative experiments on the diffusive power of different substances in aqueous solution led him to draw a distinction, which has become of the highest importance, between the behaviour of easily crystallisable substances, and that of substances which are marked by the absence of the power to crystallise So far as diffusibility is concerned, the distinction in question is based on the following figures, representing approximate times of equal diffusion hydrochloric acid, 1, sodium chloride, 23, sucrose, 7, magnesium sulphate, 7, albumin, 49, caramel, 98. The difference in diffusive power of crystal loids and colloids is very evident from these figures

The significance of the quantitative results obtained by Graham was emphasised by Stefan (Sitzungsber Akad Wiss Wien, 1878, 78, ii 957; 1879, 79, ii. 161), who showed that they were in harmony with Fick's diffusion law, that is, the diffusion of substances in aqueous solution is comparable with the distribution of heat in conductors. Fick's law is expressed algebrai-

cally by the formula  $dS = -kq \frac{dc}{dx} dt$ , where dS is

the amount of substance crossing a section of the diffusion column in time dt, the sectional area of this column being q sq. cm, and dc/dx being the concentration gradient, k is known as the 'diffusion coefficient'

The diffusion of dissolved substances, notably electrolytes, has been the subject of repeated

nvestigation, but the method employed has not differed materially from that of Graham, described above (see Scheffer, Zeitsch. physikal. Chem. 1888, 2, 390; Arthenius, sbid. 1892, 10, 51; Abegg, sbid. 1893, 11, 248; Euler, Ann. Physik, 1897, 63, 273; Abegg and Bose, Zeitsch. physikal Chem. 1899, 1, 17; Thovert, Compt. rend. 1902, 134, 826; Graham, Proc. Roy. Soc. 1903, 72, 212; Oholm, Zeitsch. physikal. Chem. 1904, 50, 309) The general result of these investigations has been to substantiate the validity of Fick's law, although the opposite opinion also has been expressed (see Wiedeburg, Zeitsch. physikal. Chem. 1892, 10, 509)

Special interest has attached to the diffusion of electrolytes since the enunciation of Arthenius's dissociation theory, according to which the ions of an electrolyte in aqueous solution are to be regarded in many respects as separate units The researches of Kohlrausch have proved that the contribution which the one ion of an electrolyte makes to the equivalent conductivity is independent of the other ion associated with it, and Nernst has shown that the mobility which is thus characteristic of each ion must be a determining factor in the diffusive power of any electrolyte of which the ion forms a part (Zertsch physikal Chem 1888, 2, 613). He has further deduced a theoretical relationship between the diffusion coefficient of a binary electrolyte and the conductivities of the two ions, and the values of the diffusion coefficient calculated on this basis are in good agreement

with the results of experimental work. By allowing substances to diffuse into a jelly the effects of convection currents and mechanical disturbances are eliminated and the difficulties attending the experimental study of liquid diffusion are diminished. The rate of diffusion is, at most, very slightly lower in a jelly than in water at the same temperature. Experiments, in which the ends of cylinders of agar-agar jelly were immersed in aqueous solutions of various substances, have shown that the total amount of substance diffusing into the jelly is proportional to the square root of the time during which diffusion has taken place. This is a result in harmony with Fick's law (see Voigtlander, Zeitsch physikal Chem 1889, 3, 316; cf. Chabry, Journ de Physique, 1888, 7, 115, Morse and Pierce, Zeitsch physikal Chem 1903, 45, 589, Hausmann, Zeitsch anorg Chem. 1904, 40, 110).

Experiments have been made also on the diffusion of various electrolytes and non-electrolytes in alcohol (Kawalki, Ann Physik, 1894, 52, 166, 300, 1896, 59, 637), of various metals in mercury, fused lead, &c (Meyer, ibid 1897, 61, 225; 1898, 64, 752, Humphreys, Chem Soc Trans 1896, 69, 243, 1079, Roberts-Austen, Phil Trans 1896, 187, 383, von Wogau, Ann. Physik, 1907, 23, 345), and of chlorine, bromine, and iodine in some organic solvents (Euler, Ann. Physik, 1897, 63, 273, Walden, Zeitsch. Elektrochem 1906, 12, 77). In the last-mentioned connection, Walden has shown that, when a given halogen is considered, the product diffusion coefficient × viscosity of solvent' is a constant, independent of the nature of the solvent. The value of the product for the different halogens is inversely proportional to the square root of the molecular.

DIGITALIS. 523

weight (cf Pissarjewsky and Karp, Zeitsch physikal. Chem. 1908, 63, 257).

The different rates of diffusion found by Giaham for different substances suggested to him that the process of diffusion might be useful in separating the constituents of an aqueous solution In this connection, he found that the difference in diffusive power between crystalloids and colloids, referred to above, was greatly accentuated by the interposition of a colloid membrane between solution and solvent, and the method of separation by diffusion through a septum of gelatinous matter he termed dialysis' A sheet of parchment paper, for instance, is tied tightly over the end of a cylindrical or bell-shaped glass vessel, provided with a flange, and into the receptacle so formed, a 'dialyser,' as it is called, the mixed solution of crystalloids and colloids is poured The outside of the parchment membrane is bathed with water, which is frequently renewed, and the result is that the contents of the dialyser, after a few days, are found to be practically free from crystalloids Instead of the apparatus just described, a sausage-skin dialysei may be employed the parchment tube is charged with the solution of crystalloid and colloid, and is hung up by its ends in a vessel of water

Collodion may be used as a membrane instead of parchiment, and it is obtainable in any desired form by the evaporation of the ordinary collodion solution (see Lillie, Amer J Physiol 1907, 20, 127, Schryver, Proc Physiol

Soc 1908, 23)

Dialysis plays a considerable part in the hineal production of beet sugar. In the technical production of beet sugar diffusion process for the extraction of the sugar, beet cuttings are treated with hot water treatment kills the protoplasm, and the cell membrane, which in the hving state is impermeable to sugar, now allows this substance to pass out into the water. The high tempera-The high temperature also favours rapid diffusion. The albuminous substances in the beet juice however, cannot readily penetrate even the dead protoplasm, which acts as a differential membrane, and thus leads to a dialytic separation of the sugar from some of the non-sugar constituents of the cell sap In the treatment also of beet sugar molasses dialysis with parchment membranes is employed. The result of this procedure is to reduce the salt content of the molasses, and so make possible the crystallisation of a further portion of the sugar (v SUGAR)

#### Diffusion of Solids.

The efficiency of certain cementation processes indicates that one solid can slowly penetrate another The occurrence of diffusion in solids has been proved and investigated by Roberts-Austen (Phil Trans 1896, 187, 383), who finds that at temperatures between 100° and 200° there is an appreciable diffusion of gold into solid lead in 30 or 40 days, although the penetration is much slower than into the fluid metal Experiments lasting over four years have shown that gold diffuses into solid lead, even at the ordinary temperature (Roberts-Austen, Proc. Roy Soc. 1900, 67, 101) J. C P.

DIGIPURATUM : DIGITALIS DIGITALINUM VERUM v DIGITALIS

Digitalis. Foxylore Digitalis folia, B.P. Digitalis, U.S.P. (Digitale, Fr., Fingerbut, Get ) The foxglove, Digitalis purpurea (Linn ), had been for some centuries a popular remedy for dropsy, when it was introduced into scientific It is medicine by Withering, about 1775 principally used for its action on the heart, it slows the beats, and makes them more powerful and regular, so that the output is increased Only the leaves are official, the seeds have a similar action, due, however, to different brinciples

Foxglove is a biennial plant, and the Brussels conference agreed that only the second year's leaf should be used, but, except for the greater difficulty of identification, there is no objection to using the first year's rosettes, which are as good as the flowering plant (Straub, Arch Pharm 1917, 255, 198) Cultivated plants up to the beginning of the flowering period, are fairly constant in activity, variations appear when the seeds upon—It would probably be the more economical to cultivate only first-year plants Mature wild plants differ greatly in various localitics (Straub). The time for gathering these is July and August, the British Pharmacopa ia prescribes leaves from plants beginning to flower. For further detail, see Nativelle (J. Pharm. Chim. [iv | 20, 81), and for culture, harvesting, and conservation, Newcomb (Amer J. Pharm 1912, 84, 201). Thapsil, which has a similar action to D purpurea, but is three times as strong, see Farwell and Hamilton, Amer J Pharm 1917, 89, 147

The active principles of digitalis (as of other plants with a like action, such as strophanthus and squill) are complex glucosides, often amorphous, and this explains the great difficulties and numerous contradictions with which the chemistry of digitalis is beset fusion is increased by the use of the same name (digitaline) for different substances, and by the application of different names to the same substance According to our present knowledge, cold water extracts from the leaves a mixture of glucosides, but hardly dissolves digitoxin, which may be subsequently extracted by alcohol From the aqueous extract chloroform removes the 'gitalm' fraction, and leaves behind one or more plucosides, designated as the 'digitalein' fraction, which is less active than either gitalin or digitoxin, and has not been obtained even approximately pure torically, the first moderately pure, but amor phous, a tive preparation was 'digitaline' of Homolic (J. Phaim Chim 1845, [iii.] 7, 57), undoubtedly a mixture Nativelle (J Pharm. Chim [v] 1869, 9, 225, 1872, 16, 430 1874, 20, 81) later prepared a 'digitaline cristallisée,' a commercial specimen of which Schmiedeberg 524 DIGITALIS.

(Arch. exp. Path. Pharm. 1874, 3, 16) declared to consist very largely of a substance to which he gave the name digitoxin, and as this substance was afterwards principally investigated in Germany, under this name, Nativelle's designation has been displaced, in spite of Fiench protests (e.g. Arnaud, Compt. rend. 1889, 109, 679) Kilmin, who has published something like forty papers on the chemistry of digitalis (Bei 1890, 23, 1555 to 1918, 51, 1613; and Arch Pharm 1892, 230, 250 to 1916, 254, 255), at one time did not agree with the identification of Nativelle's digitaline with Schmiedeberg's digitoxin, and considered the former substance identical with a crystalline leaf glucoside described by himself as digitophyllin (Arch Pharm 1897, 235, 425) Later, Kihani (Ber. 1898, 31, 2454) considered digitaline cristallisée and digitoxin very closely similar, but doubtfully identical. An attempt to restore the historically correct name for this glucoside would lead to still greater confusion, especially as German writers mean by digitalin a totally different glucoside from the seeds

The 'gitalm' fraction is, on account of its solubility in water and its physiological action, probably of most importance therapeutically, it was little studied until Kraft (Schweiz Wochenschr Chem Pharm 1911, 49, 161, 173, 236. Arch Pharm 1912, 250, 118) described the isolation of a crystalline glucoside gitalm Kiliam (Arch Pharm 1914, 252, 13) has declared Kriaft's preparation to be a mixture, but in any case it contains one or more crystalline substances of great activity, having the advantage over digitoxim of solubility in water, at least in the crude state. Indeed, the gitalm fraction seems to have been utilised some years before Kraft by Cloetta (Muench mediz Wochenschi 1904, 51, 1466), whose 'digitoximum solubile' is not digitoxim in a water soluble form (Kiliam, Ber 1907, 40, 2996), but consists largely of gitalm (Gottlieb, c.g. Arch. exp. Path. Pharm 1918, 82, 117).

1918, 83, 117)

For the preparation of their substances, both Homolle and Nativelle extracted the powdered leaves with 50 pc alcohol, and purified the extract with lead acetate. After removal of the excess of lead, Homolle evaporated to a syrup and precipitated in the cold with tannic acid The tannic acid precipitate was washed with tepid water, mixed with an equal weight of lead oxide, dried, and extracted with 90 p c alcohol After treatment with charcoal and evaporation, the residue was extracted with ether to remove impurities Tannin, apparently introduced by Homolle, was later applied to the separation of k-strophanthin (q v), and seems to be still in use for such commercial preparations as digipuratum (see below), but it is, of course, only a general colloidal precipitant, and cannot be expected to act specifically Nativelle moistened the powdered leaves with a solution of neutral lead acetate, then extracted with 50 pc alcohol, and purified the extract repeatedly with charcoal and lead acetate finally extracted with chloroform, and thus separated off the 'digitalein' fractica, which enabled him to obtain a crystalline substance Schmiedeberg (lc) introduced the preliminary extraction of the leaves with cold water, thus removing the gitalin and digitalein fractions,

and then, after pressing the leaves, he extracted with 50 pc. alcohol. After precipitation with basic lead acetate, and removal of the excess with ammonia, the alcohol was evaporated, while the solution was kept neutral. A partly crystalline substance separated, which was dried on the water-bath and extracted with chloroform. The residue, after evaporation of the chloroform, was washed with ether (which removes fat, luteolin, &c.), or with boiling petroleum ether, and then crystallised the digitoxin from 80 pc alcohol with charcoal. Kiliani's method of preparing digitoxin (Arch. Pharm 1895, 233, 311) is similar

Digitaline cristallisée, Digitoxin  $C_{34}H_{54}O_{11}$  (Kiliam) forms hydrated needles and leaflets from aqueous alcohol, which become anhydrous and sinter at  $145^{\circ}$ - $150^{\circ}$ , and anhydrous prisms from methyl alcohol and chloroform, melting at  $245^{\circ}$  ( $243^{\circ}$ - $245^{\circ}$  Arnaud) Kraft (Arch. Pharm 1912, 250, 118) could not obtain the hydrated form, and concludes Kiliam's supposed

hydrate was contaminated with gitalin

The yield of digitoxin is said to be 0.1 pc of the leaves, but Straub (lc) has concluded from physiological evidence that the amount present is very variable, and may considerably exceed 0.1 p.c. Merck's commercial preparation is stated by Kiliani to be about 90 pc pure 0 65 gram digitaline (digitoxin) dissolves at 14° in 100 cc absolute alcohol (Arnaud) Digitoxin dissolves readily in chloroform, only slightly in ether, not in water. It gives a characteristic colour reaction, glacial acetic acid and concentrated sulphuric acid are employed, 100 cc of each being previously diluted with 1 cc of 5 p.e. aqueous ferrie sulphate solution trace of digitoxin is dissolved in 1 cc of the acetic acid, and 2 cc of the sulphunc acid are allowed to flow underneath, in a narrow test tube. The zone of contact becomes duty brown, and after a few minutes the acetic acid This, Keller's begins to become indigo blue reaction, is still positive with 0 l mg in 1 c c of acetic acid Concentrated hydrochloric acid dissolves digitoxin in the cold to a colourless solution, becoming bluish-green on warming Alcoholic sodium hydroxide hydrolyses to digitozime acid  $\rm C_{34}H_{56}O_{12}$ , mineral acids hydrolyse to two molecules of digitoxose

#### CH, CHOH CHOH CHOH CH, CH O

m p  $101^{\circ}$ , and one of digitoxigenin  $C_{22}H_{32}O_4$ , m p  $230^{\circ}$  (v. e.g. Kihani, Arch Pharm. 1913, 251, 562) Digitoxose is a peculiar sugar, and gives Keller's reaction, digitoxigenin does not

Gitalin C<sub>18</sub>H<sub>48</sub>O<sub>10</sub> (?), mp 150°-155°, is amorphous, and was obtained by Kiaft by a method analogous to that of Homolle (v. supra), and extracting the glucoside from aqueous solution by shaking with chlorofoim, after drying, the chlorofoim solution is precipitated by light petroleum. Gitalin is soluble in 600 parts of water, and very readily in chloroform. By dissolving in 15 parts of alcohol and adding 0.75 part of water, a crystalline gitalin hydrate C<sub>28</sub>H<sub>48</sub>O<sub>10</sub>,4H<sub>2</sub>O, mp. 75°, is separated. Solutions of gitalin deposit on keeping mixtures of gitalin and anhydrogitalin C<sub>28</sub>H<sub>46</sub>O<sub>9</sub>, mp. 255°, crystallising from dilute alcohol and almost insoluble in chloroform. On hydrolysis by acids, gitalin, its hydrate, and its anhydride all

DIGITALIS.

yield digitoxose (see above), and hence they all stance, such as digitoxin (Rapp, Ic.), or ggive Keller's reaction; the other fission product is anhydrogualigenin C<sub>2.</sub>H<sub>34</sub>O<sub>5</sub>, mp 216°-219°, crystallising from alcohol As already stated, Kiliani considers gitalin to be a mixture, of anhydrogitalin with other substances, but this does not dispose of Kraft's contribution to the subject

Digitaleïn (Schmiedeberg) differs from gitalin and digitoxin in not producing the typical

systolic arrest of the heart

Commercial Preparations of Digitalis.—A considerable number of these have been introduced of late years, mostly in Germany Digalen (Hoffmann-Laroche & Co), introduced in 1904, has been one of the most successful Cloetta's 'digitoxinum solubile'=impure gitalin' Digifolin and digipan are similar (see above) impure active principles Digipuratum (D. R. P. 227552, 245193, 246571, of Knoll & Co ) is a purified leaf extract freed from digitonin, and apparently consists of the tannin compounds of the gitalin fraction From adigan the digitonin has been removed by cholesterol (see below) Digitalysatum, from fresh piess juice, and other preparations, are purified by dialysis Digita-Ione (Parke, Davis & Co ) is a sterile extract of For a physiological examination of these preparations, see Rapp, Pharm Zentral-H 1914, 55, 961, 978

Methods of Assay.—There is a great variation in the content of active leaf glucosides Straub (lc) found, in percentages of the air-dry leaf

Gitalin + digitalein, cultivated, 0 4-0 64, wild, 0 22-0 89, digitoxin, cultivated, 0 053-0 11, wild, 0 01 0 15

This variability has led to the introduction of standardised leaves ('folia digitalis titiata') and to methods of assay of pharmaceutical preparations (official in the USP for digitalis, strophanthus, and squill) A chemical assay (of digitoxin?) has been described by Keller (Ber Deut pharm Ges 1897, 7, 125), but Ziegenbein (Arch Pharm 1902, 240, 454) has shown that there is no relation between physiological activity and the 'digitoxin' found by Keller's method Barger and Shaw (Pharm. J 1904, [iv] 19,7249) have confirmed this, and shown that of added crystalline digitoxin less than half is recoverable by Keller's method The chloroform extract, weighed in this method, consists, according to Kraft (lc), largely of The assay must therefore be physiological, and is generally based on Houghton's method (J Amer med Assoc 1898), by which the minimum amount is determined necessary to arrest the frog's heart in systole, in, say, I hour (for length of time, cf Gottlieb, below) The isolated frog's heart may also be employed, with graphic registration of its action (Schmiedeberg, Arch. exp Path. Pharm. 1910, 62, 307) For earlier investigations, see Edmunds and Hale (Bull No. 48, Hygienic Lab Washington, 1909) and Focke (Arch. Pharm. 1910, 248, 365); for the later ones, Holste (Zeit. exp. Path. Ther. 1917, 19, 153), Focke (ibid. 1914, 16, 443), Stretch (Arch. 2012, 2012). Straub (Arch. exp. Path. Pharm. 1916, 80, 52), and Gottheb (ibid 1918, 83, 117) The susceptibility of frogs is greater in winter than in summer, and it has been suggested that they should themselves be standardised with a pure sub-

strophanthin (ouabain) (qv), suggested by Heinz, and adopted by the USP. This picsupposes a constant ratio of sensitiveness to dissimilar preparations, which has not been Indeed. Gottlieb (lc.) states that the sensitiveness of frogs to q-stropanthin is fairly constant throughout the year

525

Digitalis seeds contain entirely different glucosides, which have been examined chiefly From an alcoholic extract, purified with lead acctate, the mixed glucosides are precipitated with tannic acid (cf Homolle's method) This gives the commercial so-called digitalinum germanicum, which may be separated, according to Kiliani (Ber 1918, 51, 1613), into 'digitalinum verum,' or digitalin, digitanin,

gitonin, and a fourth glucoside

Digitalin C<sub>35</sub>H<sub>56</sub>O<sub>14</sub>, mp 210°-217°, is less active than digitoxin, and forms amorphous granules, soluble in 1000 parts of water It dissolves in sulphuric acid with a yellow colour, which, on standing, or in the presence of ferric salts or other oxidising agents, becomes cherry-red and purple It is hydrolysed by acids to equimolecular proportions of glucose, digitalose  $C_7H_{14}O_5$ , and digitaligenin  $C_{22}H_{30}O_3$ , needles, m p 210° 212° Digitalose is a syrup, and is oxidised by nitric acid to methoxydihydroxyglutaric acid (Kiliani, Ber 1905, 38, 3622. 1916, 49, 709)

Digitonin ( ${}^{1}_{54}H_{9}$ ,  ${}^{1}_{0.28}$  or ( ${}^{1}_{55}H_{91}O_{8}$ , mp 225°-235°, [ $\alpha$ ]<sub>0</sub>= -49 25°, is obtained in the crude state in a yield of about 45 pc of the 'German digitalin' employed. It is important as an example of a crystalline saponin, and probably also occurs in the leaves ilt has no stimulant action on the heart, and is thera peutically undesirable Digitonin dissolves to a clear solution in 50 parts of cold 50 pc alcohol, is more soluble on heating, and crystal-lises on cooling in fine needles. It is hardly soluble in chloroform, and forms an opalescent solution in water, which froths Keller's Acids hydrolyse to two reaction is negative molecules of glucose, two of galactose, and one of digitogenin  $C_{30}H_{48}O_6$  or  $C_{31}H_{50}O_6$ , needles, mp 240° Like other saponins, digitonin combines with cholesterol On mixing a (preferably hot) solution of 1 gram digitonin in 100 c c of 90 p c alcohol with 0 4 gram cholestorol in 60 cc of 95 pc alcohol, the addition compound C<sub>55</sub>H<sub>94</sub>O<sub>28</sub>C<sub>27</sub>H<sub>16</sub>O crystallises (Windaus, Ber 1909, 42, 238) Similar compounds with lower alcohols and phenol had already been observed by Houdas (Compt. 1end. 113, 648) This reaction has met with wide application On the one hand, digitonin can be removed from digitalis preparations (adigan, above), on the other hand, sterols can be estimated in fats, for as little as 0.1 mg of cholesterol in 1 c c of 90 p c alcohol may be detected (Windaus) Panzer, Zeitsch physiol Chem 1912, 78, 414, Marcusson and Schilling, Chem Zeit 1913, 37, 1001; Berg and Angershausen, ibid 1914, 38, 978; Prescher, Zeitsch Nahr Genussm 1914, 33, 7)

Gitonin.—Commercial digitonin (Merck) contain 5-14 pc. of a closely similar glucoside git nin C<sub>49</sub>H<sub>80</sub>O<sub>23</sub>,7H<sub>2</sub>O, mp 225° (Kraft, lc., Windaus and Schneckenburger, Ber 1913, 46, 2628), which may be crystallised (Kiliani, ib.d. 1916, 49, 701), and also forms cholesterol addition compounds.

Straub (Biochem Zeitsch 1917, 82, 48) finds that on germination the first pair of foliage leaves already contains the typical leaf glucosides, and in 4 months the maximum of 1 pc. of total glucoside is already nearly attained. This is made up of gitalin fraction, ½ pc, digitalein fraction, ½ pc, and digitoxin fraction, ½ pc. For variations, see above.

Digitalis leaves contain luteolin (= digito-flavone') C<sub>15</sub>H<sub>10</sub>O<sub>6</sub>,H<sub>2</sub>O, which imparts a yellow colour to ethereal extracts (Kiliani and Mayer,

Ber 1901, 34, 3577)

Other Drugs with a Digitalis-like Action — Schmiedeberg (Arch exp Path Pharm 1883, 16, 149, especially 162) has enumerated a considerable number of these. Strophanthus and squill (q v) are theiapeutically the most important; see also enonymus, hellebore, and the alkaloid crythrophleme.

Cymurin, a glucoside from the root of Apocynum cannabinum has been obtained crystalline (D. R. P. 255537, of Bayer & Co.) 1000 parts of the root are extracted with boiling carbon totrachloride until no longer bitter After evaporation, the residue is dissolved in 1000 parts of alcohol, and water at 50° is added, until no more resin is precipitated After filtration, basic lead acetate is added, and the excess of lead is removed, after a second filtration, by means of hydrogen sulphide evaporation to 100 parts, the solution is extracted with chloroform, and the chloroform dried with sodium sulphate. Impurities are then precipitated with other, and next the cymain with light petroleum - It is crystallised from methyl alcohol, and then has the composition

 $[a]_D^{20} = +23.5^{\circ}$  in chloroform. It gives Liebermann's cholesterol reaction (v. Strophanthidin), and Koller's digitoxin reaction (above), and is hydrolysed by acids

$$C_{30}H_{44}O_9 + H_2O = C_{23}H_{30}O_5, H_2O + C_7H_{14}O_4$$

into cymarigenin (=strophanthidin, qv) and cymarose, which is probably the methyl ether of digitoxose (Windaus and Hermanns Ber 1915, 48, 979), where the earlier investigations on Apocumum are referred to

Bulagin C<sub>18</sub>H<sub>14</sub>O<sub>4</sub>, from the parotid gland of the Central-American toad Bulo agua, has also been obtained crystalline and pure (Abel and Macht, J. Pharm exp. Therap 1912, 3, 319). It is not a glucoside—For bulotalin from European toads, see Wieland and Weil (Ber 1913, 46, 3315)

Convallamarin C<sub>12</sub>H<sub>44</sub>O<sub>12</sub> and convallarin C<sub>34</sub>H<sub>62</sub>O<sub>11</sub> are crystalline glucosides from Convallaria majalis (Linn) (Lily of the Valley), which plant was deleted from the U.S.P. in 1916 (Walz, Jahrb f Chem 1858, 518)

\*\* a-Anharm  $C_{27}H_{42}O_{10}$ ,  $4H_{2}O$  and  $\beta$ -anharm are crystalline glucosides from the latex of Anharm toxicaim, the Upas tree of Java (Kiliani, Ber. 1910, 43, 3574) Other crystalline glucosides with digitals action are thevetin  $C_{54}H_{84}O_{24}$ , from the seeds of Thevetia nevisfolia (Juss), crystallising readily (de Vrij, Pharm J. 1881, 457; Warden, ibid 1881, 417), and echujin

(C<sub>8</sub>H<sub>8</sub>O<sub>2</sub>)n, from the latex of Adenium Bæhmianum (Schinz), a South-West African arrow poison (Boehm, Arch. exp Path Pharm 1899, 26, 165) The latter substance has an activity intermediate between that of digitoxin and strophanthin

Tanghinin C27H46O8, mp. 182°, from the fruits of Tanghinia venenifera (Madagascar), is crystalline, hardly soluble in water, readily in alcohol and in other, and is not a glucoside (Arnaud Compt iend 1889, 108, 1255) Adonin C24H40O9, from Adonis amurensis (Reg. et Radd ) (Tahara, Ber 1891, 24, 2579), adonadm from A vernalis (Lum) (Cervello, Arch exp Path Pharm 1882, 15, 235), and oleandrin from Nerum oleander (Linn) (Schmiedeberg, lc) are amorphous Many of the above substances are used as arrow poisons The NO Apocynaceae seems to be especially rich in substances with a digitalis-like action (Apocynum, Strophanthus, Thevetra, Adenium, Nerium oleander). Windaus and Hermanns (Ber 1915, 48, 991) have suggested that there is a more or less close chemical relationship between many of the above sub-The non-sugar portion of the glucosides stances genin') seems to be derived from a cholesterollike complex by various degrees of oxidation, the sugars are peculiar and sometimes identical or closely related, and often contain less oxygen than carbohydrates The genins are less active than the glucosides (v k-strophanthmand Straub, Brochem Zeitsch 1916, 75, 132)

DI-HODOFORM v SYNTHETIC DRUGS

DIKA-BREAD. An edible cake made by the natives of Sierra Leone and the Gaboon from the fruit of the mango tree, indigenous to most tropical climates. The fruit iesembles chocolate in appearance, and contains a large quantity of fatty matter. It has occasionally ripened under hot-house cultivation in this country.

DIKA FAT GROUP. Under this name may be comprised several fats which are characterused by high saponification values, like the fats of the Cocoa Nut Oil group, but which differ from them by the absence of volatile fatty acids high saponification value indicates a preponderant proportion of lauric acid. These fats are further characterised by low iodine values These fats are The most prominent of this group are . (1) Dika fat, obtained from the seed-kernels of various kinds of Irringia: I gabonensis (Baill), I Barteri (Hook, fil ), indigenous to West Africa The seeds yield about 65 pc of a yellowish-white fat, which the natives separate by expressing the kernels after boiling with water The fat melts at about 30°, and has an iodine value of about 31 (2) Tangkallak fat, obtained from the fruits of Lepidadenia Wighthana (Nees; BI), Cyhcodaphne sebrfera (BI), Tetranthera calophylla (Miquel), Tetranthera laurifolia (Jacq ), Litsea Schifera (Pers.), Schifera glutinosa (Loui.) (3) Irvingia butter. Cochin China wax, or Cáycáy fat, the fat obtained from Irvingia Oliveri (Pierre), Irvingia malayana (Oliv), Irvingia Harmandiana (Pierre), Buchanania fastigiata (H Baillon) The Cay-cay tree-' candle tree '-is a tropical tree indigenous to Cochin China and Large quantities of the fat are used ves as candles The freshly prepared Cambodia by the natives as candles fat is employed for edible purposes (4) Kusu oil, contained in the fruit of the camphor-yielding tree, Cunamomum camphora (Nees), Lauracea. From its chemical characteristics, the conclusion may be drawn that it consists of pure laurin with a few per cent of olem

DIKETONES v KETONES

DIKETOSUCCINIC ACID v KETONES

DILATOMETER. A term originally used to denote an apparatus for measuring the thermal expansion of liquids Subsequently given by Silbermann to an instrument for determining the strength of aqueous alcohol

DÍLITURIC ÁCID, núrobarbituric acid, nitro-malonylurea, CO NH CO CH NO<sub>2</sub>,3H<sub>2</sub>O, obtained by treating alloxantin first with hydrochloric acid and subsequently with nitric acid (Schlieper, Annalen, 56, 24); by warming hydurilic acid with nitric acid (Baeyer, *ibid* 127, 211), by nitrating barbituic acid (Baeyer, *ibid* 127, 211), by nitrating barbituic acid (Baeyer, *ibid* 130, 140), by oxidising violuric acid (nitrosobarbituric acid) (Ceresole, Ber. 16, 1134); or by oxidising with nitric acid the compound C<sub>16</sub>H<sub>26</sub>O<sub>11</sub>N<sub>12</sub>S<sub>2</sub> obtained by condensing *iso*dialuric acid with thiocarbamide (v. Vogel, Annalen, 315, 259; Bartling, *ibid*. 339, 27).

Dilituric acid crystallises in colourless quadratic prisms or places, is sparingly soluble in cold, more readily so in hot water, is sparingly soluble in alcohol and insoluble in ether. It

forms chloropierin when warmed with bleaching powder, is reduced by hydriodic acid to uramil (aminobarbitunic acid), and suffers partial reduction when heated with glycerol, yielding violuria acid. Dilitunic acid is tribasic, but most of the salts are acidic, and contain only one equivalent of the metal, they are sparingly soluble in water, and are not generally decomposed by mineral acids. The ammonium salt

the sodium salt  $C_4H_2N_3O_5N_3, 4H_2O$ , potassium salt  $C_4H_2KO_5N_3$ , calcium salt

$$Ca(C_4H_2O_5N_3)_2,4H_2O$$

the barium compound  $BaCl(C_4H_3O_5N_3),H_2O_5$ ferrous salt  $\operatorname{Fe}(\mathrm{C_4H_2O_5N_3})_2,8\mathrm{H_2O}$ , and the silver salt  $C_4H_2AgO_5N_3, 2H_2O$ , are colourless, the ferric salt  $Fe(C_4H_2O_5N_3)_3, 0H_2O$  is bright yellow, the copper salt  $Cu(C_4H_2O_5N_3)_3, H_2O$  is greenish, the dipolassium salt  $C_4H_5O_5N_3$  is bright-yellow (Schlieper, lc), and the triargentic salt  $C_4Ag_3O_5N_3$  is lemon-yellow (Baeyer, Annalen, 130, 140) According to Holleman (Rec trav chim 1897, 16, 162), dilituric acid and its homologues are aliphatic nitro- compounds in which the iso- form (cf. Hantzsch and Schultze, Ber. 1896, 29, 699, 2251, Hantzsch and Veit, ibid 1899, 32, 607) is the stable modification. The aqueous solution of dilituric acid is faintly yellow and decomposes carbonates, the molecular conductivity for I gram-molecule dissolved in v litres of water is 323 4 (v=32), 341 4 (v=512), ( $\mu_{\infty}$  should be 356), the acid is therefore almost completely dissociated in aqueous solution; the addition of one equivalent of a base does not appreciably change the colour of the solution, but on adding a second equivalent, the solution assumes the deep-yellow colour characteristic of the aqueous solutions of the salts of this acid Assuming that the formula CO < N = C(OH) > C N OH re-

presents the constitution of the acid, Holleman states that the anion

is colourless and slowly hydrolyses into the yellow anion CO NH CO ... C N O-.

Methyldilituric acid, 1 · methyl · 5 · nutrobarbituric acid CO NH CO CH NO<sub>2</sub>,1 5H<sub>2</sub>O,

prepared by oxidising methylvioluric acid with concentrated nitric acid (Andreasch, Monatsh 1900, 21, 281), crystallises from aqueous solution, and the anhydrous acid is colourless; it melts and decomposes at 143°, is readily soluble in hot water, less so in cold water, alcohol, or acctone, and sparingly soluble in ether. The aqueous solution of the acid is intensely yellow, and decomposes carbonates, the aqueous solutions of the salts are also yellow, but the solid sales are colourless or pale-yellow and sparingly soluble, the potassium salt  $C_5H_4\mathrm{KO}_8\mathrm{N}_3$ , the sodium salt  $C_5H_4\mathrm{NO}_6\mathrm{N}_3$ . He odium salt  $C_5H_4\mathrm{NO}_6\mathrm{N}_3$ , are colourless, the barium salt  $(C_5H_4\mathrm{O}_8\mathrm{N}_3)_2\mathrm{Ba}_3\mathrm{H}_4\mathrm{O}$ , the

cadmium salt (C5H4N3O5)2Cd,2H2O, are paleyellow, the strontium salt  $(C_5H_4O_5N_3)_2Sr,3H_2O$ is colourless, but becomes yellow on losing its water of crystallisation Methyldilituric acid is stable with bases, it reacts readily with chlorine to form methylchlordilituric acid

$$CO \stackrel{NMo}{<} \stackrel{CO}{<} CCI(NO_2)$$

m p 121°; the corresponding bromo-compound melts and decomposes at 138°-139°

Dimethyldilituric acid, 13 - dimethyl - 5 nitro barbituric acid CO NMe CO CH NO. obtained by oxidising dimethylvioluric acid with concentrated nitric acid (Techow, Ber 27, 3085, Andreasch, Monatsh 16, 26), forms colourless microscopic crystals from acctone; dissolves in 5.98 parts of water at 14°, is sparingly soluble in alcohol, melts at 152° and changes into dimethylallovan (Holleman, Rec trav chim 16, 162), and is reduced by hydriodic acid to dimethyluramil

Dimethyldilituric acid is intensely yellow in aqueous solution, and this is due to the presence of the coloured anion of the isonitro- form CO NMe CO C NO OH, for on adding con centrated nitric acid, the colour almost entirely disappears, further, the molecular conductivity of the acid for I gram-molecule dissolved in v litres of water is 3133 (v=32), and 3376(r=1024),  $(\mu_{\infty}$  should be 352), so that in each solution the acid is almost completely ionised (Holleman, Rec trav chim 16, 162) salts of dimethyldilituric acid are coloured, the salts of dimenylamouric acid are coloured, one sodium salt  $({}^c_6H_6N\alpha O_5N_3, H_2O)$  is yellow, the potassium salt  $({}^c_8H_6N\alpha O_5N_3)$  is greenish-yellow, the magnesium salt  $(({}^c_8H_6O_5N_3)_2Mg, 4H_2O)$  is yellowish-green, the calcium salt  $(({}^c_8H_6O_5N_3)_2Ca)$  is bluish green, the strontium salt  $(({}^c_8H_6O_5N_3)_2Ca)$ is pale-green, the barrum salt

(C6H6O5N3)2Ba,2H2O

is rose-red, and the silver salt C<sub>8</sub>H<sub>8</sub>AgO<sub>8</sub>N<sub>3</sub> is greyish-violet (Andreash, lc, and Monatsh 21, 295)

Dimethylchlordilituric acid

prepared by passing chlorine into an aqueous solution of dimethyldilitume acid, melts and decomposes at 150°, the corresponding bromoderivative melts partially at 152° (Andreasch, lc) Dimethyldilituric acid is readily decomposed by the action of bases forming water, carbon dioxide, and dimethylnitromalonamide

**DIMETHYLGLYOXIME** ( $\beta \gamma$ -droximinobutane) CH<sub>3</sub> C . N OH was originally obtained by CH3 C NOH

Schramm, in 1883, by acting upon methyloximino-ethyl ketone with aqueous hydroxylamine hydrochloride (Ber 16, 180) It is readily prepared in quantity by the following method (Gandurin, J pr Chem 1908, 77, [u] 414) --

850 c c of commercial methyl ethyl ketone are mixed with 30 cc of hydrochloric acid of sp gr 1 19, and 1 litre of amyl nitrite is allowed to run in slowly with vigorous stirring This takes 11 hours, and the temperature should be maintained between 40°-50° When the reaction is over, 800 grams of ic are added, followed by 378 grams of sodium hydroxide in 800 cc. of water, and the mixture is shaken for half an hour. After standing, the layer of amyl alcohol adding the oxime and acetate (Brunck, Zeitschis removed, and the aqueous liquid twice extracted with ether. 100 c.c of the alkaline liquid are treated with the calculated amount of advisable to work with solutions containing not hydroxylamine hydrochloride, and the dimethylglyoxime produced is collected and weighed. If the original volume of the alkaline liquid is  $v \in c$ , a grams the weight of dimethylglyoxime obtained from the 100 cc of liquid, then the amount of hydroxylamine hydrochloride in grams required for the remaining liquid is equal to 650(v-100)a/109500 This weight of hydroxylamine hydrochloride is dis-, solved in a little water, added to the alkaline liquid, and the whole warmed on the water-bath for an hour The liquid is acidified with acetic acid, and the dimethylglyoxime, which separates, is filtered, washed, and dried This product is sufficiently pure, but it may, if desired, be iecrystallised from alcohol Yield, 650-700 grams

(For details, see Adams and Kamm, J. Amer

Chem. Soc. 1918, 40, 1281)

(For other methods of preparation, v Biltz, Zeitsch anal Chem 1909, 48, 164, Tschugaeff, Ber 1905, 38, 2520)

Properties —Dimethylglyoxime forms colourless, glistening needles, and is insoluble in water, but soluble in alcohol It melts at 245°-246° (Meyer-Jacobsen, I (ii ) 826, 1913) Its dibenzovi derivative forms rhombic plates, melting at 223° (Diels and Stein, Ber 1907, 40, 1629).

On oxidation with potassium ferrieyanide or nitrogen peroxide it yields furovane (Scholl, Ber 1890, 23, 3498), this is reduced to the dioxime again when treated with zinc and acetic acid (Rimini, Gazz chim ital 1895, 25, When heated with aqueous amfn | 266) monia at 170°-180° it yields the anhydride dimethylfurazan (Wolff, Ber 1895, 28, 69)

Application in Analysis -- Dimethylglyoxime is now an important analytical reagent, owing to its property of forming a bright scarlet insoluble nickel derivative It thus becomes possible to estimate nickel simply and accurately, in the presence of iron, aluminium, chromium, cobalt, zinc, or manganese, all of which form soluble derivatives In addition, an excellent qualitative test for nickel in the presence of cobalt is supplied. For the latter purpose, a pinch of the oxime is added to the solution containing excess of ammonia or sodium acetate, and the liquid boiled. A scarlet precipitate is obtained even when there is present only one part of nickel in two million parts of solution (Tschugaeff, Ber 1905, 38, 2520; Compt rend 1907, 145, 679, Klaut, Zeitsch angew Chem 1906, 19, 1793) 01 milligram of nickel can be detected in the presence of 5000 times as much cobalt

For the quantitative estimation of nickel, the acid solution is heated nearly to boiling, a slight excess of 1 p c alcoholic dimethylglyoxime is added, and then a small excess of either am-The precipitate is monia or sodium acetate filtered while hot on to a Gooch crucible, washed with hot water, and dried at 110°-120° Its formula is (CH<sub>3</sub> C NO)<sub>2</sub>N<sub>1</sub>+ (CH<sub>3</sub> C NOH)<sub>2</sub>, and it contains 20 31 pc of nickel, it has no definite melting-point, but sublimes at 250° Ammonium salts do not interfere; if the acetate method is employed, the original solution should be nearly neutralised with ammonia before

Vol. II.-T.

angew. Chem. 1907, 20, 1844). As the precipitate of nickel glyoxime is very voluminous, it is more than about 0 l gram nickel, owing to the difficulty of filtration, and again in order to avoid waste of material, the cobalt, if present, should not exceed 0.1 gram, otherwise a large excess of ammonium hydroxide and dimethylglyoxime is necessary in order to prevent its precipitation

By either of the above methods, cobalt and zine may be separated from nickel, but about twice the theoretical amount of reagent is Manganese, of course, can only be necessary separated by the acetate method. Iron, aluminium, and chromium may be separated by the ammonia method, if tartaire acid be previously added (and, in addition, ammonium chloride in the case of chromium) Iron may also be separated m acctic acid solution, provided it is in the ferrous state (Brunck, Zeitsch angew Chem 1907, 20, 1845, Prettner, Chem Zeit 1909, 33, 396, 411; Ivanicki, Chem Zeit Rep 1908, 32, 644, Rhead, Analyst, 1910, 35, 97, v also Analysis)

The oxime is sufficiently expensive to make its recovery desirable This may be effected by dissolving the nickel derivative in aqueous potassium cyanide and acidifying with acetic acid The precipitated dimethylglyoxime is purified by recrystallisation from hot alcohol, after decoloursation with charcoal (v Ketones).

v OPIUM and SYNTHETIC DRUGS

DIOPSIDE. A double salt meta-silicate of calcium and magnesium in which a part of the magnesium is usually replaced isomorphously by an equivalent amount of ferrous oxide, the formula being Ca(Mg,Fe)(SiO<sub>3</sub>)<sub>2</sub>. It is a member of the monoclinic series of the pyroxene group, and is of importance as a rock-forming minicial, while occasionally, when transparent and of a rich bottle-green colour, it is employed as a gem-stone. The depth of colour, sp gr (3 2-3 3), and other physical characters vary with the percentage of 4ron present, which in material of gem quality, such as the crystals from Ala in Piedmont, and the Zilleithal in the Tyrol, amounts to about 3-4 pc FeO. The hardness is 6.

DIOPTASE. Hydrous silicate of copper, H<sub>2</sub>CuSiO<sub>4</sub>, crystallising in the rhombohedral system with parallel-faced hemihedrism. The water is expelled only at a red heat, and the formula has consequently been variously interpreted as an acid ortho-silicate, or as a basic meta-silicate. F. Zambonin (1908) concludes from dehydration experiments that the formula is CuSiO<sub>3</sub> H<sub>2</sub>O, with the water held in solid solution in the meta-silicate. The mineral is of a characteristic emerald-green colour (hence the name emerald-copper; Ger, Kupfer-Schmaragd), and transparent crystals have occasionally been cut as gem-stones. For this purpose, however, the hardness (H = 5) is rathalous (spiralling) and the limestone hill of Altyn-Tübe in

the Kirghiz Steppes, Siberia, and in the copper mines near Mindouli in the French Congo.

An allied mineral, planchette (of A Lacroix, 1908,=shattuckite of W. T. Schaller, 1915), occurs as blue, fibrous concretions associated with dioptase in the French Congo. This has the composition 2CuSiO<sub>3</sub>·H<sub>2</sub>O, representing a partly dehydrated dioptase. L. J. S.

DIORITE. An igneous rock composed essentially of plagioclase felspar (oligoclase to labrado-11te) and hornblende, and with a coarse- to medium-grained crystalline-granular texture. It belongs, with granite, to the series of plutonic 10cks, and is of intermediate composition (SiO, 52-60 pc), falling between syenite and gabbio Its volcanic equivalent is andesite Other minerals may also be present as essential constituents of the lock, and accordingly the following varieties are distinguished. blende-diorite (diorite proper), augite-diorite, enstatite-diorite, mica-diorite (the mica here being biotite), quartz-mica-diorite, quartz-diorite (or tonalite) The colour is usually dark grey or greenish-black, and for this reason the rock is included under the general term 'greenstone' The sp gr ranges from 2 8 to 3 1; the porosity is low, 0.25 p.c., and the crushing strength 1640 to 1830 tons per square foot Under 1 is given Biogger's average of sixteen analyses of typical diorites, analysis II is of dionite from Strathspey, Scotland; III. of quartz-diorite from Spanish Peak, Plumas Co, California (including BaO) 0.04, CO $_2$  0.20,  $P_2O_5$  0.25,  $SO_3$  0.03), IV homblende-augite-diorite from Inchnadampf, Sutherlandshire (including CO<sub>2</sub> 0 54).

Diorites are of wide distribution and are very common in association with granitic rocks in the southern uplands and highlands of Scotland. They are extensively quarried for road-metal and paving-setts in the Channel Islands, Guernsey, Jersey, and Alderney, and at Brazil Wood near Mount Sorrel in Leiestershire. Owing to the difficulty of working the rock and its dull colour, it is not much used as a building stone, except locally. Certain coarse-grained varieties are, however, polished for ornamental purposes. For example, a variety from Corsica, known as napoleonite, coisite, or ball diorite, shows a spheroidal structure with alternating concentric layers of light felspar and dark hornblende.

L. J. S.

DIOSCORINE ('13H19O2N, greensh-yellow plates, mp 435°, occurs in Diogorea hirsuta (Blume) tubers of Japan Ritter and poisonous (Gorter, Rec trav. chim. 1911, 30, 161) Has an action like picrotoxin

DIOXYGEN. Trade name for a 3 pc

solution of hydrogen peroxide

**DIPHENAL**, Duminohydroxydiphenol, used as a photographic developer

DIPHENAZINE v Azīnes.

o-DIPHENETIDINE v DIPHENYL.

**DIPHENYL.** This hydrocarbon, which has the molecular formula  $C_{12}H_{10}$ , is structurally composed of two benzene nuclei joined together by a bond linking two carbon atoms, one in each ring. The carbon atoms are numbered for the purposes of nomenclature in the following way.—

Although of minor importance, diphenyl is nevertheless the parent substance of a large number of important bases which have found application in the preparation of the so-called substantive cotton dyes, that is to say, of colouring matters which will affix themselves to the vegetable fibres without the aid of a mordant. These bases are, however, not derived directly from the hydrocarbon, but are prepared by an inducet method which will be described later.

Diphenyl was originally obtained by Fittig (Annalen, 121, 363) from an ethereal solution of bromobenzene by the action of metallic sodium  $C_6H_5Br+BrC_6H_5+2Na \rightarrow C_6H_5-C_6H_5+2NaBr$  but it is more conveniently prepared by the method discovered by Berthelot (Ann Chim Phys [4] 9, 453, [4] 12, 185), who obtained it by passing the vapour of benzene through a redhot tube

$$('_{6}H_{5}H + H('_{6}H_{5} \rightarrow ('_{6}H_{5} - ('_{6}H_{5} + H_{2}))))$$

The following procedure is recommended (Schultz, Ber 9, 547, Hubner, Annalen, 209, 339; Smith and Lewcock, Chem Soc Trans 1912, 101, 1453; [apparatus] La Coste and Sorger, (Annalen 230, 5) The vapour from a quantity of benzene (free from thiophen), contained in a large flask heated on the waterbath, or produced by dropping the liquid into a copper flask heated to 150°, is allowed to pass through an iron tube, filled with pumice, which is heated to about 720° in a combustion furnace, the lower end of the iron tube is attached to a condenser and receiver, in which the products are collected. When all the benzene has distilled over, the distillate is again placed in the flask, and the vapour passed anew through the red-hot tube, or the process may be made continuous. The ultimate product is then fractionally distilled, and the portion boiling between 250° and 260°, which solidifies on cooling, is purified by recrystallisation from alcohol The yield is about 50-60 p.c. The pyrogenic preparation can also be effected by means of an incandescent filament of carbon, platnum, or nickel (Löb, Zeitsch. Elektrochem. 1902, 8, 777) Diphenyl separates from alcohol as large, lustrous lamine which melt at 70 5°. It boils at 254° (corr.), and is insoluble in water. The

hydrocarbon, when oxidised by chronic acid passes into benzoic acid.

531

Bennett and Turner (Chem. Soc Trans. 1914, 105, 1057) found that chromic chloride reacted quantitatively with magnesium phenyl bromide to form diphenyl Krizewsky and Turner (Chem Soc Trans 1919, 115, 559) have observed that anhydrous cupric chloride behaves similarly, yields of about 85 p c of the theoretical amount of diphenyl being thus obtained

Derivatives of Diphenyl and their Orientation -The more important derivatives of diphenyl are not prepared directly from the hydrocarbon, but from certain nitio- delivatives of benzene in a manner to be described later The hydrocarbon yields, however, halogen, nitro- and sulphonic acid derivatives analogous to those prepared from benzene, substitution taking place in either one or both rings according to the conditions of the experiment The method of orientation adopted for these compounds may be briefly described as follows (Schultz, Annalen, 174, 201, Schmidt and Schultz, ibid 207, 320). When diphenyl is treated with bromine, it yields a monobromodiphenyl, a substance which, on oxidation, is converted into p-bromobenzoic acid, thus  $\cdot$ 

$$BI \leftarrow \rightarrow Br \leftarrow CO_2H$$

It follows, therefore, that in bromodiphenyl the bromine atom must have entered in the paraposition with respect to the linking carbon atom. When bromodiphenyl is treated with intrie acid, it is converted into a monobromomonomitrodiphenyl, a substance which, on oxidation, yields a mixture of p-bromobenzous acid and p-introbenzous acid. It is therefore apparent that the formula of this bromomitroderivative must be.

The same compound is also obtained from dinitrodiphenyl by first reducing this to intro-aminodiphenyl (mp 198°) and then replacing the amino-group by bromine by means of the diazo-reaction. Hence dinitrodiphenyl and its reduction product are di-para-derivatives. Since, however, introaminodiphenyl, on reduction, furnishes the diamino-derivative, benzidine, the latter is also a di-para-compound, of 4'-diaminodiphenyl, the preparation of which is described latter.

The transformation of the simplest atomatic hydrocarbon benzene into diphenyl by the action of heat has already been mentioned. This transformation can, however, be effected much more readily by the oxidation of certain derivatives of benzene, and especially those which, like the phenols, have a reactive hydrogen in the para-position with respect to the substituting group. Thus phenol itself and also resorcin readily pass into derivatives of diphenyl when fused with potash (Barth, Annalen, 156, 95). With hydroquinone, the transformation is still more readily effected and the action of the mildest oxidising agents is sufficient for the purpose (Nietzki and Bernard, Ber. 31, 1334).

The primary bases of the benzene series, such as aniline, do not lend themselves to the production of derivatives of diphenyl, but the territary bases readily do so; thus dimethylaniline yields tetramethylbenzidine when oxidised (Michler and Pattinson, Ber. 14, 2162 and 2164)

DIPHENYL. 532

It has also been found that certain azoelerivatives of benzene can be transformed by oxidation into tetrazo- derivatives of diphenyl, and in this way Congo red can be formed by benzeneazonaphthionic acid with manganese dioxide and sulphuric acid.

$$\begin{array}{c} C_{6}H_{5}N\!=\!N\!-\!C_{10}H_{5}(NH_{2})SO_{3}H \\ +O \\ C_{6}H_{5}N\!=\!N\!-\!C_{10}H_{5}(NH_{2})SO_{3}H \\ C_{6}H_{4}\!-\!N\!=\!N\!-\!C_{10}H_{5}(NH_{2})SO_{3}H \\ \to \downarrow \\ C_{2}H_{4}\!-\!N\!=\!N\!-\!C_{10}H_{5}(NH_{2})SO_{4}H \end{array}$$

Derivatives of diphenyl can also be prepared from certain diazonium salts of the benzene Thus Kuhling has shown (Ber 28, 41, 29, 165) that when an isodiazo- salt is treated with an aromatic hydrocarbon in the presence of an acid chloride, the following reaction ensues :-

$$\begin{array}{c} \mathrm{NO_2} \xrightarrow{\mathrm{C_6H_4N_2OK+C_6H_6+CH_3COCl}} \\ \xrightarrow{\hspace{0.5cm} \rightarrow} \mathrm{NO_2C_6H_4-C_6H_5+N_2+KCl+CH_3CO_2H} \end{array}$$

This reaction has been simplified by Bamberger (Ber 28, 403, 29, 272 and 465), who uses free isodiazobenzene hydroxide, and shows that it passes, in the presence of benzene, without any condensing agent, into a derivative of diphenyl Many derivatives of diphenyl can also be formed by the method of Ullmann, in which halogen derivatives of benzene are treated with finely divided

copper (Ber 43, 2082, Annalen, 1904, 332, 38)

Benzidine and the 'Benzidine Rearrangement'—The benzidine rearrangement, which has been widely applied to the preparation of a large number of important bases used in the production of the substantive cotton dyes, is the name given to the change which an aromatic hydrazo- compound undergoes when treated with acids or ceitain acid reagents. The change is effected by the wandering of the hydrogen atom which is in the para-position in each ring on to the nitrogen atom attached to that ring, at the same time, the link between the nitrogen atoms is broken, and the two aromatic nuclei are joined together It is apparent, therefore, that only those hydrazo- denvatives of benzene which have their para- position free will undergo this transformation

$$\begin{array}{c} \stackrel{\longleftarrow}{\underset{NH-C_6H_4H}{\longleftarrow}} \\ \downarrow \\ NH-C_6H_4H \end{array} \rightarrow \begin{array}{c} NH_2-C_6H_4 \\ NH_2-C_6H_4 \end{array}$$

The history of the discovery of this rearrangement is briefly as follows. Zinin (J. pr. Chem 36, 93), in the first instance, showed that azobenzene  $C_6H_5-N=N-C_6H_5$ , when treated with alcoholic ammonium sulphide, passed into a crystalline compound which, when dissolved in alcohol and boiled with sulphuric acid, gave the sparingly soluble sulphate of a base. This base sparingly soluble sulphate of a base he called benzidine

It soon became apparent that the substance responsible for the formation of benzidine must be an intermediate product formed by the action of the reducing agent on azobenzene This view was confirmed experimentally by A. W Hofmann (Jahresbericht, 1863, 424), who prepared the intermediate product, hydrazobenzche, and for I that it passed with remarkable case muo benzidine when treated with mineral acids.

Finally, Fittig (Annalen, 124, 280) showed that benzidine was identical with the base formed by the reduction of 4-4'-dinitrodiphenyl, and hence established the constitution of the base as 4-4'-diaminodiphenyl.

Manufacture of Benzidine - A jacketed iron pan fitted with an agitator, reflux condenser, &c., is charged with 100 kilos of nitrobenzene and 50 kilos of alcohol This mixture is heated to boiling, and 150-160 kilos of zinc dust are added. The stirring must be very efficient during the next operation, which requires 5-6 hours, of adding gradually a mixture of 100 kilos of alcohol and 40 kilos of addium hydroxide solution (36°-40°B). The reaction is vigorous and is regulated by the rate of addition of the alkalı and, if necessary, by cooling. When all the alkalı has been added the mixture is stirred until it is of a uniformly grey colour, and to obtain this more zinc may have to be introduced. The alcohol is then distilled off by means of steam, and the residue is thrown on a fine sieve which retains the hydrazobenzene and allows the zine dust, zine oxide, &c, to pass through Another method of working up consists in diluting the reduction mixture with water, carefully neutralising with hydrochloric acid, and filtering off the hydrazobenzene

The latter is transformed into benzidine by mixing it with ice and acidifying with concentrated hydrochloric acid. After some time water is added and steam introduced so as to dissolve the benzidine hydrochloride, the solution is filtered, and the benzidine sulphate precipitated by adding sodium sulphate solution This is filtered off, washed, and the base obtained by boiling with sodium hydroxide solution, cooling, collecting, and distilling in a vacuum The yield is about 80 p c. of the theoretical.

The above process can also be carried out without the use of alcohol, or solvent naphtha

can be employed instead.

The electrolytic reduction of nitrobenzene to hydrazobenzene is the subject of a number of patents, but it would not appear that this method is yet applied on the large scale (cf Lob, Ber 1900, 33, 2329)

The production of benzidine from azobenzene is easily effected by an electrolytic method with titanium salts or vanadium trioxide used as catalysts The azobenzene is suspended in 30 p c sulphuric acid containing 10 p c titanous sulphate; a lead cathode is used with a current of 3-4 amp. per square dem at 3-4 volts (D R PP 168273 and 172654)

The presence of small quantities of hydriodic acid facilitates the reduction of azobenzene to benzidine by means of sulphurous acid (D. R. P. 172569)

Benzidine, when pure, forms colourless lustrous laminæ, which melt at 127 5°-128°; it boils at 400°-401° (740 mm) The base is characterised as a para-derivative by the formation of quinone when it is oxidised by manganese dioxide and sulphuric acid It can be identified by a number of colour rechlorine, bromine, potassium permanactions ganate, potassium ferricyanide, and chromic acid, producing characteristic shades. most characteristic salts of benzidine are the sulphate  $C_{12}H_{12}N_2, H_2SO_4$ , and the chromate  $C_{12}H_{12}N_2, H_1CrO_4$  Both salts are sparingly soluble in alcohol and in water.

When treated with nitrous acid, benzidine hydrochloride is transformed into a tetrazonium salt of diphenyl

 $C_6H_4N_2Cl$   $C_6H_4N_2Cl$ 

which reacts readily with the usual second components of the azo-colouring matters, forming azo-compounds, the solutions of which possess the property of dyeing the vegetable fibres without the aid of a mordant. The number of colouring matters of this kind prepared from benzidine is largely increased owing to the insulable character of the diazonium salt.

$$C_6H_4N_2X$$
 $C_6H_4N_2CI$ 

in which one molecule of a second component, XH, has combined with the tetrazonium salt derived from benzidine. These diazonium salts, when combined with some other second component, YH, yield mixed azo-colouring matters of the formula.

$$\begin{array}{c} C_6H_4N_2X \\ \dagger \\ C_6H_4N_2Y \end{array}$$

Benzidine in the presence of hydrogen peroxide is used as a test for blood, with which it gives a blue colouration. The test solution is made by taking 10 drops of a concentrated solution of benzidine in glacial acetic acid, and adding 2 c c of a 3 p c solution of H<sub>2</sub>O<sub>2</sub> Sensitiveness—I part in 200,000 (Utz, Chem Zeit 1907, 31, 737, Schumm, Pharm Zeit 1907, 52, 604, McWeeney, Sci. Proc. Roy Dubl. Soc. 1909, 12, 216, Bordas, Compt. rend 1910, 150, 562, Gigli, Boll chim, farm. 1910, 49, 955, cf. O. and R. Adler, Zeitsch. physiol Chem. 1904, 41, 59.)

Homologues and Derivatives of Benzidine used in the Preparation of the Sushtantive Cotton Dijes—Although a great many of the derivatives of benzidine yield azo- colouring matters which are substantive to the vegetable fibres, yet this property is largely dependent on the position of the groups substituting the hydrogen atoms of the diphenyl molecule—Thus it has been found that when the substituting groups are in the meta-position to the coupling bond, as in

$$\begin{array}{c|c} \operatorname{CH_3} & \operatorname{CH_3} \\ \operatorname{NH_2} & & \operatorname{NH_2} \\ \\ \operatorname{OCH_3} & \operatorname{OCH_3} \\ \end{array}$$
 and 
$$\operatorname{NH_2} & & \operatorname{NH_2} \\ \\ \bullet \cdot \operatorname{Dianisidine} \\ \\ \bullet \cdot \operatorname{Dianisidine} \\ \end{array}$$

the azo- colours formed are substantive to cotton. If, however, groups are in the orthoposition, as in the contract of the c

the property of the azo-colours of dyeing unmordanted vegetable fibre is lost. The orthooderivatives nevertheless yield substantive cotton dyes if ring formation takes place between the substituting groups in those positions, thus

Benzidine sulphone

yield azo- dyes substantive to cotton.

Benzidine-o-disulphonic acid is prepared by heating benzidine sulphate with 2 parts of sulphuric acid for 36-48 hours at 210° (Ber 1889, 22, 2464, Eng Pat 1074, 1884, D R P. 27954)

o-Dichlorobenzidine is prepared from ochloronitrobenzene, and is also produced by chlorinating diacetylbenzidine (Eng. Pat. 25725, 1896; Fr. Pat. 265155, D. R. P. 94410, U.S. Pat. 625174). It melts at 133°

m-Nitrobenzidine, obtained by treating a solution of benzidine in sulphuric acid with one equivalent of intile acid or potassium nitrate (Tauber, Ber. 1890, 23, 796, Eng. Pat. 13475, 1892; Fr. Pat. 223176, D.R. P. 72867, U.S. Pat. 493583), melts at. 143°; when two equivalents of the intrating agent are used, m-dinitrobenzidine, in p. 214°, is produced. Monointration of diacetylbenzidine or phthalylbenzidine, and subsequent hydrolysis of the product, furnishes o-nitrobenzidine, in p. 190° (Koller, Ber. 1904, 37, 2883, Fr. Pat. 203468), whilst two different o-dinitrobenzidines, in p. 275° and 233°, are obtained by the dinitration of diacetylbenzidine and diphthalylbenzidine respectively (Trans. Chem. Soc. 1912, 101, 2298)

The following compounds, prepared from the corresponding nitro-derivatives of benzene, are of importance —

o-Toldine, 4 - 4' - diamino - 3 - 3' - dimethyl diphenyl  $\mathrm{NH}_2$  ( ${}^{}_{6}\mathrm{H}_3(\mathrm{CH}_3)$ —( ${}^{}_{6}\mathrm{H}_3(\mathrm{CH}_3)\mathrm{MH}_2$  from o-nitrotoluene, forms glatening plates, melting at 129° It is spaningly soluble in water, but readily soluble in alcohol and in ether. The sulphate is spaningly soluble in water

o-Diamsidine, 4-4'-diamino-3-3'-dimethoxy-diphenyl NH<sub>2</sub> ('aH<sub>3</sub>(O('H<sub>3</sub>)—('aH<sub>4</sub>(O('H<sub>3</sub>)NH<sub>3</sub>, from o-nitroanisole, forms colourless leaflets, melting at 135° (For its manufacture, see Jansen, Zeitsch Farb Ind 1913, 12, 247)

o-Diphenetidine, 4-4-diamino-3-3-diethoxy-diphenyl NH $_2$  C $_6$ H $_3$ (OC $_2$ H $_5$ )—C $_6$ H $_3$ (OC $_2$ H $_5$ )NH $_2$ , from o-nitrophenetole, forms needles or leaflets melting at 117° J F T

DIPHENYLAMINE was first obtained by Hofmann, in 1864, by distilling amline blue (Annalen, 132, 163), and in small quantity by distilling rosamline and leucaniline. De Laire, Girard, and Chapoteaut discovered an easier method of prepaining it by heating amiline with the hydrochloride at 210°-240° (Zeitsch Chem. 1866, 438, Compt. rend. 63, 91)

 $C_6H_5NH_2+C_6H_5NH_2HCl=NH(C_6H_5)_2+NH_4Cl$ 

This reaction is greatly facilitated by the use of certain catalysts. It may also be obtained by heating phenol with the double compound of

and line and zine chloride at 250°-260° (Merz and Weith, Ber. 13, 1298, 1880)  $^{\circ}$ 

$$C_6H_5NH_2+C_6H_5OH=(C_6H_5)_2NH+H_2O$$

and by heating aniline and diazoaminobenzene to 150° till the evolution of nitrogen ceases. In this last reaction, ortho- and para- aminodiphenyl are formed at the same time (Hirsch, D. R. P. 62309). Diphenylamine has also been prepared by the action of aniline on bromobenzene in presence of cuprous iodide (Goldberg, D. R. P. 187879, 1906). Aniline, when heated with ferric chloride, finely divided copper, and iodine, is converted into diphenylamine. Other catalysts can also be used (Rogers and de Nemours, U.S. Pat. 1314538).

Manufacture —Aniline (1 mol ) is heated with aniline hydrochloride (1 mol ) for 30-35 hours in an autoclave at 220°-230°. The product is extracted with hot dilute hydrochloric acid which dissolves the aniline hydrochloride and converts the diphenylamine into the free base, forming an oil which solidifies on cooling. The cake of diphenylamine is washed and then distilled alone or in a current of steam. Yield, 60-70 p.c. of the aniline employed. It is used in the manufacture of diphenylamine blue, diphenylamine orange, and aurantia (v. infra).

Properties — Monoclinic laminæ, mp 54°, b p 310°, almost insoluble in water, soluble in alcohol, benzene, and ether—It is feebly basic, and the salts are hydrolysed by an excess of

water

Reactions—The hydrogen of the imino-group is replaceable by alkyl or acyl radicals (Boseken, Roc trav chim 1912, 31, 350) With methyl rodide it gives a methyl derivative, with benzyl chloride, a benzyl derivative With formic or oxalic acid it yields formyldiphenylamine, mp 74°; with acetic acid or the acid chloride, an acetyl derivative, mp 103°, and with benzoyl chloride, a benzoyl derivative, mp 180° When heated with zinc chloride, the acyl derivatives lose water and form acridine derivatives. Formyldiphenylamine gives acilding

$$C_{6}H_{5} \stackrel{N}{\underset{CHO}{\mid}} C_{6}H_{5} = C_{6}H_{4} \stackrel{N}{\underset{CH}{\mid}} C_{6}H_{4} + H_{4}O$$

The acetyl compound yields methylacridine (Bernthsen and Bender, Ber 1883, 16, 767) Diphenylamine also gives acridine by heating with chloroform and zine chloride or aluminium chloride

$$(\mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{5}})_{\mathbf{2}}\mathrm{NH} + \mathrm{CHCl}_{\mathbf{3}} {=} \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{4}} {<} \bigvee_{\mathrm{CH}}^{\mathrm{N}} {<} \mathrm{C}_{\mathbf{6}}\mathrm{H}_{\mathbf{4}} {+} 3\mathrm{HCl}$$

(O Fischer and Korner, Ber 1886, 17, 101) With excess of oxalic acid, diphenylamine is converted into diphenylamine blue

$$3(C_{6}H_{5})_{2}NH+CO_{2}=C \underbrace{C_{6}H_{4} \ NH \ C_{6}H_{5}}_{C_{6}H_{4}=NC_{6}H_{5}}+2H_{2}O$$

Carbon tetrachloride reacts like oxalic acid, and gives the same blue colour With sulphur, thiodiphenylamine, the parent substance of methylene blue, is produced

$$(C_{6}H_{5})_{2}NH + 2S = C_{6}H_{4} \underbrace{\begin{array}{c} NH \\ S \\ \end{array}} C_{6}H_{4} + H_{2}S$$

(Berntheon, Ber 1883, 16, 2897) When the varour of diphenylamine is passed through a red-hot tube, carbazole is formed.

$$C(_{\mathbf{0}}\mathbf{H}_{\mathbf{5}})_{2}\mathbf{N}\mathbf{H} = \begin{bmatrix} \mathbf{C}_{\mathbf{6}}\mathbf{H}_{\mathbf{4}} \\ \mathbf{C}_{\mathbf{6}}\mathbf{H}_{\mathbf{4}} \end{bmatrix} \mathbf{N}\mathbf{H} + \mathbf{H}_{2}$$

(Graebe, Annalen, 167, 127); and the latter is also obtained from thiodiphenylamine and copper powder (Goske, Ber 1887, 20, 233).

Tests —A solution of diphenylamine in cone sulphuric acid gives a deep indigo-blue colour with nitric, introus or chloric acid (Ber 1912, 45, 2641, 1913, 46, 2286, Chem Zeit 1912, 26, 1239, Bull Soc Chim 1914, (14), 15, 186. The commercial product is a pale-yellow solid, melting not much below 54°, it should contain no oil, possess no unpleasant odour, nor turn blown on exposure to air

Derivatives -By passing chlorine into a solution of diphenylamine in acetic acid, a tetrachlorodiphenylamine is formed 4- chloro-2.6 dinitrodiphenylamine has been prepared (Ullmann and Shinang, Ber 1911, 44, 3730 Bromine in alcoholic solution produces a tetrabromodiphenylamine, in acetic acid, a hexabromo-derivative, and at a high temperature in presence of rodine, an octo- and deca-bromocompound. Diododiphenylamine is formed by the action of iodine in alcoholic solution in presence of mercuric oxide Bromine derivatives of nitrodiphenylamine are also known (H and P Ryan, Proc Roy Irish Acad 1919, By nitration in acetic acid solution, a tetranitro-derivative is formed, whilst direct nitration yields a hexanitro- compound, crystallising in yellow prisms, and melting at 238° The latter has strongly acid characters, and gives an ammonium salt which is used as a yellow dye known as aurantia (q v) Nitrosodiphenylamine is obtained by acting upon the base with amyl

Alkyl Derivatives—Methyldiphenylamine is obtained by heating together diphenylamine (100 parts) cone hydrochloric acid (68 parts), and methyl-alcohol (24 parts) for 10 hours to 250° in an autoclave (Girard, Bull Soc. chim [11]23, 2) It is a liquid, b p 282° The ethyl derivative is obtained in a similar way, b p 293° The amyl derivative boils at 330°–340° Benzyl chloride produces a benzyl derivative which is used in the preparation of viridine and alkali green

Amino- Derivatives —2-Chloro-5-ntrobenzenesulphonic acid combines with p-phenylenediamine to form 4-nitro-4-aminodiphenylamine sulphonic acid SO<sub>2</sub>H

which, on reduction, gives p-diaminodiphenylamine sulphonic acid (Baeyer & Co., D. R. P. 86250, 1894, Farb vorm Meister, Lucius and Bruning, D. R. P. 265197, 1914). Similar derivatives are obtained by the action of p-aminophenol, animophenol sulphonic acid, and p-aminosalicylic acid. The sulphonic acid group may be removed by heating with dilute acids under pressure (Meister, Lucius, and Bruning, D. R. P. 112180, 1899). Paraphenylenediamine and phenol in presence of copper salts and a solution of hypochlorite are oxidised to p-amino-phydroxydiphenylamine (Aktien Gesell. D. R. P. 204596, 1907). Aminohydroxydiphenylamine is also obtained by the electrolytic reduction of m-introdiphenylamine (Piccard and Lassen, J. Amer. Chem. Soc. 1918, 40, 1079). Diphenylamine derivatives prepared by the action

primary aromatic bases such as p-phenyleneamine, p-aminophenol, and aminosalicylic acid (1.34)-dintrochlorobenzene, (1.346)-ditrodichlorobenzene, and (1.43)-nitrochloronzene sulphonic acid, are used in the preparaon of sulphide colours, of which the most imrtant is dinitroxydiphenylamine

 $C_6H_3(NO_2)_2NH C_6H_4(OH)$ 

tained from p-aminophenol and dinitrochloronzene. Phenoxydinitrodiphenylamine is obnied from 1 3 dichloro 4 6 dinitrobenzene, tassium phenate and amine (Borsche, Ber 17, 50, 1339)

Diphenylaminedicarboxylic acid is obtained the action of anthramilic acid on o-chloronzoic acid in presence of finely divided copperher amino-acids behave similarly (Meister, icius, and Bruning, D. R. P. 148179, 1902, irgotti, Gazetta, 1914, 44, 1, 386)

Diphenylamine combines with formaldehyde, d the product forms an additive compound the sodium bisulphite

 ${}^{1}_{6}{}^{1}_{5}{}^{1}_{2}N]_{2} + {}^{1}_{1}SO_{3}Na$ 

=(C<sub>6</sub>H<sub>5</sub>)<sub>2</sub>N CH<sub>2</sub> SO<sub>3</sub>Na + (C<sub>6</sub>H<sub>5</sub>)<sub>2</sub>NH ad. ### DIPHENYL-DIMETHYLOLID

e dilactone of dihydroxy-diphenyl dicarboxylie d, is the mother substance of a small series colouring matters, of which but one natural resentative, ellagic acid, is as yet known to st. The methylolid grouping —CO—O—sent in the compounds has a feebler chromoric character than the carbonyl itself, and this account the dyeing properties of the mbers of this class are inferior as regardsingth to those of the benzophenone, flavone, I allied dyestuffs. That the diphenyl linkage exerts an influence is certain, for gallonin containing as it does digalloyl nuclei:

)H)  ${}_{1}C_{6}H_{2}$ —CO—O—C( ${}_{6}H_{2}(OH)_{2}$ —CO—O—

JH)  $(C_6H_2 - CO - C_6H_2(OH)_2 - CO - C_6H_2$ 

for whereas the former is colourless, the latter possesses a strong yellow tint.

Though diphenyl-dimethylolid is at present unknown, diphenyl-methylolid:

needles, melting at 92.5°, has been prepared by various methods, and of these that of Richter (J pr Chem [2] 28, 294), who obtained it by the action of phosphorus oxychloride on ethyl salicylate

is the simplest

Colouring matters derived from diphenylmethylolid itself do not appear to exist in nature, though certain of them can be readily prepared by the action of alkali on diphenyl dimethylolid compounds, in which case hydrolysis followed by the elimination of a carboxyl group occurs:

By a more diastic action of the alkali, hydroxydiphenyl derivatives are produced

Interesting is the fact pointed out by Graebe (Ber 1903, 36, 214) that by distillation with zine-dust diphenylmethylolid yields fluorene.

in addition to diphenyl and methyldiphenyl Formerly the production of the first-named hydrocarbon from ellagic acid proved a stumbling-block in attempts to obtain a clear conception of its constitution.

A. G. P.

DIPHENYLENEMETHANE v FLUORENE.
DIPHENYLHYDRAZINE v HYDRAZINES.
DIPHENYLHYDRAZONES v HYDRAZONES
DIPHENYLKETONE v BENZOPHENONE and
KETONES

**DIPHENYLMETHANE** was first obtained by Jena, in 1870 (Annalen, 155, 86), by the dry distillation of barium diphenylacetate

According to Zincke (Annalen, 159, 374), it is produced by the action of finely divided copper, non, or zinc or their chlorides, on a mixture of benzyl chloride and benzene or by heating benzoylbenzoic acid with soda-lime Friedel and Crafts (Bull Soc chim [n] 41, 324) and Schwartz (Ber. 1881, 14, 1526) obtained it by the action of benzene on methylene chloride in presence of aluminium chloride; E & O. Fischer (Annalen, 194, 253), as by-product in the formation of triphenylmethane from chloriform and benzene in presence of aluminium chloride, the Friedel-Crafts reaction applied to arominate

alcohols in presence of benzene (Huston and Friedemann, J. Amer Chem Soc. 1916, 38, 25): and Hirst and Cohen (Chem Soc. Trans 1895, 67, 826), by the action of the aluminium-mercury couple on a mixture of benzyl chloride and benzene It is also formed by the reduction of benzophenone (Zincke, Thorner, Ber. 1877, 10, 1473, Staedel, Annalen, 194, 307; Graebe, Ber. 1874, 7, 1624), and by the action of phosphorus pentoxide on benzyl ethyl ether Meyer, J prakt chem 1910, n. 82, 538) But But the methods which have found a technical application in the production of diphenylmethane derivatives, as well as of the parent hydrocarbon, are those of (1) Meyer and Wurster, which consists in heating a mixture of benzyl alcohol, benzene and conc sulphuric acid (Ber 1873, 6, 693), and of (2) Baeyer, in which benzene, formaldehyde, or methylal are shaken together in presence of cone sulphurie acid (Ber 1873 6, 221)

$$CH_2O + 2C_6H_6 = CH_2(C_6H_5)_2 + H_2O$$

Properties -- Diphenylmethane crystallises in long, colourless, prismatic needles, possesses a fragrant smell, melts at 26°-27°, and distils without decomposition at 261°-262° solves easily in alcohol, ether, and chloroform

Reactions -On oxidation with chromic acid, it yields benzophenone On passing the vapour through a red-hot tube, it is converted into o-diphenylenemethane. On heating it with sulphur to 250°, it gives tetraphenylethylene, and on prolonged chlorination with iodine chloride at 350° it breaks up into hexachlorobenzene and carbon tetrachloride (Ruoff, Ber 1876, 9, 1485)

Nitro Derivatives — On nitration, diphenylmethane yields two dinitro- derivatives, one of which melts at 183°, and the second, which is the chief product, at 118° Other dinitro- derivatives are obtained from nitrobenzyl chloride, benzene and aluminium chloride, nitrobenzyl alcohol, benzene and sulphuric acid or nitrobenzene, formaldehyde and sulphuric acid, in a similar manner to the parent hydrocarbon Also nitrohydroxy- derivatives can be prepared by condensing nitrophenols and their ethers with formaldehyde and cone sulphure acid (D. R. P. 72490) The prolonged action of mitric and sulphuric acids gives rise to a tetranitro-derivative

Amino- Derivatives — The only substances possessing at the present time an industrial value are the amino- derivatives of diphenylmethane. They may be obtained by the reduction of the nitro- derivatives by tin and hydrochloric acid, but the more common method is to effect condensation between the aromatic base and formaldehyde, a general process for which a number of patents have been granted in recent years. Thus, by heating amline, aniline hydrochloride and formaldehyde, 40 pc, to 100°, 44'-diaminodiphenylmethane is produced (D. R. PP 53937 and 55565). The reaction appears to occur in two stages, for on heating aniline, formaldehyde, and a strong alcoholic solution of potassium hydroxide, the following change takes place :-

 $\begin{array}{l} \mathrm{CH_2O} + 2\mathrm{C_6H_6NH_2} \\ = \mathrm{C_6H_6NH\ CH_2\cdot NH\ C_6H_6 + H_2 O} \end{array}$ 

and the latter when heated with aniline and its h, in mioride passes into the diphenylmethane

derivative. A tetramethyldiamino- compound is obtained in a similar manner from dimethylaniline and formaldehyde in acid solution Similarly, a diphenyldiamino- derivative

C6H5NH C6H4 CH2 C6H4NH C6H5 has been prepared from diphenylamine and formaldehyde (D R P. 58072), a tetramethyldiaminodihydroxy- derivative

 $(CH_3)_2N(OH)C_6H_3CH_2CH_3(OH)N(CH_3)_2$ from dimethyl-m-amino phenol (D R PP 63081 and 67001), and a diethoxydiaminodiphenylmethane NH<sub>2</sub>(C<sub>2</sub>H<sub>5</sub>O)C<sub>6</sub>H<sub>3</sub> CH<sub>2</sub> C<sub>6</sub>H<sub>3</sub>(OU<sub>2</sub>H<sub>5</sub>)NH<sub>2</sub> from o-phenetidine and formaldehyde in presence of hydrochlone acid (D. R. PP. 70402, 72490, 73951, 73946)

Other methods for obtaining 44'-diaminodiphenylmethane are (1) the action of p-aminobenzyl alcohol on aniline hydrochloride in aqueous solution (D R P 96762), and (2) heating p-aminobenzylaniline with hydrochloric acid (D. R. P. 107718)

 $\begin{array}{c}

\text{has been}
\end{array}$ The 4.4 diaminodiphenylmethane has been prepared from p-aminobenzylaniline by heating with aniline and similar aromatic bases

 $\begin{array}{l} \mathbf{NH_2C_6H_4\ CH_2NH\ C_6H_5+C_6H_5NH_2} \\ = \mathbf{NH_2\ C_6H_4\ CH_2\ C_6H_4\ NH_2+C_6H_5NH_2} \end{array}$ 

(v Braun and Kruber, Ber 1913, 46, 3952) For diaminoditolyimethane see Farb vorm. Meister, Lucius and Bruning, D R. P 252916,

A 1 1' dichloro 2 2' diamino diphenylmethane is described by Duval, Compt rend 1912, 154, 780, and by Meyer, Ber 1914, 47, 1161, who prepared it from formaldehyde and o-chloraniline

A tetrahydroxy derivative was obtained by Ghosh and Watson (Chem. Soc Trans. 1917, 111, 824) from quinol and formaldehyde

Aryl derivatives of diphenylmethane, prepared by the Grignard reaction, are described by Boudroux, Compt rend 1915, 161, 131

Sulphonic acids of diphenylmethane have been obtained by Wedekind and Schenk, Ber 1911, 44, 198, and Staudinger and Pfenninger, Ber 1916, 49, 1941.

Diphenylmethane mono- and dicarboxylic acids have been prepared by Mitter, Ber 1912, 45, 1207, by the action of oxalyl chloride in presence of aluminium chloride on diphenylmethane J. B C

DIPHENYLMETHYLAMINE. Methyldiphenylamine v Diphenylamine.

DIPHENYLTOLUQUINOXALINE v Azines.

DIPICOLINIC ACID v BONE OIL.

DIPLOSAL. The salicylic ester of salicylic acid OII C<sub>6</sub>H<sub>4</sub> COO C<sub>8</sub>H<sub>4</sub> COOH, a white crystalline powder, mp 147°; almost insoluble in water and dilute acids. Used in the treatment of rheumatic diseases (v. SYNTHETIC DRUGS).

DIPPEL'S OIL V BONE OIL

DIPROPÆSIN. A derivative of urea containing the residues of 2 mols of proposin.

DIPROPYLACETIC ACID v OCTOIC ACIDS.

**DIPYRIDINE** v Bone oil.

DIPYRIDYL v BONE OIL

DIRECT BLUE, -BROWN, -GREY, -INDONE BLUE, -ORANGE, -ROSF, -YELLOW v. Azo-COLOURING MATTERS,

DISALOL. Trade name for phenyl salicylsalicylate

DISAZO- and TETRAZO- COLOURING MATTERS. The terms 'disazo' and 'tetrazo' are both used to indicate the presence of two azo- groups (N.N) in the molecule of a colouring matter, but at the same time they indicate the mode of preparation of such dyostuffs rather than, strictly speaking, their constitution. Tetrazo- colouring matters may be regarded as a special division of the disazo-colouring matters, as will be seen from the following classification.

Primary disazo-colouring matters are obtained by the action of two molecules of a diazo-compound (derived either from two molecules of an amine or from two different amines) on one molecule of an amine (e.g. m-phenylenediamine, m-tolylenediamine), a phenol (e.g. phenol, resorcinol, a dihydroxynaphthalene) or an amino-phenol (e.g. aminonaphtholsulphonic acids). The position taken up by the diazo-groups may be illustrated by the commonest cases (see also Azo-colouring matters) m-Phenylenediamine. The azo-groups occupy the two positions parawith respect to the two amino-groups. When one of these para-positions is occupied, as in m-tolylenediamine, the second azo-group enters the ortho-position with respect to the second amino-group; thus

$$CH_3 \underbrace{\hspace{1cm} N_2 - N_1}_{NH_2 - N_2} NH_2$$

Phenol, a-naphthol The para- and orthopositions with respect to the hydroxy- group are occupied

Resorcinol Two isomeric disazo- dyestuffs may be formed. When the combination is effected in alkali hydroxide solution, the symmetrical compound (I) is obtained, but when

the reaction takes place in the presence of sodium acctate or sodium carbonate, the unsymmetrical

compound (II) is produced

Dihydroxynaphthalene enter the usual position with respect to the hydroxy- groups, as would be expected if these groups represented two independent naphthols (of Azo- Colouring Matters)

Aminonaphtholsulphonic acids. In this case also, the compound may be regarded both as an independent naphthylamine and as a naphthol, one molecule of the diazo-compound is combined in acid solution, when the position taken up by the azo-group is the same as if the substance were a naphthylamine, and the second molecule is combined in alkaline solution as if the substance were a naphthol

Secondary disazo- colouring matters are obtained by the action of a diazoazo- compound on an amine or phenol; their general formula is  $X:N_2:Y:N_2:Z$ , the essential difference from the primary class being that Y does not contain auxochrome groups  $(NH_2 \text{ or } OH)$ .

Tetrazo- colouring reatters are produced from diamines, both amino- groups of which are diazotised (i.e. the diamine is tetrazotised) and combined with two molecules of the same or

different components (amines or phenols) These are mostly derived from benzidine, tolidine, dianisidine, &c; some, however, are prepared from p-phenylenediamine, and in this case direct tetrazotisation cannot conveniently be effected, but the monoacetyl compound is first diazotised and combined, the acetyl-group being then eliminated and the free amino- group is diazotised and combined with the second molecule of a component 1 When the first combination has been effected with an amine (in practice nearly always a naphthalene derivative), and in consequence a diamino- compound is produced on saponification, treatment with one molecule of nitrous acid leads to the diazotisation of the benzenoid amino- group, that attached to the naphthalene ring not being attacked

For the sake of completeness, it is necessary here to describe those dyestuffs which contain

three or more azo- groups

Trisazo- colouring matters are obtained in the following ways (1) Combination of three molecules of a diazo- compound with a phenol method is of only theoretical importance, and has hitherto been applied only to the cases of phenol (Wallach and Fischer, Ber 1882, 15, 2814, Grandmougin and Freimann, ibid 1907, 2814, Grandmougin and Freimann, volu. 1907, 40, 2662, J pr Chem 1908, [n ] 78, 384; Heller and Notzel, volu. 1907, [n ] 76, 58; Heller, volu. 77, 189), phloroglucinol (A G Perkin, Chem Soc Trans 1897, 71, 1154), and resorcinol (Orndorff and Ray, Ber 1907, 40, 3212; Amer Chem J 1910, 44, 1) (2) Combination of one molecule of a diazozo- and a diazo- compound with a pharmal course and a diazo- compound with a pharmal course and a diazo- compound. with a phenol, amine, or aminophenol diazoazo- compound may be produced, for example, by diazotising an aminoazo- compound such as p-sulphobenzeneazo-a-naphthylamine, or the intermediate product, obtained by combining a tetrazotised diamine (benzidine, &c) with one molecule only of a component (such as salicylic acid, &c ), may be used, or the formation of the diazoazo-compound may be left to the last stage of the operation, for example, a tetrazotised diamine (benzidine) may be combined with one molecule of an aminonaphthol (H acid) in acid solution, a diazo-compound (diazobenzene) now added in alkaline solution and the diazodisazo-compound coupled with a component (m-phenylenediamine or phenol) (Ene direct black GX and Ene direct green DT). (3) Combination of a diazotised tetrazo-colouring matter (which must, of course, contain a diazotisable amino- group) with a phenol or amine, either in substance of on the fibre bination of a triamine (eg magenta), having each amino- group diazotised, with three molecules of a component

Tetrakisazo- colouring matters, containing four azo- groups, are obtained (1) by the combination of two molecules of a diazoazo- compound with a phenol or amine (e.g. Anthracene acid brown B, v. Azo- colouring matters). (2) by combining two molecules of a diazo- compound with one of a tetrazo- colouring matter (e.g. Benzo brown G); (3) by combining a tetrazo- compound with two molecules of a monoazo-colouring matter (e.g. Hessian brown BBN);

<sup>1</sup> An alternative method is first to combine diazotised p-nitroniline with the component, then to reduce the nitro- group with sodium sulphide, and diazo<sub>v.</sub> <sup>1</sup> amino- group thus formed.

(4) by tetrazotising a tetrazo- colouring matter (containing two diazotisable amino- groups) and combining with two molecules of a component (e.g. Dianil black PR), (5) by diazotising a trisazo-colouring matter (containing one diazotisable amino- group) and combining with a phenol or amine either in substance or on the fibre

Colouring matters, containing more than four azo-groups, can be prepared, but, generally speaking, their functorial power is little or no greater than those described above. J. C. C.

DISINFECTANTS. A disinfectant is agent that will kill lower organisms which act injuriously on the higher forms of life though most disinfectants are also antiseptics and deodorants, a clear difference between the three classes lies primarily in their uses and Disinfectants are germicides, anti septics may only retard or inhibit the growths It is not essential for a disinfectant to effect absolute sterility in practical disinfection, there is nearly always a residue of highly resistant and non-pathogenic organisms destroy these involves great additional time and cost, and may even be disadvantageous when they act as natural scavengers in removing objectionable organic matter and antagonising dangerous forms The choice of an agent will obviously depend on considerations of safety, convenience, and economy in use

#### INORGANIC SUBSTANCES,

Ordinary oxygen acts slowly by the aid of Its activity is slightly inaerobie organisms creased by compression; it becomes exceedingly energetic when converted into Ozone. Since ozone is decomposed by heat and absorbed by most metals and by otherwise mert organic matter, the chief conditions for success and economy in working are (1) avoidance of sparking; (2) keeping the gas and the apparatus cool; (3) straining the air, and also partially drying when it is desired to prevent the formation of oxides of nitrogen, (4) parts in contact with ozone must be made of, or lined with, unoxidisable materials. (5) the grosser organic impurities, as well as sulphuretted hydrogen and ferrous non, should be removed before disinfection. The use of ozone on the large scale for punifying water is now well known, and the principal types of apparatus have been described by Don (Inst Mechan Figureers, Jan and Feb. 1909, see also S Rideal, J. R. San Inst. 30, 1, 1909, Rideal found at St Maur Waterworks, Paris, that with the sand-filtered (Marne) river water, containing a fluctuating number of bacteria, 28-320 per c.c, with a mean frequency of coli organisms of 1 per 100 cc (in more than onethird of the tests it was 1 in 40 cc), ozone in the proportion of about 0.6 gram per cubic metre of water (6 lbs per million gallons) destroyed all bacteria except an average of I per c c. of innocuous spore-bearing organisms of the subtilis type. The ozonised air was applied in a De Frise tower at the rate of about 40 p.c of the volume of water treated, and contained 1.4-18 grams of ozone per cubic metre (determined at frequent intervals by neutral potassium iodide) An advantage of ozone is that in disinfecting it adds no mineral proved that where water is not too contaminated

with organic matter, sulphuretted hydrogen, or ferrous iron, ozone will destroy all pathogenic organisms at a reasonable cost. In the dry state, like chlorine, it has very little action on micro organisms, and therefore does not act powerfully on bacilli in air. S grams per cubic metre of air in a room ordinarily closed accomplish disinfection in 3 hours. Its use as an adjunct to ventilation has often been proposed, but its irritant action on the lungs prohibits its use in these quantitites. It is most active when moist. Ozonised air, under pressure, has been used successfully for destroying moulds and bacteria in brewers' foul casks, and has been introduced into wort in the latter part of the fermentation 'to destroy noxious germs' (Fng. Pat. 22355, 1898) Will and Beyersdorfer (Zeit ges Brauw 1912, xxxv 73) showed that air containing 0 6-0 7 gram of ozone per cubic metre destroyed organisms mimicable to the On account of its rapid consumption by oxidisable substances, it can only be effective in disinfecting the surfaces of organic solids the Pittsburg Homoropathic Hospital,  $\mathbf{At}$ ozone, besides purifying the water supply, is used for sterilising instruments, bandages, &c and for dressing wounds and ulcers storage it would probably be useful for destroying injurious organisms and odours, thereby possibly lessening the amount of refrigeration required Many attempts have been made to utilise it for disinfecting, combined with bleaching, textiles, feathers, and other surface-contaminated articles, and have been only limited by questions of expense

Patent 4153 of 1902, for 'fixing ozone in liquids,' states that pure acetaldehyde dissolves 2823 times its volume of ozone, that 10 pc solutions of acetaldehyde in water dissolve 536, in alcohol 748, in ether 859 volumes of ozone; that these solutions are very stable, and have

been successfully used in surgery.

Hydrogen peroxide. The first experiments (Ber 15, 1585) showed that this was a bactericide which, in the dilute state, appeared mert to enzymes such as diastase,1 ptyalin, pepsin, and pancreatin; did not injure foods; and is also innocuous and non-corrosive These properties suggested its use for killing pathogenic organisms, and those that cause change in articles of diet, especially milk (Renard), and also as an internal disinfectant. Altchoefer (Centr Bakt 1890, viii 129) and most later observers give 1 per 100 of H<sub>2</sub>O<sub>2</sub> as required to destroy pathogenic organisms in 24 hours. In 1903 S. Rideal found that in milk raised to 50°, then treated with 0.6 gram of H<sub>2</sub>O, per litre, and the heat maintained at 52°-55° for 8 hours, pathogenic organisms and even the spores of *B anthracis* and subtilis were killed, the milk was not physically altered, and kept for over a month unchanged in the closed receptacles (Budde's patent 10903, 1903) Similar results have been obtained by Lewin and others, by Hewlett (Lancet, Jan 27, 1906), and Reichel (Zeit f Hyg 1908, lxi 49) So that hydrogen peroxide aids pasteurisation, and enables it to be efficient The solution is at a lower temperature.

The enzyme catalase (present in malt, yeast, milk, and many organic liquids) and hydrogen peroxide mutually decompose one another (Van Laer, J Soc. Com Ind 1906, 489, 1909, 950), but the above statement remains practically true. (See also that 1909, 1267.)

frequently used as a spray, gargle, or dressing, and has had a wide application for war service in dealing with gas gangrene infected wounds (see reports by Capt M Page, R.A M S., Lancet, Sept 1914, Col Makins, ibid. August, 1914)
Peroxide of hydrogen is present in 'Sanitas' (qv) 'Perhydrol' is a 30 pc or 100 volume solution of  $H_2O$ . The use of peroxide of hydrogen in medicine depends partly on its bactericidal action Registered names of solu-tions are 'Dioxogen' (3 pc), 'Hydrozone,' 'Glycozone' and 'Pyrozone' (dental practice), and 'Peroxols' are mixtures of  $H_2O_2$  with various disinfectants Peroxides of sodium, magnesium ('Hopogan'), zinc ('Ektogan' or 'Dermogen') and mercury, generate oxygen or H<sub>2</sub>O<sub>2</sub>, and have analogous use Hydrogen peroxide is more stable in ether than in water, 'ozonic ether' is an ethereal solution containing about 12 pc of H2O2, which has been used in whooping-cough and scarlet fever 'Perhydrit' or 'Hyperol' dressings, containing H<sub>2</sub>O<sub>2</sub>, urea, and a trace of citric acid, have recently been introduced

Foregger and Philipp (J Soc Chem Ind. 1906, 298) treat at length on the applications of peroxides, and suggest calcium peroxide ('Bicalzit') instead of H<sub>2</sub>O<sub>2</sub> for sterilising milk, as more lasting in effect. For water sterilising, tablets of magnesium perovide and citiic acid are made; Park found that 01 gram of this peroxide killed upwards of 2 million typhoid organisms in 150 cc of water in 30 minutes, and 0.2 gram gave the same result in 1 minute Although Croner (Zeit f Hyg 1908, lvin 487) obtained sterility in water with the use of 07-10 gram MgO, per litre, more recent investigations by Young and Sherwood (J. Ind. Eng Chem 1911, 3, 495) have indicated that over five times this quantity must be used to ensure sterility Patents for similar uses of  $H_2O_2$  and other peroxides are very numerous.

Nitric acid and oxides of nitrogen. The corrosive action of nitric acid limits its value as an active disinfectant. J. C. Smith used it with success in 1780 for fumigation in a violent outbreak of typhus fever in the British fleet (Vallin, Désinfectants, 1882, 265). Disinfection of rooms by nitrogen peroxide was carried out during the siege of Paris. 48 hours were occupied, and the cost was very high. Severe bronchitis and several deaths from poisoning have resulted from breathing this gas, and intre disinfection has been replaced by safer methods, except in the local destruction of bacteria as in laboratories

Sulphur. Dusting with sulphur is used for killing insects and fungi on plants, as sulphurous acid is gradually formed. The use of sulphur internally is due to its forming sulphuretted hydrogen in the system, and thereby destroying or enfeebling micro-organisms and higher parasites. A solution containing calcium polysulphides, made by boiling milk of lime with sulphur, has been extensively used as an insecticide (see Agric. Bull. 319 and 320, New York, 1909)

Sulphur dioxide disinfection is still a subject of controversy, but certain of the unfavourable results adduced have been due to faulty application. Spores are not generally killed by it, and the dry gas has very little effect on microorganisms, but it destroys all vermin, and therefore is of special value in combating insect-borne

As to its effect on the lungs, about diseases 5 pc in the air has produced fatal results, but pc. can be tolerated for some time, and a larger amount with the protection of a wet 1 lb. of towel alkalised with washing soda sulphur burnt in a room of 1000 cubic feet produces theoretically an air-content of 115 pc SO,, and requires 0 56 lb. of water to turn it into sulphurous acid Such an amount of moistening is, however, not necessary, on account of the natural moisture of the air. Prescriptions as to the proper quantity of SO, have varied greatly, partly because in some cases it has been considered sufficient to destroy only a special organism Klein, Houston, and Gordon (Report, Med Off LCC 1902) found that with 31 lbs. S per 1000 cubic feet in 24 hours, B typhosus, diphtheria, pyocyaneus, and Staph p aureus were killed, but not anthrax spores nor B tuberculosis in dried sputum In America, 5 lbs per 1000 cub feet have been found sufficient to kill all spore-bearing organisms after 16 hours' exposure (Rosenau) S Rideal's results with the liquefied gas were as follows Silk threads and paper slips infected with B coli and Staph p aureus were sterilised after 24 hours' exposure in a sealed room of 1500 cub feet, into which 20 ozs of  $SO_2$  were passed Subtiles spores were not killed With 10 ozs, the threads were again sterilised, but the paper shps were not shallow pans of water were exposed in the room to supply moisture, the SO<sub>2</sub> content of the air was actually lowered after the 24 hours (through absorption by the water), from 0.5 p.c. present in the previous experiment to 02 pc, and the organisms were still living Therefore moisture should only be supplied by washing or lightly spraying the surfaces In chemical disinfection, it is generally recommended that walls should be previously stripped and fabrics spread out on lines, but spreading the infection must be carefully avoided The room must be sealed by obvious means, and, observing this condition, heating is advantageous Liquid SO, in canisters is more convenient than burning sulphur, and avoids risk of fire one pound of SO<sub>2</sub> has the liquid = 5} cub feet of the gas the disadvantage that it attacks metals and organic substances from the production of sulphuric acid; a good deal is also absorbed by plaster It has little penetrating power, and therefore bedding and thick articles must be removed and sterilised by heat The 'Clayton method 'of disinfection is much used for the holds of ships, and has been favourably reported on by Wade and Eyre for the Local Government Board (Rep 232, 1906, and Med Off Rep 1903-4, 330). Sulphur is buint in a special apparatus, and the gases, consisting of air, SO,, and a visible cloud of sulphuric acid, are forced in till the SO, reaches about 10 pc of the air in the infected space (For experience of its use, see Rev d'Hyg Oct 1902, NSW. Agric Gaz 1900 and 1901)

Sulphurous acid is used beneficially as a germicidal spray or wash in various parasition affections (eq. diphtheria), also internally in cholera and gastric fermentation, for rectal injections, and other allied objects 'Thiocamf' is a liquid obtained by the action of the gas on camphor It can be preserved without pressure in well-closed vessels, and on exposure to '1. a 6-oz bottle should evolve about 20 litres of SO<sub>2</sub>.

Sulphurous acid and bisulphites are widely used for checking fermentations and preserving food. Lehmann states that an amount equivalent to 0 004 p.c of SO<sub>2</sub> may be allowed without injury to health The Report of the British Departmental Committee on Preservatives, 1901, 26, leaves the matter open. Some commercial preparations are 'Meat preserve crystals,' 'Freeze-em,' and 'Hawke's anticrystals,' 'Freeze-em,' and 'Hawke's anti-ferment' For objections to the use of sulphites in food, see Thresh and Porter, Preservatives, 1906, 70-77, also an article by Durham in the J of Hygiene, April, 1909 The latter recommends the fixing of a maximum legal limit, not exceeding 0.01 p.c. of 'total sulphur dioxide, with a declaration of the amount, but less than 0 001 or 0 002 pc might be simply declared as

Sulphuric acid, like acids generally, is antiseptic, and in some cases disinfectant (which is a palatable strength) is fatal to Sp. choleræ in 15 minutes Stutzer found that this strength disinfected iron pipes, cleaning out sust and sediment without sensibly attacking the metal With 0.04 p.c. Ivanhoff destroyed cholera organisms in Berlin sewage, and with 0 08 pc in that from Potsdam In the laboratory it was found that 0 035 p c kills B typhosus in 30 minutes, and 0 07 pc in 15 minutes, in impure water infected ordinarily with typhoid, but with very heavy infections the latter strength requires 45 minutes He recommended 0 09 p c. as having advantages over heat sterilisation for dealing with the drainage from hospitals and other infected areas. the acidity would speedily be neutralised on mixing with the bulk of the sewage (But Assoc 1901)

Sodium bisulphate has been introduced by one of the writers and Dr. Parkes, as a means of sterilising drinking water for armies in the field and travellers 15 grains of NaHSO4 to a pint of water in 15 minutes destroys B typhosus and enteritedrs, Spirillum cholera, and internal parasitic worms. In effervescent tabloids, yielding a slightly acid solution, it was used with success in the South African, Russo-Japanese, and the European wars

Persulphates give off oxygen when moist, and are useful as hand disinfectants (Lancet, 1905,

n 1106)

Carbon disulphide, if it were not for its other properties, would be a valuable disinfectant and preservative. As well as its alkaline compounds, the xanthates, it has been found useful against fungi, and insect parasites such as the vine phylloxera. Ckeandi Bey's lamp burns it safely

for generating SO<sub>2</sub>.

Boric acid is not a disinfectant, but has a power of restraining bacteria which act injuriously in foods Rideal and Foulerton found that I in 2000 of a boric mixture, containing 3 parts of H<sub>3</sub>BO<sub>3</sub> and 1 part of crystallised borax, keeps milk sweet for 24 hours without appreciable effect on digestion The British Departmental Committee already referred to, recommend that the only preservatives allowed to be used in cream, butter, and margarine be boric acid, or mixtures of boric acid and borax, not exceeding 0 25 p c of H<sub>3</sub>BO<sub>3</sub> for cream, and 0.5 p c for butter and margarine Later, as this quantity appeared insufficient in the cream tande an official report by Hamill advised that 0 4 p.c H<sub>3</sub>BO<sub>3</sub> should be allowed in cream from

May to October inclusive (Food Report 10, LG.B 1909) Soluble borates are used as a larvicide in manure heaps. It has no action on the crops as they are rendered insoluble (Cook and Wilson, J Agric. Research, 1917, 10, 591).

The Halogens, chlorine, bromine, and iodine, act as disinfectants in several ways: (1) they can combine with H2 and liberate O, in water; (2) they can combine directly with organic matters, or replace the hydrogen in them, precipitating albuminous substances and rendering them imputrescible, killing organisms by combining with and coagulating protoplasm, removing their food or rendering it unsuitable, acting toward them as irritants or direct poisons, also producing substances which have that effect

Chlorine and the hypochlorites, like other oxidisers, are consumed by otherwise mert organic and inorganic matters present, but in ordinary disinfection leave behind them as substitution compounds which maintain germicidal power—the chloramines, hydrazine, and the chloroproteids (Rideal, J. R. San Inst. 31, 2, This paper shows that in dilute solution of hypochlorites the Rideal-Walker coefficient of 2 18 for 1 pc of available Cl is increased to 6.36 by the addition of an equivalent of ammonia, remains near this level for 24 hours, and even after 72 hours has an enhanced value Therefore, since the coefficient of chlorine itself averages 220 units, that of ammonia less than 0.7, and ammonium chloride nil, that of the chief product, chloramine NH Cl, must be over 600 units, hence this substance, but for its instability, would probably be the most valuable of disinfectants. It has a pungent odour, hitherto often mistaken for chlorine or hypochlorous acid, and gives the blue reaction with KI and starch With excess of ammonia, as in sewages, it gradually disappears, forming a salt of hydrazine, which still has a germicidal value (R W. coefficient of the base at least 24). The action of chlorine on nitrogenous compounds gives compound chloramines, many of which are insoluble, they have a tendency to become fixed on cellulose, and in this way attack the envelopes of organisms.1

Various substituted chloramines have been introduced by H D Dakin for use as sterilisers and disinfectants Amongst the more important may be mentioned chloramine-T, p-toluene sodium sulphochloramide, p-sulphodichloraminobenzoic acid, and dichloramine T (BMS Aug. 1917) The former, under the title Halozene, has been used for water sterilisation on a small scale.

The addition of ammonia solutions to bleaching powder solutions preparatory to the sterilisation of water has effected a considerable economy in the quantity of materials used in the public water supply at Toronto, Canada.

The chloramine is about five times as strong as the corresponding molecular concentrations

of sodium hypochlorite

The bromamines of the benzene series, the naphthaline chloramines and the protein chloramines, are all strong germicides, but suffer from lack of stability in solution.

Chloride of lime, or 'calx chlorinata' (about 33 p c. available chlorine), has some advantages

<sup>1</sup> Also see Cross Bevan and Bacon, Chem. Soc. Trans 1910, 244.

from being a solid, but is quickly deliquesced; and decomposed by air, takes some time to dissolve, and gives a quantity of insoluble waste Klein found that 1 p c of bleaching powder only killed less resistant organisms in 24 hours There is, in many respects, a preference for the sodium solutions. chlorinated soda or 'Eau de Labarraque' (often called 'Eau de Javel,' which was originally the potash salt), contains about 25 pc av Cl, 'Chloros,' 10 pc av. Cl, 'Antiformin' is a solution of caustic soda and hypochlorite used in breweries. Electrolytic preparations are 'Oxychloride,' up to 115 pc av 'Cl, and 'Hermite fluid,' used successfully at Poplar In the latter solution magnesia is employed as an adjunct in the electrolysis contains free hypochlorous acid av Čl 42 to The effective strength for local dis-48 pc infection is 0.35 p.c av Cl, which kills non-aatring organisms in 5 to 10 minutes, and anthrax and enteritidis spores in  $1\frac{1}{2}$  hours Chloride of lime has the objection that it leaves the surface for a long time damp from the presence of calcium chloride The same salt imparts its bitter taste, and increases the hardness, when chloride of lime is applied to the purification of drinking water, while the soda preparations tend to soften the water and are not sensible in the flavour. In trials at Guildford in 1904 (J. R. San. Inst. xxvi. 891) with electrolytic hypochlorite in the proportion of 0.75 to 1.0 part per nullion of av (1, one of the writers found that water containing an average of 90 organisms per c c was practically sterilised, while after standing 11 hours the odour and taste were normal, and there was no need for further treatment Candy's patent, 4212, 1909, removes excess of av Cl by filtration through coke, Thresh's, 3023, 1909, by treatment with metallic iron Other methods of removal are suggested. (1) by the addition of ferrous salts, subsequently removing the ferric salt formed by a 'Permutit' filter, (2) by the addition of gaseous sulphur dioxide, (3) by the addition of sodium bisulphite After the Maidstone typhoid epidemic, 1897, the infected reservoir, mains, and pipes, were sterilised with 1 pc solution of chloride of lime during 48 hours · no corrosion of the non was observed During a similar outbreak at Lincoln, in 1905, the water supply was sternised by sodium hypochlorite (av. Cl, 1 per million) with most satisfactory results In 1910 Toronto (reated its water supply with 0 14 part per million of av Cl as chloride of lime Since June, 1909, the writers have been applying 'Chloros' in the proportion of 1 to 2 parts av Cl per million to 100,000 gallons daily of the drinking water of a town in the north of England: the liquid is made practically sterile, coli is absent from 75 to 85 c c, and there is no effect on the taste At Cambridge, in 1910, a portion of the supply (lower chalk) was treated with one in 4 to 8 millions of av Cl as chloride of lime, and Houston found that this minute quantity destroyed 66 to 98 p c of the bacteria, and coli, which was always present before, was afterwards absent in 500 cc. This water, however, contained hardly any organic matter. America, treatment of the entire water supply of Jersey City (about 40 million gallons per la ger works, considerably reduce the cost, and day, from the Rockaway river) with chloride of lis cheaper than sand filtration. Itellerman, lime, has been adopted since the beginning of Pratt, and Kimberley (U.S. Dept. of Agric.

1909: the proportion used is now 0.2 part per million of av Cl, and the daily examination shows that coli is absent from 10 cc of the treated water In England, the 'De-Chlor system was applied at Reading to the prefiltered river water in 1910. Since the war chlorine treatment has been adopted for the London supply (11th Annual Report, M W B.)

Recently an impulse has been given to the sterilisation of water by means of gaseous chlorine injected by means of suitable dosing apparatus, owing to the convenience of handling and transporting chlorine in the liquid state contained in steel cylinders of 100 lbs capacity. Injection into the water may be direct through diffuser, as in the Wallace and Tieman apparatus, or indirect through the addition of a minor volume of more concentrated chlorine water to the bulk volume, as in the Electrobleach and Patterson plants NH<sub>3</sub> does not seem to enhance the germicidal value in the absence of alkaline bases

With sewage, of course, a larger dose is required, and the first experiments at Nice, Brest, and Worthing, in 1894, with the Hermite fluid, showed that, as with ozone and other disinfeetants, the agent should be applied, not to a raw liquid (except in special cases), but as a finisher' to one that was partially purified 1898, using an electrolytic brine (Woolf's 'Electrozone') for purifying an effluent at Maidenhead, one of the writers found that with three parts per million of av Cl, and a contact of 5 minutes, the bacteria were reduced to 10 per 50 cc, and that 17 parts per million killed all the organisms in 15 minutes. His long series of trials at Guildford commenced in 1904, using 'Oxychloride,' and proved that with 2.5 parts per million of av CI, tertiary effluents could be practically sterilised, but that the raw sewage and septic effluents required 30 to 70 parts, the contact period was  $4\frac{1}{2}$  hours (J. R. San Inst. xxvi 7, 1905) The oxygen consumed from permanganate in 5 minutes in the cold, as measuring the H2S and other easily oxidisable substances, was a guide to the amount of the agent used, and in the earlier experiments it was found that when the av (I added was 1.7 times this figure, the availability of the chlorine was sufficiently prolonged to ensure the desired sterilising effect, and the subsequent experiments frequently yielded excellent results with an amount equal to this oxygen figure, that is, one to one (Sec further, Rideal, Trans Farad. Soc iv 3, 1909) An important point shown was that the necessary factor of safety could be ascertained by simply testing with KI and starch, and noticing the persistence after 4½ hours of the blue colour, due in this case, as has been mentioned, not to chlorine, but to chlor-Schumacher (1905), at Hamburg, found that with raw sewage sufficient sterilisation is attained if after 4 or 6 hours the test shows a reaction equal to 19 and 17 parts per million of av Cl respectively Investigations on sewage filter effluents with chloride of lime were continued in America by Phelps and Carpenter (U.S. Technological Quarterly, Dec. 1906), who remark that the use of electrolytic chlorine manufactured on the spot would, in the

Bull 115, Oct 1907) conclude that with a hypochlorite, disinfection costs less than with copper sulphate. Later American experiments at several centres have proved that 2 to 5 parts per million of av Cl destroy 95 to 98 pc of the bacteria in 2 hours, and that 3 parts are sufficient for the trickling filter effluents tried (Mass Inst Technol 5, 1909; 6, 1910).

The Royal Commission on Sewage obtained results at Guildford which were in agreement with those of the writer (Appendix iv 1910, 87, also *ibid.* 84-171, and Rep. 1908, 195-201)

Sod. hypochlorite solutions are the best means of sterilising swimming baths, they remove from the surfaces growths of alga and fungi which harbour dangerous organisms. (Also see Rideal and Orchard, J. San. Inst. 556, 1906.)

'Ferrochlore' (Duyck) is the name of a treatment with 8 parts per million of ferric chloride and 0.5 part of chloride of lime, which at the same time clarifies water and liberates

hypochlorous acid 1

Hypochlorous acid has been employed as an antiseptic for wounds by Dakin, Daufresne, and Lorraine Smith, and is also known as "Eupid" and 'Eusol'. In these solutions hypochlorous acid is obtained by double decomposition of bleaching powder with sodium carbonate, with the addition of bone acid or sodium bicarbonate. The presence of sodium borate or sodium carbonate in the resulting solutions when freed from the precipitated calcium carbonate ensures the stability of the solution owing to the 'buffer' action of the easily hydrolysable salt.

Chlorine peroxide, obtained from potassium chlorate and sulphutic acid, has been successfully employed in the Howatson-Bergé process at Brussels, Ostend, and Lectoure (South France), for sterilising (previously clarified) polluted waters. The writer found that 20 parts of CIO, per million did not kill B typhosius in a vigorous pure culture in 2 hours, but that 50 parts killed it in half an hour. (See also Reychler, Bull Soc chim [3] xxv 13, Chem

News, 1901, 316)

On a large scale, chlorine and ozone are both in successful use at present for sterilising water. The latter seems preferable for drinking supplies, the former is suitable for effluents. From questions of efficiency as well as cost, both require that the liquid should be previously clarified, and as free from organic matter as

possible, that is, they are finishers

Time as in all disinfections, is an important factor, in an effort to get the work done quickly, it is sometimes forgotten that a longer time is advantageous, and economises the reagent. For rapid sterilisation of a small quantity, as in the field, a larger proportion of reagent is required, and from questions of portability, bromine and iodine have been used instead of chlorine, but are attended by residual products having a taste and physiological effect. These, in the quantity required for dealing with the moderate pollution ordinarily met with, have been proved to be negligible, although, with heavier contamination, the amount of the halogen consumed by the organic matter before a sterilising excess is present, may become in-

jurious in its products. Cash showed that the quantities of chlorine, bromine, and iodine required for disinfection of anthrax and tubercle were nearly in the ratio of their atomic weights

Bromine is a powerful disinfectant, but its is obviously limited by its danger. In 1897 use is obviously limited by its danger Altmann patented a solution of Br in KBr for sterilising water, using 40 parts per million of Br with 5 minutes' contact, and removing excess by ammonia The solution is, however, bulky, and the use of a potassium salt has disadvantages. Braithwaite introduced 'Biomidine,' a dry mixture of sodium or potassium biomido and bromate with sodium bisulphate, which with moisture liberates bromine Schumberg recommended free bromine in thin sealed tubes for the same purpose (Zeitsch f Hyg 1900, 53) in the proportion of 60 parts per million with 5 minutes' contact, removing excess by thio-sulphate (Braithwaite advised 57 parts) Schoder (ibid xxvii 306) and others have stated that this treatment is insufficient to sterilise, and the presence of residual bromides is against the process (see also Parkes and Rideal, Trans. Epidem Soc. xx 1901, Fraser, Publ Health, Sept 1902) It was tried in the Soudan campaign of 1898 20 parts per million of Br sterilises typhosus (in water) in less than half an houi It is more rapidly absorbed by organic matter than iodine

India owes many of its uses to its germicidal action, as in parasitic diseases. Grossich, in 1908 (Centi f Chiruig No 4), adopted the tincture as a cutaneous disinfectant before operations, the surface being previously cleansed by a 1 p c solution of iodine in benzene (Bogden, abid Jan 15, 1910) Instead of the tineture, Chassevant (Lancet, March 26, 1910) suggests the solution in chloroform, as it does not, like the former, cause desquamation, its use is specially advised prior to hypodermic injections (see also But Med J Feb 6, 1909, and Aug 14, 1910, Lancet, April 16, 1910) Solutions of iodine and iodine trichloride, both as field diessings, and enclosed in friable glass compounds as emergency first-aid sterilisers, have been extensively employed during the war (see B. M. S. Jan 2, 1915, Lancet, Dec. 12, 1914) During the Sikkim and Thibet expedition, rodine (in some cases as tincture) followed by sodium sulphite, was successfully employed for sterilising drinking water, and Nesheld recommends triple tablets of (A) include and indate, (B) citrie or tartain acid, followed after 2 minutes' contact by (C) sodium sulphite, and states that used in this way 3 8 to 5 parts per million of free iodine sterilises the organisms of typhoid, cholera, and dysentery. One of the writers, in 1905, confirmed this result as regards distilled water infected with 20,000 per e.c. of B typhosus, the A and B tablets used gave 4.75 parts of 10dine per

Iodine trichloride was introduced by Von Langenbach for sterilising the hands and instruments and for other surgical uses 50 parts per million are required to kill typhoid (in water) in 30 minutes fodine cyanide is said, by Kobert, to be universally destructive to lower forms of life, and is suggested for preserving biological specimens.

Organic substitution compounds of chlorine, bromine, and iodine, as a class, inhibit organisms,

<sup>&</sup>lt;sup>1</sup> For an account of trials at Marseilles of ozone, chlorine, and ultra-violet rays, see Engineering, Jan. 27th and reb. 3rd, 1911.

and may sometimes kill them. The germicidal power of a large number of these has been determined by Bechhold (Zeitsch Hyg. Infect 1909, lxiv 113), he finds that a Br atom gives a greater power than a sulphonic group \*Chloroform\* is often used to preserve perishable specimens and infusions Fairel and Howles (J Soc Dyers, 1908, 24, 109) state that CCl<sub>4</sub> kills typhoid, and that pure CHCl<sub>3</sub> does not kill it, whist 0 62 p c aqueous CHCl<sub>3</sub> kills it in less than 30 minutes

Iodoform was formerly much employed in surgery, and a large number of other rodine compounds have been introduced into medical and surgical practice. Many of them are non-irritant, but their bactericidal power is much inferior to that of dilute solutions of the element Funigation of sick rooms with rodine, sometimes in conjunction with other disinfectants, by burning prepared candles or lamps, has been tried, but apart from the fact that the method is unsatisfactory, no chamber can be disin-

fected while occupied.

The organic iodo compounds owe most, if not all, their germicidal power to the gradual liberation of iodine by the alkaline wound secretions. Iodoform itself gives rise to symptoms of poisoning owing to the too rapid evolution of iodine. Amongst the more important organic iodine derivatives may be mentioned hexamethylenetetramine compounds, chrysoform, iodoformin, phenol, and homologous compounds, aristol, iodothymoloform, curophen, traumatol, isophon, iodoamsol, iodocol, iodised albumen, tannin, gelatine, casein, gluten peptone lecithin, and various iodised oils have been protected under fancy names.

Fluorides, like bone acid, check bacteria, but do not kill them As food preservatives, they are only moderately efficient, and are not innocent physiologically, as they hinder pancreatic digestion Sodium silicofluoride ('salufer ') and borofluoride ('pyricit') have been tried Effront introduced the use of hydrofluorie acid and its acid salts for cheeking injurious fermentation, and J. Brand (Zeitsch. f. Brauw 1904, xxvn 115) states that 0.5 to 1 pc solution of acid ammonium fluoride is largely used for disinfecting rubber hose in breweries (see also Hehner, Analyst, 1902, 173, Richmond, Dep Comm on Preservatives, appendix xxxII, Thresh and Porter, Preservatives, 1906, 87) Hydrofluosilicic acid is the active constituent of 'Montanin' (obtained from by-products in the pottery industries), and 'Keramyl' (about 25 p c H SiF<sub>6</sub>) (J Soc Chem Ind 1904, 34, 1909, 904) Frank (Wasser u. Alwasser) recommended the use of aluminium silicofluoride for water sterilisation. They are stated to have no injurious action on health (Public Health, Oct 1908)

Carbonic acid seems to have a certain amount of disinfectant action, since 'aerated' beverages have been shown to be in many cases stoilised, and CO<sub>2</sub> under pressure preserves food (c<sub>I</sub> J Soc Chem Ind 1907, 1290)

Cyanogen and hydrocyanic acid are more destructive to insects than to lower organisms Funnigation of fruit trees with HCN is extensively practised in America, and is considered better than straying. For greenhouses, zinc capsules containing sodium cyanide are made; they are placed in dilute sulphuric acid,

and while the zinc dissolves the operator has time to retire.

Acids. An acid medium is unfavourable to the growth of most bacteria, and acids generally possess considerable disinfectant power Kitasato found that the growth of B typhosus in nutrient broth or gelatine was entirely prevented by the following percentages of different acids. 0 08 H<sub>2</sub>SO<sub>4</sub>; 0 2 HCl or HNO<sub>3</sub>; 0 28 SO<sub>2</sub>, 03 to 04 phosphone, acetic, carbolic, formie, oxalie, or lactic, 0 476 tartarie, citrie, and malie, 166 tannie, and 27 bone One of the writers has shown that in infected waters. 0 035 p c of H<sub>2</sub>SO<sub>4</sub> kills typhosus in 30 minutes, that in terms of acidity nitro-hydrochloric was slightly more active, and that with tartaric and citric at least three times the amount of acidity was required (Epidemiological Society, Jan 1901) But like other disinfectants, the activity of dilute acid solutions is considerably modified by the presence of added matters, for instance, in 1 pc peptone broth, Sp. cholera is killed by 0.01 pe hydrochloric acid in half an hour, but in 2 pc peptone broth, 004 pc HCl is required

Paul, Kronig, and Sawey (Phaim J 1900) conclude that the germicidal activity of acids generally, depends upon the degree of ionisation in solution, exceptions being HF, HNO<sub>1</sub> and trichloracetic, which excises specific toxic influences. In normal solutions, the three latter killed anthrax spores exposed on gainets in 24 hours, while H<sub>2</sub>SO<sub>4</sub>, HCl, HBi and HClO<sub>3</sub> were less active. Working with more dilute acid solutions, Winslow and Lochridge (Mass Inst. Tech. 1906) have compared the effect on B coli and tuphosus in tap water and in a 1-pc peptone water. With upwards of 10,000 organisms per ccc, sterilisation was obtained by the following percentages of each acid after

In agreement with the results of other workers, larger amounts of each acid are required to disinfect in the presence of peptone, with the organic acids, benzoic and acetic, this diminished activity is not so pronounced. Winslow and Lochridge find that the disinfectant power of the acids is not proportional to their strength in terms of normality, but, in the case of the mineral acids, hydrochloric and sulphuric, to the degree of ionisation of the solution, 99 to 100 pe reduction of B coli or typhosus being effected with either acid at the same concentration of dissociated hydrogen The evidence tends to show that the alteration in ionisation in a dilute acid solution brought about by the presence of otherwise mert substances in solution, as, for example, neutral salts of the acid, accounts for the variation in germicidal activity In practical disinfection, the subject is often rendered still more complex by a further interference -the absorptive effect on solids in Therefore the acidity, as found by titration, does not give the germicidal value of an acid solution unless these disturbing factors are considered.

Metallic derivatives. Warm alkaline leys are the most ancient of disinfectants: potassium and sodium hydroxides are sterilisers in the proportion of not less than 2 to 5 pc, their carbonates in 5 to 10 pc. At 60° a contact of 5 minutes ensures the death of most organisms (Zeitsch. f. Hyg. 1903, 349), hence ordinary soaps have a slight disinfectant value. Strong bline is preservative, but not disinfectant, and the practice, formerly frequent, of washing out milk cans and other utensils with it, is not a safe one. Lode shows (Chem. Zentr. 1902, i. 1122) that 50 pc. salt solution does not kill the spores of common moulds.

Lime, as quicklime, is fatal to bacteria when it comes in contact with them in an almost dry condition, and has been much used where there is a considerable space and bulk of material to be dealt with. It is not safe, however, to trust entirely to the old method of burying infected bodies in lime, as, on disinterring, the live spores may again be diffused, unless a long period has clapsed The disinfecting power of milk of lime and whitewash has been much overrated, as to milk of lime, Liborius stated (Zeitsch f Hyg n 25) that in the proportion of 74 parts per million of CaO, it destroyed typhoid bacilli, and that 246 parts per million were required for cholera organisms, while 2 p c of dry lime was needed for cholera discharges, with in each case 'a few hours' 'contact When lime is added to sewage, a great number of bacteria are carried down, but are not killed, and the supernatant liquid is not sterrlised. Dr Houston (7th and 8th Reports of the Metropolitan Water Board, 1911 and 1912) found that 0.02 pc of quicklime effectively destroyed B coli in raw Thames water in from 5 to 24 hours Zinc chloride, 'Burnett's fluid, formerly in high repute as a disinfectant, is not reliable m its effect, and ranks below copper sulphate and mercune chloride The sulphate has still less energy (R W coeff 0 09)

Aluminium chloride, 'chloralum,' was classed by Miquel between zinc chloride and copper sulphate. Iron salts, especially ferrous sulphate, were at one time in vogue for sanitation, but are ineffective

Permanganates and manganates were first introduced as Condy's red and green fluids oxidisers generally, they are largely consumed by otherwise mert matters before attacking organisms, and as complete disinfection cannot be ensured unless an excess of reagent remains, evidenced by a pink colour, which is not always easily visible owing to the brown oxide of manganese produced, their use may be very costly and its execution frequently imperfect writer carried out experiments in street-watering of two similar areas of ordinary soiled asphalt roadway (a) with water alone, (b) with permanganate solution 1 in 5000 (six times the amount then customary), and examined the liquid from the surface. The permanganate was almost immediately decolourised (b) was nearly inodorous, on keeping became much less foul than (a), and the reduction in the number of organisms was 96 pc, but the survivors included a large proportion of the dangerous forms (Rideal's Sewage, 1906, 117) For polluted water Rosenau recommends addir; permanganete drop by drop till the pink colour

persists for 24 hours. 'Pinking' of wells was many years ago adopted by Hankin in India as a precaution against cholera Permanganates, used in various ways, are still being patented, chiefly for water purification.

Chromic acid, although a powerful oxidiser and instantly coagulating albumen, is excluded by its cost and poisonous and corrosive nature from the list of useful disinfectants or of pre-

servatives.

Arsenic, like cyanogen, has more effect on higher than on lower forms of life, and is the basis of valuable insecticides, such as the sheep-dip solutions of arsenious oxide or sulphide in soda, frequently associated with tar products and mootine. See Chemist and Druggist, June 11, 1904, Rep. Dept Comm B of Agric, leading to the Sheep-Dip Act of 1903, and Quibell, J Soc Chem Ind 1907, 1266 The copper compounds, Paris green' (acctorisemite) and others, are used for spraying or dusting trees, combining the actions of arsenic and copper Several organic arsenic compounds have been introduced as medicinal parasiticides (see Lancet, Brit Med J, &c, 1910 and onwards)

Arsenicals and similar organic metallic compounds are frequently selectively germicidal Salvarsan, p-p-dihydrosia, m-m-diamino arsenobenzene has a strong antiseptic action on anthrax, eryspiclas, and glanders, as well as syphilis. The selective action is more pronounced in scrum (Zeitsch f Hyg u Infeht Krankh 1914, 77)

Among the more important arsenicals may be mentioned .—

Salvarsan

Cacodylic acid and its salts
Atoxyl sodium aminophenylarsenate
Asyphil mercury ammophenylarsenate
Arrhenal methyl disodium aisenate
Aisacetin p-acetyl aminophenyl sodium
aisenate
Sommi sodium aisenate

Soamin sodium arsanilate Neosalvarsan sodium 3 3-diamino-4 4'-dihydioxy arsenobenzene methanal sulphoxylate

Some metals in the free state are antagonistic to germs. Dievert states (Compt rend 136, 707) that agitation with granulated zinc kills B typhosus and coli in a few hours, and Baeyer's method of treating polluted waters with zinc-dust, charcoal, and lime causes, according to Margosches (Leip: Monats Textilind 1901, vi), practical sterilisation Rankin (Proc Roy Soc 1910, B, 82, 78) shows that clean strips of Al, Zn, or Cu, in air-free water, do not reduce the number of col, whilst when air is bubbled through there is a great reduction after 1 hour with Cu, peroxide of hydrogen was produced, but the amounts of this and of the metal dissolved were too small to account for the germicidal effect, which is ascribed to the metal and oxygen together Metallic iron has long been used for purifying water, as in Anderson's process (J. Soc Arts Feb 14, 1896), in this case, galvanic action and the oxides formed come largely into play, but Frankland proved that the metal itself was, to a certain extent, bactericidal Old Hindoo writings direct water to be kept in vessels of copper; among modern observers,

Nageli, Galeotti, and Israel and Klingman hold that there is formed a colloidal solution which renders the water toxic to many algae and bacteria. In 1904 the U.S. Dept. of Agriculture reported that I sq. cm. of bright copper per 100 c.c. of water was sufficient to exterminate Uroglena and some forms of Spirogyra, and Kraemer showed that the same treatment destroyed colon and typhoid bacilli in 4 hours, whilst colloidal copper was quickly fatal to these organisms For household purification, he commended the use of strips of copper, about 3½ sq inch to each quart (2 sq cm to 100 c.c.), immersed in the water for 6 to 8 hours ln a similar way, Rideal and Baines (J. San. Inst. 1904, 594) obtained sterilisation of typhosus, coli, and S py aureus in less than 24 hours Bassett Smith (J Prev Med July, 1904) found that in a bright copper vessel, B typhosus was still living at 12 hours, but was dead at 24, and that of ordinary water organisms, 1020 per cc at first, only 8 per ce (none of them liquefying) were left after 24 hours He concluded that clean iron or zinc was nearly equal to copper in first effect, but soon lost the power by oxidation

Copper salts have a distinctly poisonous action on lower organisms, and are now used in many places to retard algae development early in their seasonal growth in water reservoirs Kroncko considered cuprous chloride to be the most active of the salts he treated Elbe water containing 40 to 50 thousand organisms per c c. with 50 parts per million of Cu Cl<sub>2</sub> and 20 parts of ferrous sulphate, allowed 6 hours' contact, then agitated with 10 parts of lime After settling and filtration through sand, the water was sterilised, clear, and colourless, and free from iron and copper Schumberg (Chem Zentr 1900, n 203) corroborated the sterility at the end of 6 hours The efficiency of soluble cupite salts is generally dependent on their percentage of copper (Green, Zeitsch f. Hyg 1893, 495, Rideal and Baines, lc), but the sulphate is commonly used as most convenient For disinfecting sowage effluents (and inferentially for ieservoirs), American investigations conclude that copper sulphate 'is not so efficient as chlorine compounds, is more seriously affected by carbonates, and is much more expensive' (U.S. Geol Survey, Water Supply Paper 229, 1909, 32; also see Bull U.S. Dept. of Agric No 100, 1906)

Disinfection of excreta and morbid products, even with considerable quantities of copper salts (e g 5 to 10 pc of the sulphate), is not For killing agricultural parasites, their use is well known, including that of the sulphate for soaking soeds and against potato blight, also verdigris (acetate), 'Paris green' (arsenite), copper-lime-sugar and copper-soap washes for trees, and Bordeaux mixture' (copper sulphate and lime) The last named was introduced for vines, but has been since extended to other crops. In reference to the general practice of employing the metallic compound in the precipitated or solid form, instead of in solution, the main points stated are (1) that, in the former way, it is not liable to injure the plant or contaminate its tissues; (2) that the copper should remain as an external coating, because the spores germinate on the surface: (3) that uncertainty of composition

and inequality of application are overcome by certain piecautions and definite prescriptions. See British Board of Agriculture leaflets 23 and 225; the latter (May, 1909) gives a method of preparing and using Bordeaux mixture: 'for a 3 pc solution, 3 lb copper sulphate and 2 lb. freshly burnt quicklime to 10 gallons of water. See also J Soc Chem Ind 1896, 332; 1907, Chuard Compt 1end 1911, 152, 532 (ibid 1910, 150, 839), estimating that 12,000 tons of copper are thus consumed annually in France, expresses anxiety as to the result of its accumulation in the surface soil, and with a view to reducing the quantity states that a half pe aqueous mixture of the oxychloride is as adhesive and effective as the usual 2 pc paste of the Cupile sulphate impregnation for preserving or 'kyanising' timber has been superseded by creosote oils, since the former washed out of the wood. 'Microsol,' sold as a soluble disinfectant for stables and drains, contained 75 p.c of copper sulphate with sulphocarbolate and some free sulphur dioxide.

Mercury -Mercuric chloride, 'corrosive sublimate,' has long been recognised as one of the most powerful of disinfectants, and a 1 per 1000 solution was the earliest standard for companisons Apart from cost, points limiting its utility to special purposes are: (1) the poisonous effect on higher animals and plants; (2) its precipitation by so large a number of substances, such as hard water, alkalis, and numerous salts, metals, sulphides, and many organic bodies, causing its action to be liable to great variations and inconveniences often form a pellicle over organisms without killing them, and it is inapplicable to the disinfection of sputum, excreta, and the like, from its producing a coagulum which prevents further Sodium or ammonium chloride is penetration sometimes added to increase the stability of the aqueous solution, but considerably diminishes the germicidal power The Local Government Board recommended for disinfecting purposes  $HgCl_2$   $\frac{1}{2}$  oz , HCl I fluid oz , aniline blue 5 grs (a colouring for safety), water 3 gallons (I in 962)

Kionig and Paul in 1897 showed that mercury salts followed a general rule that the germicidal power depends on the metallic ion, and is in proportion to the degree of ionisation, so that a 1 in 500 solution of Hg(1, is much less than twice as active as 1 in 1000 moreover, the chloride is more active (in equivalent solutions) than the bromide, and 4 times more active than the cyanide, which is almost non-ionised tions of the orycyanide are used in surgery, are distinctly alkaline, and only slightly precipitate albumen, a strength of 1 in 1500 is antiseptic. does not really attack instruments, and is not Mercuric iodide, dissolved in potassium ırrıtant iodide, is a powerful disinfectant, and is made up as 'iodic hydrarg' It is less affected by albuminoids and less irritant than the chloride, and is incorporated in a disinfectant soap. Mercury-zinc cyanide, 'Lister's antiseptic,' has the disadvantage of being of variable composition. A great number of organic mercurial compounds, introduced into medicine and surgery, trace their main effect to an antiseptic or garmicidal action 'Sublamin,' mercuricethylenediamine sulphate (43 p.c. Hg), is easily

soluble in water, is much less irritant than mercuric chloride, does not coagulate albuminous solutions nor precipitate soap, and is a valuable hand-disinfectant 'Protectyl' contains about 96 pc water, 1 pc salicylic acid, 0.2 pc.

mercury, and about 3 p c gelatin

Sodium hydriodic mercurobenzoate was carefully investigated as a disinfectant by Schreller and Schranth (Zeitsch f. Hyg u Infect Kranh 1911) They found that the germicidal powers could be enhanced by the introduction of halogens, methyl, methoid, or a second hydroidic mercury group into the nuclous, whilst a corresponding depression was caused by sulphonation or the introduction of an amino grouping, sodium oxymercury orthonitrophenolate 'Mercurophen' is said to have a carbolic acid coefficient by the R W method of over 10,000, to be less toxic than mercuric chloride, and to exert less than one-quarter of the precipitating power which this salt has on blood scrum (S Schamberg, J Amer Med Assoc 1917)

Silver nitrate stands next to mercuric chloride in germicidal power, and has similar limitations in its use, with the additional one of being precipitated by chlorides. The writer found that 1 in 1000 killed B coli and S py aureus in 24 hours, but a small quantity of chloride or organic matter prevented the effect Among other silver salts are the citrate, 'Itrol,' recommended as a non-irritant antiseptic dusting for wounds (Pharm Zentr 38, 460); 'Actol,' the wounds (Pharm Zentr 38, 460); 'Actol,' the lactate, for antiseptic injections 'Tachiol silver fluoride, easily soluble, and a powerful non-toxic bactericide specially useful for the urmary tract (1 in 1000 to 1 in 5000 is suggested by Paterno and Cigolani for sterilising water in a concentration of 1 in 400,000. Chiefly with the object of avoiding irritant action, incompatibility with chlorides, and coagulation of albuminoids, a large number of organic preparations of silver have been introduced, such as 'argentamine' (ethylenediamine-silver-phosphate), and the proteid compounds 'argonine' (casein), 'argyrol' (gluten), 'largin' (albumen), and 'protargol' (protein) A report to the British Med. Assoc in 1906 gives the time in minutes required to kill S. py aureus by the preparations used as · silver nitrate (1 to 2 p c), 2 to 5; protargol (2 to 4 p.c), 3 to 5; largin (10 pc), 2 to 5; argonine (5 pc), 3 to 6; whilst argyrol and 'collargol' (colloidal silver, J. Soc. Chem. Ind 1903, 315) had very little bactericidal power (Lancet, 1907, 1. 675). Many of these are destructive to gonococci and to ophthalmic disease organisms.

Osmic acid was found by Koch and Klein to be powerfully bactericidal; it is very poisonous and a strong oxidiser. The former stated that an extremely dilute solution of potassium auricyanide, 1 part  $Au(CN)_3$ , in 2 millions, checked the growth of B tuberculosis

Chick and Martin (J of Hyg 1908, 634) observe that for spores, metallic salts rank highest as germicides; with mercuric chloride, the reduction of efficiency caused by blood srum is much greater than with phenol.

## ORGANIC COMPOUNDS.

Compounds related to the alcohols. It has long been known that 'wood spirit,' crude

methyl alcohol, in a dilution as low as about 5 p.c., can kill insects and most micro-organisms, and preserve perishable organic materials owing to the tar products that it naturally contains. The alcohols, by themselves, are only efficient in a very much higher strength by coagulating albumen and (when absolute) by withdrawing water Wirgin (Zeitsch Hyg 1904, 46, 149) has tested methyl, ethyl, butyl, and amyl alcohols with anthrax spores, and S py aureus, and concludes that the disinfecting power is low, that it increases with the molecular weight, and that there is scarcely any action on dry spores It has been suggested to add alcohol vapour in steam disinfection, but Seige (Chem Zentr. 1902, 1, 130) finds no advantage Hand disinfection with alcohol is not reliable (Goenner; Harrington, Boston M J. May 21, 1903), although Hansen found that epidermal bacteria, e.g eczema, ere, when moist, destroyed in one minute by absolute, and in most cases by 50-60 p c alcohol (Centr Bakt 1907, 466) This statement is supported by A Zabludowski (Deut. Med. Wochenschrift, 1911, 405), who advised the addition of 5 pc of tannic acid. Sterility of the hands could be obtained by 2 minutes' immersion Glycerol in strong solutions (25 pc and upwards), is antiseptic, but in weaker ones it rather promotes the growth of bacteria Allyl isothiocyanate, mustard oil, has figured in a number of patents, and is capable of killing many organisms, but not economically.

Formaldehyde is found in commerce as the 40 pe solution 'formalin' or 'formol'; it is antiseptic and germicidal, and is official in the German, Austrian, Belgian, United States, and Formalin, diluted Japanese pharmacopæias 10 times, is used for embalming and for preserving bodies for dissection and museum specimens, but for antisepsis generally, a much weaker solution is efficient. The Board of Agriculture (Dec. 1906) found that fruit of all kinds immersed for 10 minutes in a solution of 3 pints formalin to 10 gallons water (= $1\frac{1}{2}$  p c CH<sub>2</sub>O), then allowed to drain and dry, keeps 10 to 21 days longer than when untreated, and that one lot of liquid can be used for a number of batches S Rideal and Dr Foulerton have . proved that 1 in 50,000 of formaldehyde (=1 in 20,000 of formalin) suffices to keep milk sweet for 24 hours, even in warm weather, without injury to health (Pub Health, May, 1899; Lancet, 1899, 1427, 1571). Apparently because experiments with larger doses showed effects on nutrition, the British Dept. Committee on Preservatives, in 1901, recommended 'that the use of formaldehyde or formalin or preparations thereof in foods or drinks be absolutely prohibited' And yet its agency in the preservation of food is as ancient as that of salt. The disinfectant and preservative power of woodsmoke is in part due to formaldehyde, which is present on the surface of smoked provisions,1 and was found by Trillat in amounts varying from 10000 to 100000 of the weight of the substance consumed, in smoke from wood and cellulose In tobacco smoke, he found 0 05 to 0 12 pc., and in soot from house chimneys, 0.28 to 0 35 p.c.

<sup>1</sup> Perrier finds zobon to zoobono in bacon, ham, sausages, and herrings; remarks that a strict regulation against formaldehyde would forbid these foods; and contends that a limit should be fixed instead of prohibition.

as paraformaldehyde Typhoid and cholera organisms were killed by products from the combustion of 2 grams of sugar passed into a 12 litre vessel, and by burning 4 kilos. of sugar in a room of 100 cub metres 'even very resistant organisms were destroyed.' (Rouguier has made this the basis of Fr. Pat 360476, 1905) With straw, the best results were obtained by burning it in a heap of alternate dry and wet layers using 18 kilos, of straw in a room of 140 cub. metres (4944 cub feet), B. coli and diphtheriae were destroyed after contact with the smoke for 12 hours; the room temperature rose to 35°, and up to 2 grams of formaldehyde were generated per kilo of straw (Compt rend 138, 1613; 139, 742, 140, 797, 141, 215; 150, 339)

H Will (Zeitsch. Brauw. 1905, 28, 330, 347) gives formalin a very high place among brewery disinfectants. He notices, like other observers (Kingzett, Slater and Rideal, Lancet, April 21, 1894), that it is more powerful against bacteria than against yeasts and mould fungi. Limits recorded as preventing development are sareina and bacteria, 0 003 to 0 031 pc, yeasts, 0 007 to 0 062 pc; moulds, 0 031 to

0 125 pc.

Advantages in formaldehyde disinfection are. (1) that it can be easily applied in the state of gas or vapour for fumigation, in the liquid condition as spray, wash, dipping, or in higher dilutions as an antiseptic, or in the solid form as its polymers, compounds, or mixtures; (2) that unlike mercuric chloride and many other agents, it is not thrown out of action by albuminous matter or by most chemicals, (3) that it is effective in strengths which are not irritant or poisonous, and does not injure fabrics or metals At quarantine stations, large quantities of bulbs, roots, nuts, fruits, &c, coming from plague or cholera-infected regions are disinfected by immersion in a 5 p c solution of formalin, which does not injure the food value and much retaids decay. In the Linley process, meat is treated with formaldehyde vapour, 'I oz formalin per cub foot of space in the chamber,' the gas after a time removed by a fan, and the meat frozen for shipment Buchanan and Schryver (L G.B Food Report, No 9) state that the gas commonly penetrates for about 20 mm under a thin layer of connective tissue, that the amount absorbed often reaches 1 in 3500, that it is reduced or removed by boiling or roasting, but that grilling seems to make it penetrate further

In surgery, formaldehyde and its preparations have been of wide service. Amongst the more important may be mentioned the following formaldehyde and formaldehyde ammonia (hexa-

methylene tetramine) compounds:-

With formaldehyde
Inorganic compounds Glyceroborate
or boroform
Alumnum sileate or dreiaform

Aliphatic derivatives Iodoform or eteasodoform Acetamide or formicin With hexamethylene tetramine
Triborate or
borovertin
Dichromate or
chromoform
Acid phosphate
or hexanitrine
Dibromoduodo
chrysoform
Sodium acetate
cystopurin
Iodoform iodoformin

With forms	aldehyde	With hexamethy- lene tetramine
Aromatic deri-	Phenol	Resorcinol
vatives	Resorcinol	Guaiacol
	Guaracol	Salicylates
	Thymol	Salicyl-sulpho-
	Cresols and	nates
	potash or	
	tysoform	
	Tar and pitch	
Carbohydrates	Lactose	Mılk sugar
January and January	Dextrin	sugar
	Milk sugars	
Miscellaneous	Starches	Silver albumin
	Casem	Camphorate
	Gelatin	
•	Dextrin Milk sugars Starches	Ü

Geronzi found that the addition of 5 pc of sodium carbonate to the 5 pc formalin which he successfully used for obstinate ear disease mereased the tolerance and enhanced the germicidal power (Arch. Ital. di Otologia, 1903).

Formaldehyde antiseptic powders for dressing are 'Amyloform' (starch), 'Proteol' (casein); 'Steriform' and 'Sterisol' (lactose), 'Glutol' (gelatin) These, especially the last, when moistened as in a wound, slowly regenerate formaldehyde. Formalised gelatine is now largely used with success instead of surgical collodions Formamint tablets, 'for infectious diseases and as a prophylactic,' are said to contain 0.01 gram of ('H<sub>2</sub>O in each, combined with milk sugar (Eng. Pat. 2672, 1906), Pharm J. 1907, in 838) M. Jones states that with B. diphtheriæ the R. W. coefficient is only 0.01 as against 0.30 for cyllin pastiles

Paraform, paraformaldehyde, trioxymethylene, or 'triformal,' is a solid polymer, only slightly soluble in cold water, and dissociated into CH<sub>2</sub>O gas on heating. It was introduced as an internal antiseptic and for disinfecting instruments, and said to be as active as β-naphthol, but its chief use is for evolving formaldehyde either alone or in mixture, for which a large number of methods have been proposed, many of them patented. Mixtures with Na, Ba, or Sr peroxide, when brought into contact with water, yield formaldehyde and hydrogen peroxide. It is stated that 'Autan' contains I part of paraform to 2 of BaO<sub>2</sub> (Lancet, 1908, 1–139), and that 50 grams mixed with water kills all organisms in a cubic metre of air bubbled through it (Fr. Pat. 366605, 1906).

Room disinfection with formaldehyde cannot be economically effected by simply evaporating the solution, under ordinary circumstances, only a portion of the substance is volatilised, the remainder polymensing and remaining behind as a solid, while reliable disinfection requires a definite large volume of gas to be produced in a short time. For this object, very numerous methods and apparatus have been devised, which may be grouped as follows:—

been devised, which may be grouped as follows:—

A. Direct production of CH<sub>2</sub>O gas, by passing methyl alcohol vapour and air over hot surfaces of platinum (Hofmann) or partly oxidised copper (Loew). The various lamps on this principle have had the faults, among others, that the oxidation is incomplete and inconstant. Kenv ood found that 1½ litres of methyl alcohol were required to disinfect a room £ 2000 cub. feet.

B Heating the solution (formalin) under pressure was used by Trillat, calcium chloride being added to raise the boiling-point In his autoclave, 1 lb formalin was required for 1500 cub feet By this method, Kenwood obtained sterilisation of diphtheria swabs, and S. Rideal with various articles infected with B typhosus, diphtheria, coli, S py aureus, and anthrax spores, found that in 24 hours all were sterilised, whilst fabrics, furniture, metals, and leather were (See also J R San Inst 1903, 508) not injured

C Formalin, mixed with glycerol, is distilled at nearly the ordinary pressure, as in the Trenner-Lee, Lentz, and Lingner apparatus The latter, according to the Russian National Health Society's Journ 1900, was mainly instrumental in extinguishing the plague at Astrachan, in 1899 Klein (report of 1902), by 3 hours' exposure in a sealed room with the Linguer generator, sterrised anthrax spores and tuberculai sputum Houston and Newman also report favourably (Practitioner, Sept. 1902)

An important point to notice is that in method (B), the CH<sub>2</sub>O is chiefly liberated at the beginning of the operation, in (C) at the end, mixed in the latter case with steam and glycerol spray, which deposits as a film on the surfaces, and assists in the penetration and disinfectant

D Formaldehyde has also been used in conjunction with acetone (Eng. Pat. 10398, 1908), SO<sub>2</sub> (Fr Pat 379998, 1906), alcohol, and

some fatty acids

E Evolution by mixing with other chemicals Dehydrating agents disengage very little CH,O gas from formalin, since most of it polymerises With quicklime, S Rideal has only obtained 8 p c of the theoretical yield (cf Eng Pat 8259. 1899, Fr Pat 323041, 1902, and U.S. Pat 790468, 1905) Carteret observes (Compt. rend. 1908, 146, 819) that 1 part formaldehyde and 2 parts bleaching powder added to 3 parts water evolve 70 p c of the theoretical yield (D R P 217941 of 1908) Potassium primanganate behaves similarly, generating great heat, U.S. Pat 885223 relates to a mixture of this Major Munson (Trans Inter Congress Hygiene, Washington, 1913, 756) has obtained 86 p c of the formalin vapoused, and S Rideal (Blackpool Congress, 1914) used a paper bag for sterilising clothes, using 40 grams per-manganate to 100 c c formalin. The action of The action of peroxides has been already mentioned

F. The simplest process is heating paraform by a small flame (avoiding ignition), when it melts and is resolved into CH<sub>2</sub>O. The 'Alformant,' or Schering lamp, uses 1-gram tablets placed in a perforated cup, and it is directed to use 10 tablets per 1000 cub feet with 6 hours' exposure S Rideal found that this quantity killed B coli, typhosus, diphtheria, and S py aureus in 20-24 hours, and that double the quantity in the same time killed moist, but not always dry anthrax spores He recommended spraying with  $\frac{1}{2}$  pc solution of formalin before using the lamp, as the gas is evolved with insufficient moisture. The latter defect is remedied in the 'hydroformant' lamp, in which 12 ozs. of water in an annular vessel is simultaneously evaporated. Rosenau considers this method of generating CH<sub>2</sub>O useful fc the disinfection of closets and small enclosures of in this way.

less than 100 cub feet, with not less than 12 and preferably 24 hours' exposure, and not less than 2 ozs. of paraform per 100 cub feet (about 2 grams per cub metre). Klein, Houston, and Gordon (London County Council, 1902) record that with 23 grams of paraform per 1000 cub feet, B typhosus, diphtheriæ, pyocyaneus, and S py aureus were killed in 5 hours, but not anthrax spores nor (with certainty) tuberculosis in sputum. It will be noticed that the time is not even that given in the directions issued with the lamp, and the humidity and temperature of the room are not stated Allan, Newman, and Cribb had previously obtained generally satisfactory results with 10 grams paraform per 1000 cub feet, under moist conditions (Brit Med J Aug 13, 1898) Kenwood's experiments pointed to an average of 25 grams per 1000 cub feet being necessary Werner and Bonhoff (Berl Klin Woch 1904) find that tubercular sputum is certainly disinfected by 5 grams per cub metre (141 grams per 1000 cub. feet) acting for 7 hours, which is double the quantity Flugge first recommended In Breslau a large number of formaldehyde disinfections are carried out for scarlet fever and measles. and the disease has in no case recurred in the same room

Spraying with the solution should be the invariable practice except with the large CH,O generators, which are capable of filling the room also with steam and spray When spraying is used alone, there is a danger of not penetrating into crevices, and the solution must be of higher strength, Dr Mackenzie's extensive experience in the disinfection of houses and hospital wards, proved that 1 p c CH2O (4 ozs formalin per gallon) is attended with success, he adds 5 ozs glycerol per gallon of formalin to prevent too-rapid drying Thresh and Sowden in 3 to 4 hours sterilised diphtheria, typhosus, cholera, pyoq aweus, and produgosus with ½ p c CH,O, but pyocyaneus (on whitewash) only with 2 p c, they, therefore, recommend the latter strength

Where the space has to be occupied soon afterwards, any residual formaldehyde can be neutralised by volatilising ammonia The product, under the name of Urotropine, is a serviceable antiseptic in cystic affections, and is administered to typhoid 'carriers' to destroy the bacilli of the disease in the urine Urotiopine is the basis of a large number of antiseptic

preparations (see above)

Disinfection of excreta is attained by mixing with 3 to 5 pc of formalin and keeping in a closed vessel for at least an hour Rosenau states that faces are rendered sterile at the end of 10 minutes by an equal volume of a 4 pc solution of formalin Houston prescribes 1 to 2 pints (according to bulk) of 5 p c formalin, acting for at least an hour (Practitioner, Sept. 1902).

Formaldehyde, as an insecticide, is much inferior to SO2, although Brough (J. Mass. B. of H. March, 1898, 51) observed, in his disinfections with the former gas, that all the flies were invariably killed, and generally the bed-bugs. It

13 an excellent deodorant.

No acidity is produced by continuous spraying or distillation of formaldehyde, therefore it is not readily converted into formic acid

Formic acid.—We have discussed the germicidal action of acids generally in an earlier section of this article. Formic acid has this power to a considerable extent, and is a strong antiseptic Kitasato's results, as summarised by Horrocks, gave acetic acid a slightly higher activity in nutrient media, stating that with B typhosus the amounts pc in cases of (1) growth, (2) growth restrained, (3) no growth, were respectively formic acid, 0 22, 0 278, and 0 356, acetic acid, 0 2, 0 225, and 0 3, with Sp cholerw, formic, 0 11, 0 167, 0 22, acetic, 0 1, 0 153, 02. But very different results are obtained in water and most organic solutions. The writer has found that typhosus is killed by 0.5 p.c. of formic acid in less than 15 minutes and by 0.1 p.c. in about 30 minutes, and in 1907 he made the R W typhosus coefficient of formic acid many times higher than that of acetic also found the preservative action to be higher with vegetable substances, I pe of formic acid was equal in effect to 5 pc of acetic (time of trial, 2 months) Raw fish were mounted in 053 pe forme, in 5 pe acetic, and in 03 pc boric, acids, heated for 20 minutes to 80°, and the jar closed with cotton wool, in a week, the last was brownish, disintegrated, and uncatable, though not distinctly putrid, while the first two kept sweet and of natural characters for 3 months Experiments with bread-pulp infected with a mixed mould-growth proved that 01 pe of forme acid entirely inhibits the growth for several days, even under the most favourable conditions of culture But in the destruction of the spores, formic and is less effective than formaldehyde Lebbin (Chem Zert 1906, 30, 1009) effectively preserved different classes of foods by 0.15 p  $\epsilon$  of formic acid, and others have proved that in the quantities mentioned above it is physiologically harmless, the taste is more pleasant than acetic acid, and the odour is not noticeable B H Smith (J Amer Chem Soc 1907, 1236) preserved vegetables with formic, with salicylic and with benzoic acid, in unprotected jars Under conditions in which the untreated samples became sour and mouldy in 2 days, 01 pc formic acid preserved them for 7 days, 0 3 p c for 12 to 18 days, 05 pc for 25 days, 07 pc and 1 pc for 45 to over 85 days, and 2 pc for over 85 days He states that 0 1 p c of benzoic acid kept his sample for 85 days, whilst with the same quantity of salicylic acid it was sour in 9 days. In ordinary preserving practice, as we have seen, the articles would have remained good for the longer time with the smaller quantities of formic acid, which, even if it must be applied in a somewhat higher proportion, is from physiological and physical reasons preferable to salicylic or benzoic The chief formic acid preservatives used in commerce, mainly for fruit preparations, are 'Werderol' and 'Fructol' (10-14 p.c. formic acid, '1-1} p.c. of the liquid to be added'); and 'Alacet' (made synthetically from CO and NaOH at the Nitritfabrik, Kopenick, about 50 to 60 pe formic acid, 'use 03 p c. of the liquid') The result in the three cases would be about 0 14-0 18 p c of the acid In an investigation of these articles by Croner and Seligmann (Zeitsch. f. Hyg. 1907, 56, 387), they find that inhibition of moulds, yeasts, and acid-forming organisms

begins at 0 15 p c formic acid, that sterilisation is effected in 24 hours by 02 pc., and in 10 to 30 minutes by 1 p c

Only the free acid is active against organisms. although the salts do not favour the growths as do the alkaline acetates Sodium formate helps the solubility of many antisepties without lessening their power, therefore figures as an adjunct in a number of patents

Acetic acid is one of the most anciently used of preservatives, 'aromatic vinegar,' a more or less concentrated acid containing essential oils, had a partially-justified reputation against infection. The writers find that  $B \ coli$  is killed by 5 pc HA in 5 minutes, by 25 pc in 15 minutes, while with 05 and 01 pc it is alive after 40 minutes Pyroligneous acid, or crude wood vinegal, owes it's antiseptic power chiefly to the presence of creosote and formaldehyde

Acetyl peroxide and benzoyl-acetyl peroxide are stated by Freer and Novy (Amer Chem J 1902, 27, [3] 161) to be strongly germicidal, since solutions corresponding to 0.037-0.074 p.c. of the former, or 0.056-0.112 p.c. of the latter, =0 005-0 01 pc of active oxygen, destroyed within a minute all known disease-producing bacteria, and even spores of B mescutericus, which are not killed by 5 p c phenol, whilst  $H_2O_2$  solution containing 0.05 p c of active O was without action on many bacteria even in Benzoyl peroxide had no oxidising action, and was without effect on bacteria solution of acetyl peroxide was introduced under the name 'acetozone,' but the title is now applied to a more convenient and stable mixture of the benzoyl-acetyl compound with infusorial earth, said to be useful in typhoid, dysentery, and cholera (Lancet, 1904, n. 1160, Brit Med J 1907, 1 634)

Propronic acid has been tested comparatively by Duggan (Amer Chem. J 7, 62) with the highly resistant B subtiles He gives as the strengths necessary for killing tormic acid, 7 pe; acetic acid, 9 pe, propionic acid, 12 pe (numbers proportional to the molecular weights). According to A C Jordan (Practitioner, Sept 1902, 297), 01 pc of butynic acid in broth tubes infected with vigorous B coli or typhosus caused them to remain sterile, S pyog aureus required 0.2 p.c. Valeric acid is a teeble antiseptic, but has been introduced along with a little crossote, as an internal antiseptic called 'geosote

Oleic acid, the fats, 'Lanolin,' &c, have but slight antiseptic power in themselves, but when applied to the skin may prevent infection by the exclusion of germs Reichenbach (Zeitsch f Hyg u Infect 1908, 59, 296) showed that the alkali salts of the palmitates had the strongest bactericidal action of the soaps investigated. The potassium salts of the saturated fatty acids are comparatively strong bactericides, but those of the unsaturated acids, with the exception of elaidic, are not Vicario, however, observed that the fatty matters sometimes aheady contain germs, and Baldas (Giorn R S Ital d'Igiene, Feb. 1901) proved that B coli and typhosus, S pyog aureus and albus, retained their virulence in oils for 2 months; therefore ointment bases require to be s'errlised by heating to 100°, or preferably to 120°, as various bacilli survive ir oil far longer than in aqueous solution. In fatty media antiseptics and disinfectants, as a rule, are much less active than in water, hence the ineffectiveness of carbolised oil as shown by Koch and Breslauer Lanoline and cold cream contain water, so can enable agents in aqueous solution to come in contact with micro-organisms Some metallic cleates are parasiticide. cupric cleate in ringworm and favus (Lancet, 1907, 1510); mercuric cleate for pediculi, zinc cleate is said to cure chronic eczema.

Vegetable acids have the general power of inhibiting bacteria which prefer a neutial to an acid medium, but their effect is much less than that of mineral acids, and their solutions quickly become mouldy in warm weather. Citric acid was formerly recommended for sterilising water: Dr. Christmas in 1892 stated that cholera organisms were killed by 0.08 p.c. and typhoid by 0.10 p.c. Kitasato's figures for tartaric, citric, and malic acids added to neutral media containing typhosus are in p.c.'s growth, 0.338; growth restrained, 0.384, no growth, 0.476. Succime acid is slightly antiseptic. 'Alphogen' or 'Alphozone,' succinyl peroxide, is said to be a powerful germicide (Lancet, 1905, 1.367).

Aromatic acids.—The introduction of —COOH groups or aliphatic acid radicals into the benzene ring yields acids of relatively low antiseptic power, increasing with the molecular weight of the extense acid.

the entering acid Benzoic acid is strongly antiseptic in solution and vapour, and to a rather less degree in its soluble salts  $\,$  It dissolves in about 400 parts of cold water, and the saturated solution kills B typhosus in a few minutes  $\,$  When molecular proportions, i e sodium benzoate 0 026 p.c. potassium benzoate 0 029 p.e., benzoic acid 0 022 p.e., are separately mixed with milk, the writer observes that all retard the souring, the acid more than its salts, but the effect comes to an end sooner than with inorganic salts like the fluorides, since benzoic acid is itself decomposed by some organisms (Analyst, 1907, 32) Not being poisonous, it has been much used as a food preservative, particularly in countries where salicylic acid was forbidden. Following a report of the Referee Board of the US Board of Agric that doses of benzoates under 0.5 gram per day were not injurious to health, and that even 4 grams per day did not act as a poison, the US. Board, in Pamphlet 104, 1909, have announced that they will make no objection to the use of sodium benzoate in food, provided it is plainly labelled on each package, both as to presence and quantity. The taste and odour are difficult to mask. It has long been used as an antiseptic in surgery, e g. in 'Friar's Balsam' (tinct benzoini co) Benzoic aldehyde is official in the US Pharmacopæia, and in the form of commercial oil of bitter almonds owes its parasiticide power in ointments mainly to the hydrocyanic acid it contains, which, of course, necessitates care in Benzoyl-sulphonic-imide, 'Saccharin' 'Gluside,' has some preservative power, and has been given internally to stop decomposition of urine in cystitis, but its use for sweetening is less on account of this power than because it

is itself unfermentable.

Salicitic acid.—The saturated aqueous solu-

tion contains 1 in 500. tested with typho pyog., aureus, and anthrax, Westcott found t in 3 hours only the former was killed. A food preservative, it is about equal to benz their relative activities varying under differ circumstances Its physiological effect is n distinct than that of boric or formic acid formaldehyde in the small quantities requi but there is no clear evidence that it can injury to adults if the amount is limited British Depart Committee's suggested rest tion is that it 'be not used in a greater propor than 1 grain per pint in liquid food and 1 g per lb in solid food,' or 0 0114 and 0 014 respectively, which practically would amoun a prohibition, since moulds and ferments only reliably inhibited by 0 1 pc, the amo commonly employed, though often exceed Addition of the acid to foods is forbidder France, Austria, and some other count Traces are present in a large number of fr (Analyst, 1903, 149). Dr Linsa G. Andei used extensively a saline gelatined salicylic : paste containing 2 p c of the acid as a wo dressing with satisfactory results Compoun Compoun with an equal weight of boric acid it is used as a first dressing under the name Borsul 'Salol' is phenyl salicylate, an ternal antiseptic which is decomposed in duodenum into phenol and salicylic a According to Lowenthal, when mixed a pancreatic juice, it rapidly kills Sp cho (Compt. rend 107, 1169) 'Salophen,' aminophenyl acetyl salicylate, is said to hav 1ather stronger antiseptic power (Practitio March, 1907). A large number of derivat of salicylic acid have been introduced, and m of them patented

Cinnamic acid, at 2 p c, prevents the glo of bacteria, and at 4 p c. destroys them. I contained in Peru and storax balsams, where parasiticide in skin diseases. Fr 371091 preserves butter by enclosing it in wrapper impregnated with cinnamic acid, where the prevents butyric fermentation. Acetylomaric acid, "Tylmarin," is another internal a septic, said to have a R W coefficient of The use of halogen substituted hydrosic act especially 6-chlor-3-hydroxy-p-toluic acid, been suggested for disinfectant purposes Soc Chem Ind 1914, 33, 807)

Tannin is antiseptic to proteids through property of forming with them insoluble c pounds such as leather, but none of the tai extracts have even the power to preserve t own solutions.

Phenols and phenoloids. The introduc of aliphatic side chains into the nucleus of phraises the germicidal activity; the o- and positions for the entering groups have a gre influence than the m. Morgan and Co-found the following CA coefficients for t cresols, o=21, p=24, m=20. Whilst methol trimethyl methoxy phenol is said have a RW. coefficient of 40 when properulsified.

For general purposes of disinfection, 'car' fluids, having as their chief active stituents bodies allied to phenols, are rextensively employed. They are usually cayrupy liquids smelling of coal tar, and maroughly divided into two classes: (1) t

which on the addition of water form a more or | less clear dilution; and (2) preparations miscible with water but producing an emulsion. former usually consist of saponified tar-acids: the liquor cresoli saponatus, Ph G, consisting of equal parts of potash soap and crude cresol heated together, is of this nature. In the manufacture of these fluids, potash soap, glycerol, alcohol, and other agents are employed to aid the solubility in water. With the second group, the mostly insoluble, active ingredients are emulsified by the aid of soda, soaps, resin, neutral oils, or gelatin

Polyhydric phenols and naphthols. antiseptic powers of the di- and trihydroxy-

benzenes are less than those of phenol.

Resorcinol, m-dihydroxybenzene, is a powerful medicinal antiseptic, and a 1 pc solution kills most organisms 'Andeer's lotion' contains 40 grains in 1 oz 'water 'Anusol' is a bismuth iodo-resorcin sulphonate. Quinol or hydroquinone, p-dihydroxybenzene, is said to be a stronger antiseptic than the last, and has been suggested for typhoid in doses of 3 to 8 grains. The ortho-compound, catechol or pyrocatechin, is also antiseptic. Duggan finds (Amer. Chem J. 7, 62) that the amounts of the three isomerides required for preventing development of B subtilis in broth are ortho-20, meta-25, para- 30; phenol being 20 and pyrogallol 15

Morgan and Cooper (8th Int Cong App Chem. 1912, viii cl) give the following figures for the carbolic acid coefficients of the =0 48,

meta-=0 29, para-=1 1.

Pyrogallol, tri-hydroxybenzene, is antiseptic, and a 3 p c solution kills most bacteria, particularly aerobes, but it stains, is unstable, and very

poisonous

Guaracol (methyl-catechol) and creosol(methyl-guaiacol) are the active ingredients in wood creosotes, and have been widely useful as antiseptics and parasiticides, especially tuberculosis. Guaiacol has an antiseptic power (but not bactericidal—see Table) 21 times that of phenol, and a ½ to 1 pc solution destroys B. tuberculosis in 2 hours (Marfori, Ann di A one in 150 solution of (Morson's) Chim 12, 3) creosote kili pyog aureus and typhosus in 3 hours (Westcott) 'Little's Soluble Phenyle' contains wood creosote, and Corfield's experiments give it a high value for wounds and against Kenwood and Hewlett (J R San Inst 1906, 13) make its R W. coefficient 1.2

Beta-naphthol is official in the British (1898) and in a number of other Pharmacopæias, the dose in the former being 3 to 10 grains in a cachet for internal antisepsis, especially in typhoid and in cholera as a preventative. Its solubility in water is increased by boric acid Schneider observes that naphthols dissolved in alkaline carbonates have greater disinfectant power than alkaline naphtholates, the former solutions contain naphthol in the free state. He states that staphylococci and typhoid are killed in a short time by 05 to 10 pc of \$\beta\$-naphthol alkaline carbonate solution (Zeitsch. Hyg. 1906, 52, 534)

Ointments containing 10 to 15 pc are containing and psoriasis 'Betol,' efficient in scables and psoriasis β-naphthol salicylate, is less soluble than naphthol, and is now seldom used. 'Alphol' is its analogue from a naphthol, and is very similar.

A number of easily soluble compounds have been introduced, such as the \$\beta\$-naphthol sulphonates, 'Asaprol' or 'Abrastol' (calcium), and 'Alumnol' (aluminium). Helbing states that an aqueous solution of the latter, 1 in 250, prevents all growth of gonococci, pus cocci, and allied bacteria Bechold (Zeitsch angew. Chem. 1909, xxu. 2033) finds the odourless and nonpoisonous halogen-substituted naphthols more powerful than any disinfectant except HgCl2, and that tribromonaphthol kills staphylococci in dilutions of 1 in 250,000

Dihydroxynaphthalene The 23-substituted compound has a relatively high germicidal activity, with a ('A coefficient of 44 The 2.7- derivative has a coefficient of 2.8

Amidobenzene derivatives. The introduction of -NH<sub>2</sub> groups into the ring produces substitutes of low germicidal activity

Aniline is open to the same objection as the nitro- derivatives; it has a carbolic acid coefficient of 0 57, whilst o-toluidine, the next homologue, has a coefficient of 100, and m-toluidine one of 1 30

The dyestuffs. A number of amiline dyes are germicidal, owing to their power of penetiating and combining with living tissue. This action is very variable, but it is stated that I pe prevents development of organisms, whilst I in 500 to 4000 retards their growth

The investigation of the parasiticidal powers of the dyestuffs was conducted by Ehrlich and his pupils in their search for compounds containing strongly developed parasitotropic groupings, but only with feeble organotropic groupings It was found that tetrazo colours derived from naphthalene-3 6-disulphonic acid, basic dyes of the triphenylmethane series, and certain azocolours were equally effective Symmetrical colours were found to be less organotropic than unsymmetrical ones

'pyoktanın,' Methyl violet or violet, certain auramines, safranine, methylene and toluidine blue have been used in surgery and in malaria Malachite green, injected into the blood, kills trypanosoma in 48 hours (Birt Med J 1904, ii 1449, 1645, Deutsche Med. Woch Leipzig, 1906, 21, 463) Methylene blue, with atropine and benzoic acid, according to Lelean (Lancet, May 3, 1902), was the only drug he found of use against Bilharzia.

Derivatives of acridine, especially acriflavine-3.6-diamino-10-methyl acridinium sulphate and proflavine-3 6-diamino acridine sulphate, have been shown to be somewhat superior to malachite green when used for wound dressing Originally prepared for Ehrlich, their selective action on bacteria was first tested at the Middlesex Hospital, London. For wound dressing, the derivatives are made up as soaps, gelatine, or starch mucilages

Linked benzene derivatives. Both the chemical constitutions and the germicidal activities of the higher boiling tar acid fractions are as yet unknown. The direct linkage of two phenoloid groupings or linkage through =CH<sub>2</sub>, =CHOH, =CHOX where X is an aliphatic group, in some cases elevates the germicidal powers. Linkage through =CO or =SO<sub>2</sub> groupings is said to depress the coefficient.

Aromatic nitro- and halogen substituted compounds, such as nitro-benzene, have often been proposed as disinfectants, but are precluded by their odours, poisonous action, and sparing solubility. Trinitrophenol, 'pieric acid,' is rapidly fatal in saturated solution (about 1 p c) to bacteria and spores, but causes yellow stains, is irritant and very poisonous Cotton wool, soaked in the solution, is used very successfully in the aseptic treatment of burns, hence it is recommended by H M Inspector of Explosives to keep handy for this purpose The R W. coefficient is about 6 Potassium dinitro-orthocresol, 'Antinonnin,' 1 in 400, is destructive to all common injurious parasites, and does not injure plants.

Trichlorphenol has been used at Petrograd as a disinfectant It is said to be 25 times

stronger than carbolic acid

Hydrocarbons.—Petroleum, mainly consisting of hydrocarbons of the parafim series, has long been a well-known insecticide, and is mentioned by Marco Polo in the 13th century as used to kill acarı ın mange

For protecting burns and wounds from exposure, various substitutes for 'ambrine,' consisting essentially of paraffin wax or asphalt with a fatty oil have been suggested (BMJ 1917, 789)

A J Hull introduces into these burn dressings 'scarlet red,' 'bulliant green,' 'flavine,' and dichloramine-T on account of their antiseptic

Naphthalene is feebly antiseptic, but is not a disinfectant It is useful by its odour to drive

away domestic insects

It has been stated that articles are dismfected by dry-cleaning with petroleum-benzine, or by benzenc Farrel and Howles (J. Soc. Dyers, 1908, 24, 109, 166), however, find that acting on infected threads for 61 hours, neither benzene (C<sub>6</sub>H<sub>6</sub>) nor petroleum-benzine killed typhosus, whereas carbon tetrachloride killed it in 30 minutes, whilst 'benzine soap,' dissolved in benzine, has no germicidal power

Ether is used for sterilising catgut

Essential oils and camphors. Perfumes, chiefly composed of terpones and their oxidised products (eg the camphois, menthol, thymol, and eucalyptol), have a limited sanitary value All of them are very sparingly soluble in water, but impart to it a more or less antiseptic effect Early estimates of their power have not been concordant, chiefly owing to their having been tried variously in aqueous or alcoholic solution, or in suspension A saturated solution of thymol in water (0 3 pc) arrests fermentation and putrefaction Peppermint (containing menthol and menthane) has had a high reputation, and a number of recipes for 'plague water,' have it as a basis The use of hops in brewing partly rests on the power of the essential oil to check fermentation 'Terebene,' made by the action of H,SO<sub>4</sub> on terpentine, was once reputed as a disinfectant, but now hardly figures except as terebene soap Among other artificial products from turpentine are terpin hydrate (said by Colpi to arrest the growth of tubercle bacilli in 0 25 pc. strength), and terpineol (anthrax is stated to be killed by 1 p.c., and staphylococci by 10 p.c in 60 minutes. (H. Maix, 5. infra, also D R P 207576, 1906))

Camphor is much spoken of as a personal

the vapour to sterilise the air. It is an ingredient in many remedies for cholera and diarrhoea, and in several 'block disinfectants' such as 'Sanoscent,' 'Camphortar, &c Eucalyptus globulus and other species which have long been famous as antimalarial, are largely planted on the Continent in marshy districts. The essential oil is decidedly germicidal, having a carbolic acid coefficient of 12, and has been given with some success in typhoid, and also against tape- and threadworm.

Pinol is a liquid of similar character from Pinus pumilo H Marx has investigated the action of various perfumes on anthrax and S pyog aureus (Centr Bakt 1903, [1] 33, 74). Kobert (Chem Zentr 1907, 1 419) finds that the terpenes have, by themselves, in general only a weak antiseptic action The proportions needed for sterilising exceed the solubility in water, and can only be reached by a spirituous solution or

an emulsion

But it has been recognised, since Schonbein pointed out the fact about 1840, that essential oils have a disinfectant power conferred on them by their slow oxidation in the presence of an and moisture, whereby ozone is produced, that as long as air and oil are present, the ozone is continually regenerated and absorbed, forming oxidising and antiseptic products, which dissolve in the water, along with peroxide of hydrogen This was the principle of the 'Sanitas' patent 274, 1876

Pyridine, quinoline. and related bodies. Pyridine is volatile, mixes freely with water, and is strongly insecticide, but has a very unpleasant odour, which has militated against its use in horticulture. Tobacco smoke, indeed, owes its powers, not to nicotine, which is almost entirely decomposed by the heat, but to the products pyridine and its homologues, which are formed Tessman destroyed the bacilli of cholera and pneumonia by tobacco smoke passed for 10 to 30 minutes through a tube containing infected nutrient gelatin. Wynter Blyth killed the bacillus of nasal catarrh by 1 pc solution of pyridine and its homologues (from bone oil), or by tobacco smoke There is proof that smokers and workers in tobacco enjoy comparative immunity from epideinics, but pyridine inhalations (eg in asthma and whooping cough) require care, as it is a cardiac depressant The above experiments confirm the general view that disinfectant preparations containing the basic constituents of coal tar are to be preferred to those which only include the phenols

Tobacco juice, of course, contains nicotine, and in France is sold as an insecticide under an official guarantee as to its nicotine strength In England, a solution of the pure base in water is sometimes used as more definite Richard's cakes for fumigation are nicotine and camphor. the writer found a sample in 1909 to contain 1 17 p c of nicotine and to be completely volatile

at a gentle heat.

Chinosol is potassium oxyquinoline sulphonate  $C_9H_6NO$  OSO $_3K$ , a vellow powder easily soluble in water to an acid yellow solution, which does not stain, has only a slight aromatic odour, is permanent on keeping, is not poisonous, and does not coagulate albumen Cumphor is much spoken of as a personal has been patented as a disinfectant, and more prophylactic, but there cannot be sufficient of especially as an antiseptic. Klein compared its action on S pyog. aureus, B coli and anthracis with that of earbolic acid, and reports that a solution of the latter of 1 in 20 strength is required to kill aureus or coli in 5 minutes with certainty, whereas chinosol does this in a strength of 1 in 150 Anthrax spores are not appreciably affected in 48 hours by 5 to 6 p c carbolic, whereas chinosol of 1 p c acts germicidally on them in 5 minutes. In the writer's laboratory, B coli was not sensibly affected after 4 hours by 1 in 1000 chmosol, whilst 1 in 2000 of HgCl, produced sterility under the same conditions in 15 minutes, so that it is difficult to explain the much higher powers that some observers have found for chinosol Thresh and Sowden state that chinosol spray of not less than 1 pc, is a reliable disinfectant (J San Inst Jan 1903) Houston did not succeed in killing B coli in excreta by 1 in 75, and on linen by 1 in 62 (Practitioner, 1902, 331) On account of its acidity, it acts on non and steel Alkaline solutions interfere with its power the writer showed that a soap containing 5 p c of chinosol was inferior to a 0.5 mercuric iodide soap F G Muller reports encouraging results with chinosol in leprosy (Zeitsch Oest Apoth Vei xxxv 858) 'Cresochin' (Pharm Centialhalle, xxxvii 247) is said to be a neutral sulphonate of quinoline and tricresol, which is recommended for disinfecting instruments, as it does not darken the steel

Ichthyol --- Various derivatives from sulphurated tars and fossilised fish or petrolcums have been suggested for mild disinfection and the treatment of skin diseases Ichthyol ammonium ichthyol sulphurated has been compounded with various substances, such as albumen, formaldchyde, and metals, such as silver and mercury, under a variety of names

Quinine, which has a quinoline nucleus, probably owes its action against fevers as much to its antiseptic power as to its effect on the

nervous system

A Raal (Pharm Zeit 1900, xlv 569) asserts that strongly fluorescent bodies much increase the action of sunlight on organisms, whilst they are almost mert in the dark. A 1 in 20,000 solution of acridine killed infusoria exposed to sunshine in 6 minutes, in the dark they survived for 24 hours Similar results were noted with quinine sulphate and with cosin inference is that the effect is caused by the fluorescent rays Fluorescein has been patented as an antiseptic by Turpin, chiefly for toilet preparations (Fr Pat 346363, 1904) The biomofluoiesceins, particularly eosin, are found to have greater power. He claims a large number of other phthalein compounds as disinfectants

Certain faults of many antiseptics and disinfectants in the free state have led to an immense number of attempts to improve them by converting them into various derivatives Although the effort to produce new proprietary substances, has given rise to a multitude of often misleading titles, many of these preparations have been proved to have utility The modifications may be generally classified as follows

1. Metallic salts.—Compounds with the alkalis or earths are generally less active than the free substance Other metals have been introduced, with the object of adding their special properties, as Al for astringency, Zn, Cu, Ag, and Hg for developing germicidal effect; but it must be remembered that a combination of this kind, though it may have some lateral advantages, is commonly weaker than either agent singly The same remark applies to the two next

2 Substituted compounds —Those with iodine are exceedingly numerous, including a large number which have been improvements on iodoform when it was unduly valued. Where organic radicals (basic like methyl or ethyl, acid like acetyl or benzoyl) are introduced, the physiological properties are usually entirely altered

3 Esters, sulphonic, and other colligated compounds which, while less poisonous or irritant than the parent bodies, slowly yield the latter by gradual decomposition Several of

these have proved of great value

already indicated, the proprietary articles of this nature bearing fancy names are very numerous Since the Privy Council Orders of 1900 and 1902, the uncontrolled sale of liquids containing upwards of 3 p.e. carbolic acid or its homologues is prohibited, and the germicidal value of the more insoluble and higher boilingpoint tar acids has been recognised generality of commercial disinfectant fluids are now practically free from carbolic acid, and, in comparison with the latter, are non-poisonous These disinfectant preparations should not be employed to destroy resistant spores without prolonged exposure, according to the nature and amounts of active ingredients present, they are usually germicidal with non-sporulating organisms in dilutions far greater than is the case with absolute phenol. However, the strength of these proprietary articles varies considerably, and beyond the requirements of germicidal value specified in contracts with various authorities, there is at present, unfortunately, no legal control over the efficiency of disinfectants as sold to the public. There are instances of so-called disinfectants which enjoyed great popularity and even were advocated by the medical profession, yet possessed little or no germ-killing power under the conditions in which they would be employed

Since the adoption of the R W test, there has been a steady rise in the efficiency of com-

mercial disinfectants

The Mechanism of Disinfection -King and Paul, in 1897, first drew attention to the relationship between germicidal action and the ionic concentration of certain germicidal ions such as mercuiion, argention, hydrion, and formulated the rule that the germicidal activity of a solution was proportional to the ionic concentration of the germicidal ions recent work, such as that of Kitasato, Horrocks, and Winslow, on the common acids, and more especially the development of the organometallic group of disinfectants, indicated that this generalisation was by no means correct Ehrlich and his pupils attributed to disinfectants the possession of at least two specific properties, the presence of an organotropic and a parasitotropic grouping indicating the 'affinity' of the germicide to living tissue and the parasite or bacterium respectively

Neither of these theories will serve to

explain the phenomena observed in disinfecting | with ionised and unionised solutions, with emulsions and other colloids. Bacterial sus-censions must be regarded as suspensoids coated by, or containing, an emulsoid, and are o be classed as definite colloidal systems

The reactions between agglutin and the bacteria, similar to the reactions between toxins and antitoxins, resemble in many respects weak base, a view advanced and supported by Arrhenius ('Immunochemie'), or the usual absorption phenomena observed at colloidal surfaces. Although experimental evidence (notibly that of Marsden, Nyman, and Chick, sarried out at the Lister Institute) is not suffinently accurate to distinguish between the two, ret the other general characteristics of bacterial suspensions lead us to infer that absorption is the first stage of disinfection We can thus distinguish between the following types of action .

(1) Absorption of cations (ionic disinfectants) with simultaneous anion absorption, which may affect the activity

(2) Absorption of substances in solution, e g

phenol.

(3) Mutual action between bacteria and other colloids, such as emulsions (tar acids) or suspensoids (colloidal metals) The next stage, common to all, is penetiation and chemical attack by the absorbed disinfectant. It is evident that the germicidal activity of a substance after absorption is determined by its penetrative or intradiffusive powers as well as its chemical reactivity or 'parasitotropic' properties. The enhanced germicidal powers of the chloramine is doubtless due to their possession of a reactive -NH<sub>2</sub> group, but it is by no means clear that dyestuffs are germicidal on account of their possessing certain parasitogroupings or that their activity is not due to a medium diffusivity accompanied by gradual decomposition into germicidal constituents It appears probable that more light will be shed on this somewhat complex subject by a close study of the phenomena of absorption and the mechanism of intradiffusion of substances in colloidal material rather than by the development of the concept of ionic activity or postulation of certain parasitotropic groupings or valencies endowed with exceptional and unexpected properties

Testing of Disinfectants -Before 1881, when Koch introduced the use of pure cultures, tests depending upon the prevention of putrefactive changes in various organic infusions were mainly employed, and to a great extent the antiseptic or preservative value was noted rather than the actual germ-killing power (see first edition of this dictionary) Since then, an increasingly large number of investigators have worked upon practical methods of testing With the phenolic disinfectants, valuations were made upon the total amount of tar acids present, but the widely differing activity of these bodies, which is also modified according to their physical condition on dilution (in solution, tricresol has only one-third the germicidal value of that in emulsion), has led to the general adoption of bacterio-

logical tests

In the 'hread method (Koch), silk threads

are impregnated with the test organism, as exposed for a definite time to the action of the diluted agent, and then, after the removal adhering disinfectant, sub-cultures are inoc lated from the threads to determine the surviv or death of the organism (v. Lancet, July 3 1900; and J R. San Inst. 1907, xxviii). place of threads, small garnets can be employe (Kronig and Paul), stones of uniform size beil coated from cultures of the organism, and adde directly to the disinfectant, sterility beindetermined by inoculating sub-cultures intervals (Zeitsch angew Chem 1901, xiv. xv The chief points to be considered are (1) time (2) age of culture, (3) choice of mediur reaction of same, (4) temperature of incubation and (5) of disinfection, (6) variation in vit resistance of same species and (7) of differe species; (8) proportion of culture to disi In order to facilitate the compariso of disinfectants, Rideal and Walker (J. R. Sa Inst 1903, 424) suggested their carbolic ac coefficient method as the basis for a standar In this test, which has been extensive adopted in England and abroad, the efficience of the disinfectant is expressed in multiples absolute phenol performing the same wor It is briefly as follows: add 5 drops of a : hours' blood-heat culture of the organism both to 5 cc of a particular dilution of tl disinfectant in sterile distilled water, shall and take sub-cultures with a platinum loc every 21 minutes up to 15 minutes; Incuba sub-cultures at 37° for 48 hours Allowu 30 seconds for each operation, four differen dilutions of the disinfectant with one carbol control are tested against the same culture ar under strictly comparable conditions example.

This test has for many years been official used by the War Office, Admiralty, India Office and other Government departments at hon and in the Colonies It is impossible in ar one test to include the greatly varying condition of practical disinfection, but numerous modific tions of the RW coefficient test have bee suggested, mainly with the object of testing the presence of considerable quantities organic matter. Sterilised sea-water, urin sewage, starch, and gelatine emulsions, nutriei broth and milk, have been incorporated with tl diluting water—also testing with organisms their natural environment, as with coli sewage, in place of pure cultures mentation test for emulsified fluids allows 1 p c solution to stand 24 hours before preparii final dilutions for testing (Lancet, Sept 19, 1908 The Lister test' (U.J. Martin) is made in the presence of 3 p.c. of fæces, previously sterilise dried, and powdered. Sims Woodhead at Ponder (J. Path. and Bact. 1909, 148) replace tl moculating loop by platinum spoons, used with a special sterilising apparatus, and extend the

time to 30 minutes. A mean coefficient is taken for two values obtained at the beginning and end of the experiment with B. coli and subculturing into McConkey's bile-salt fluid. The Lancet (Nov. 1909) has suggested, in conjunction with the above method, a chemical analysis for the valuation of emulsified fluids as follows 10 grams of disinfectant with 100 cc. of water and 15 grams baryta, are heated for 30 minutes at 100° under a reflux condenser, then cooled and decanted through asbestos, washing with warm baryta water; the tar acids are extracted with ether from an aliquot portion of the filtrate, after adding calcium chloride and acidifying with HCl, dried at 38°, weighed, and their bromine absorption determined hydrocarbon oils are extracted from the baryta residue with acetone, and the insoluble soaps and resins treated with HCl and shaken out with For estimation of water, 25 grams of the sample are acidified with 10 cc. of 10 pc H,SO4 and shaken with 25 c c of white petroleum spirit, taking the volume less 10 c c of the aqueous layer after standing. In presence of the higher phenoloids, the weight of tar acids obtained is too low. The coefficients obtained for B coli were found to be approximately onethird of the difference between the percentage of tar acids and the bromine value

In the United States, the National Hygienic Laboratory method of L Anderson and T B McClintic (1912) is now widely adopted The method, which follows closely the RW in technique, differs in the following points of detail. The standard temperature of medication of 20°C, instead of 18°C, is adopted 01 cc of broth culture is added to 5 c c of disinfectant solution instead of 5 drops. The coefficient is determined from the mean of the following two

Weakest strength of disinfectant which kills in 2½ minutes

Weakest strength of phenol that kills in the same time

and the similar ratio for death in 15 minutes From time to time various modifications

have been introduced in which solid media such as nutrient agar have been substituted for broth An emulsion of an agar slope culture of an organism is made with the various disinfectant dilutions and phenol controls, whilst the sub-culturing is either performed direct into agar slopes or spread out on agar plates, thus permitting counts to be made Nutrient agar made up with fresh meat is certainly less inhibiting than standard broth, whilst certain advantages attend the use of plates, giving approximate data as to the number of organisms surviving after specified periods of disinfection, as against the 'end point' method of the fluid media tests These advantages are nearly entirely negatived by the difficulty of obtaining a uniform agar streak growth emulsion for medication, and the extra labour involved in plating a number of tests

The germicidal power expressed in terms of carbolic acid with B typhosus is shown for a number of disinfectant substances in the following table; while most of the figures are Rideal-Walker carbolic acid coefficients, some of the results have been obtained by modifications of colloid mercury.

the original test as noted, and these are obviously not comparable with the others.

The extremely high values once given for mercuric chloride were due to the powerful inhibitory action of the traces carried over with the sub-cultures in the inoculations.

S & E R. DISPARGEN. Trade name for a form of 556 DISPERMIN

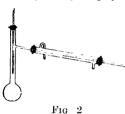

DISPERMIN. Trade name for piperazine DISSOCIATION v. CHEMICAL AFFINITY DISTHENE v. KYANITE.

DISTILLATION. The object of distillation is the separation of a volatile liquid from a nonvolatile substance, such as pure water from seawater, or more commonly the separation of two or more liquids of different volatility

The apparatus required consists essentially of four parts a still or boiler, a (Fig 1), in which

the liquid is boiled, an upright tube or head, B a condensing tube, c, sloping downwards and cooled by suitable means—a Liebig's condenser, L, through which a current of water is passed, being generally employed in the laboratory,

lastly, a receiver, R. to collect the dis-tilled liquid The tilled hquid form of apparatus shown in Fig 2 is convenient for many purposes, the still, the head, and the condensing tube are scaled together in one piece

The stılÎ usually heated by the flame of a Bunsen burner, for very volatile and inflammable liquids a water-bath is generally used, but the rate of distillation can be better regulated by a very small flame in contact with the bottom of the still, the Liebig's condenser is unnecessary for liquids which boil above 160° or 170° if the condensing tube is fairly long. For many purposes, notably for distillation under reduced pressure, it is convenient to employ an electrically heated coil of platinum, German silver, or nichrome wire as the source of heat (Richards and Matthews, J. Amer Chem Soc 30, 1282, 31, 1200, Beckmann, Zeitsch physikal. Chem 64, 506, Bailey, J Amer Chem Soc 33, 447, Rosanoff and Easley, ibid 31, 964)

If the temperature at which the liquid boils is to be ascertained with accuracy—and this is generally the case in fractional distillation, especially in the final purification of a liquid—the following points should be attended to

1 The thermometer should be carefully calibrated, and it would be a great advantage if all thermometers were compared with an air thermometer, for different kinds of glass expand very differently when heated, and therefore two thermometers, constructed of different varieties of glass, will give different readings, especially at high temperatures

2 The zero point of the thermometer should be redetermined from time to time. It is a good plan to heat the thermometer for several hours to about 300° or 360° before calibrating it; the subsequent clanges of zero point, which other-

wise might be considerable at high temperatures, are thereby greatly reduced (Crafts, Comptrend. 95, 910, also several earlier papers) Thermometers treated in this manner may now be purchased

3 All thermometers, except those which do not register temperatures higher than 60° or 70°, should contain nitrogen to prevent volatilisation of mercury in the heated stem; if the thermometer is provided with a small bulb at the top, rise of pressure owing to compression of the gas

in the thermometer is avoided

4 The thermometer should, if possible, be so placed in the apparatus that not only the bulb but also the column of mercury in the stem is surrounded by the vapour of the boiling liquid, otherwise the following correction, which, at the best, is somewhat uncertain, must be applied -N = length of column of mercury in scale degree

not heated by vapour T = temperature of vapour (the approximate temperature directly read on the thermo-

meter is usually sufficiently accurate) mean temperature of column of mercury not heated by vapour This temperature may be approximately ascertained by attaching a small thermometer to the other by means of thin indiarubber bands or wire, with its bulb at about the middle of the unheated column

Correction add 0 000143(T t)N

 The coefficient 0 00016 is usually employed. but Holtzmann pointed out that this is too high, and adopted the number 0 000135 however (Chem. Soc. Trans. 37, 1 Thorpe, 159), has shown that the coefficient 0 000143 gives the best results 1. The table for the correction of thermometer readings is taken from Thorpe's paper, and shown in next column

MOMETERS

5 When the amount of liquid in the bulb is very small, the vapour is hable to be superheated by the flame, and unless the bulb of the thermometer is thoroughly moistened with condensed liquid, too high a temperature will be registered If a very little cotton wool or, for temperatures above 230°, a little fibrous asbestos be wrapped round the bulb of the thermometer, it remains thoroughly moist, and with a pure liquid the theirmometer registers a perfectly constant temperature until the last trace of liquid in the bulb has disappeared (Ramsay and Young, Chem Soc Trans 47, 42)

6 The barometer should always be read, and corrected to 0°, and in a long distillation or in unsettled weather it should be read frequently, for the boiling-point varies greatly with the pressure The observed boiling-point is corrected to that under normal pressure by means of the formula  $\theta = c(700 - p)(273 + t)$ , where  $\theta$  is the correction in centigrade degrees to be added to the observed boiling-point,  $t^{\circ}$ , c is a constant; and p is the barometric pressure. For the

<sup>1</sup> Rimbach (Bet 22, 3072) has constructed tables of ¹ Rimbach (Bet 22, 3072) has constructed tables of corrections by interpolation from experimental data up to 220° for two kinds of thermometer graduated in degrees, and up to 100° for thermometers graduated in tenths of a degree — All these thermometers were constructed of Jena glass, and from the results it would appear that the form of the their nometer, and doubtless also the nature of the glass, have a notable influence on the magnitude of the correction. majority of liquids the value of c may be taken. without serious error, to be 0 00012; but for water and the alcohols it is about 0.00010, and for a few liquefied gases it is considerably higher. A table of corrections was first given by Crafts (Ber 20, 709) The values of c for a large number of substances have been collected and

tabulated by Young (Chem. Soc Trans. 81, 777; Fractional Distillation, 15)

The various parts of the simple apparatus (Figs 1 and 2) may require modification under certain circumstances.

The still -For larger quantities of liquid, a tin or copper vessel is preferable to glass.

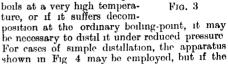

The head -The modifications of this part

of the apparatus will be considered under Fractronal distillation.

The condenser .- For very volatile liquids, the condensing tube must be cooled by ice or a

freezing mixture (pounded ice and salt or ice and concen. trated hydrochloric acid, &c) In this case, a spiral or worm' tube should be used (Fig 3). Condensation of moisture in the receiver is prevented by the drying tube a V CONDENSERS.

The receiver -If a liquid boils at a very high temperature, or if it suffers decom-

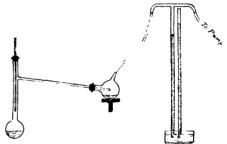

Fig. 4

distillate is to be collected in separate portions. as in fractional distillation, the removal of the receiver would necessitate the admisapparatus and a sion of air into the fresh exhaustion after each change This inconvenience may be obviated by the employment of stopcocks arranged in such a manner that air may be admitted into the receiver and a fresh one put in its place while the distillation bulb remains exhausted (Thorner, Ber 9, 1868, F D Brown, Chem Soc. Trans 35, 554, L T Thorne, Ber 16, 1327 (Fig 5),

Fig 5

Lothar Moyer, ibid 20, 1834, Wade and Merriman, Chem. Soc. Trans. 99, 984; Rosanoff and Easley, lc; Rosanoff, Bacon and White, J. Amer Chem. Soc 36, 1806) Or again, a series of receivers on a revolving stand placed under an exhausted bell-jar may be empl-yed (Gorboff and Kessler, Ber. 18, 1363, Bruhl, *ibid.* 21, 3339 (Fig. 6)).

Many liquids absorb moisture from the air or are acted upon by oxygen, and in these cases special precautions must be taken, the moist air in the apparatus being expelled and replaced by dry air, carbon dioxide, nitrogen, or hydrogen;

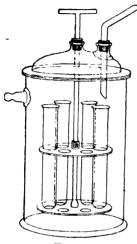

Fig. 6.

the receivers must also be protected by drying tubes (For example, v Thorpe, Chem. Soc Trans 47, 120 , Young,  $\imath bid$  59, 923)

Theory of distillation.—Investigations of the vapour pressures of liquids have thrown much light on the subject of distillation If a pure liquid be confined in the space above the mercury in a barometer tube, it will evaporate until the pressure of its vapour-measured directly by the depression of the mercury column—has reached a definite amount, which, for a given substance, and, if liquid be still present, depends solely on the temperature From the readings of pressure at various temperatures we may construct a curve to illustrate the relations of temperature to pressure for a given substance, but this curve has a twofold meaning, for it represents not only the vapour pressures at definite temperatures, but also the boilingpoints of the liquid under definite pressures. Thus the vapour pressure of pure water at 100° is 760 mm of mercury at 0°; and under a  $100^{\circ}$  is 760 mm of mercury at  $0^{\circ}$ ; and under a pressure of 760 mm water boils at  $100^{\circ}$ . Again, the vapour pressure of water at 0° is 46 mm, and if the pressure in a distillation bulb containing water be reduced to 4.6 mm, the water will boil at 0°. The truth of this general statement was conclusively proved by Regnault (Mém de l'Academie, 21 and 26)

Regnault also investigated the behaviour of a few mixed and heterogeneous liquids, which he divided into three classes: (1) liquids which are quite or almost insoluble in each other; (2) liquids which are miscible only within certain limits; (3) liquids which mix in all proportions. Regnault employed both the statical and dynamical methods of investigation; that is to say, he determined, on the one hand, the vapou pressures of the liquids at vanous temperatures

in the barometer tube, and, on the other hand, the boiling-points of the liquids under various

The behaviour of two liquids, A and B, when brought into contact with each other, must be affected (a) by the attraction of the like molecules; those of A for each other, and those of B for each other, and (b) by the mutual attraction of the molecules of A and B If the attraction of the molecules of A and B tion of the unlike molecules is relatively very slight, it may be expected that the liquids will be non-miscible, or nearly so, as in the case of benzene and water If the attraction of the unlike molecules is greater, but still relatively small, miscibility within limits may be expected, as, for example, with aniline and water. In such cases there is frequently slight expansion and slight absorption of heat on admixture. Comparing together various pairs of liquids, as the mutual attraction of the unlike molecules increases relatively to that of the like molecules, the following changes may be expected; (a) increasing and finally infinite miscibility; (b) slight expansion, diminishing to zero, and followed by increasing contraction; (c) diminishing absorption of heat, changing to increasing These changes do not, in many heat evolution cases, run strictly pari passu, and among liquids which are miscible in all proportions, it is not unusual to find a small amount of contraction attended by a slight absorption of heat, as, for example, when a little water is added to normal propyl alcohol, but when certain compounds, such as chlorobenzene and bromobenzene, which are chemically closely related, are mixed together, there is no appreciable change of volume or temperature For such substances it is probable that the different molecular attractions, A for A, B for B, and A for B, are very nearly equal, and that the relation suggested by Galitzine (Wied. Ann 41, 770; and by D Berthelot, Compt rend. 126, 1703), namely, that  $a_{AB} = \sqrt{a_A a_B}$ , holds good, where  $a_{AB}$  represents the attraction of the unlike molecules, and  $a_A$  and  $a_B$  the respective attractions of the like molecules

It would appear, then, that there are two very simple cases I that in which the liquids are non-miscible; II that of two infinitely miscible and closely related liquids which show no heat or volume change on admixture

I. It was found by Regnault that when two non-miscible liquids are placed together over the mercury in a barometer tube, the observed vapour pressure is equal to the sum of the vapour pressures of the two liquids when heated separately to the same temperature. It is only necessary that both substances should be present in sufficient quantity, and that the tube should be shaken or sufficient time allowed for the evaporation of the heavier liquid. liquids evaporate independently of each other, and Dalton's law of partial pressures is therefore applicable to the distillation of non-miscible liquids. Each vapour behaves to the other as an indifferent gas, and the boiling-point of each liquid depends on the partial pressure of its own vapour. The temperature is necessarily the same for both liquids, and the total pressure, if the distillation is carried out in the ordinary manner, is equal to that of the atmosphere. The boiling-point is, therefore, that temperature it which the sum of the vapour pressures of the components is equal to the atmospheric pressure. For example, at 90·23° the vapour pressure of water is 530·1 mm; and that of chlorobenzene is 210.1 mm; total, 740·2 mm; and it was ound that when chlorobenzene and water were listilled together under a barometric pressure of 740·2 mm, the temperature varied only between 90·25° and 90·35°, until there was carcely any chlorobenzene left in the residue, when it rose rapidly to 100°. The boiling-point of a pair of non-miscible liquids is necessarily lower than that of the more volatile component, and may be far lower than that of the less volatile.

The process of distillation with steam is very frequently employed in the case of subtances of high boiling-point, which are insoluble in only slightly soluble in water, such as amline in introbenzene (For the application of steam listillation to the preparation of ethereal oils, von Rechenberg, Theorie der Gewinnung ind Trennung der atherischen Oele durch Destillation, Schimmel & Co. 1910)

The composition of the vapour—and thereore of the distillate—from two non-miscible iquids, like the vapour pressure and boiling-point, is independent of the relative amounts of the components, provided that both are present n sufficient quantity and that evaporation can ake place freely Calling the vapour densities  $D_A$  and  $D_B$ , and the vapour pressures at  $t^\circ$   $D_A$  and  $D_B$ , there will be, in a litre of the mixed vapour, 1 litre of A at  $t^\circ$  and  $p_A$  mm., and 1 litre of B at  $t^\circ$  and  $p_B$  mm. The weights of vapour vill therefore be:

$$-\frac{0.0899\times {\rm D_{A}}\times 273\times p_{\rm A}}{(273+t)\times 760} {\rm and} \, \frac{0.0899\times {\rm D_{B}}\times 273\times p_{\rm B}}{(273+t)\times 760}$$

espectively, and the relative weights will be  $O_A \times \underline{P_A}$  (Naumann, Bor. 10, 1421, 1819, 2014,  $O_B \times \overline{P_B}$  (Soumann, Bor. 10, 1421, 1819, 2014, 1999; Brown, Chem. Soc. Trans. 35, 547)

The vapour density of chlorobenzene is 562, and that of water is 9; and at 9023° the elative weights of vapour will be

$$\frac{m'_{A}}{m'_{B}} = \frac{562 \times 210 \cdot 1}{9 \times 5301} = 2475,$$

nd the percentage weight of chlorobenzene rill be 71.2. In the actual experiment to which eference has been made, the percentage of hlorobenzene in the distillate was found to e 71.4. Both boiling-point and vapour omposition agree well with the calculated alues

II The vapour pressure of a mixture of we infinitely miscible liquids which are chemially closely related to each other, or, probably, or which  $a_{\rm A}_{\rm B} = \sqrt{a_{\rm A}.a_{\rm B}}$ , is given by the formula  $00p = {\rm M}p_{\rm A} + (100 - {\rm M})p_{\rm B}$  where M is the moleular percentage of A, and  $p, p_{\rm A}$ , and  $p_{\rm B}$  are he vapour pressures of the mixture and of and B respectively, at the same temperaure,  $t^{\circ}$ . In other words, the relation between apour pressure and molecular composition is epresented by a straight line (Van der Waals,

Proc Roy Acad. Amsterdam, 3, 170; Young, Chem. Soc. Trans. 81, 768; Young and Fortey, 1b1d. 83, 45; Zawidski, Zeitsch physikal. Chem. 35, 129; Vanstone, Chem Soc Trans. 97, 429; Price, 1b1d 115, 1116) The relation has been found to hold accurately for chlorobenzene and bromobenzene, and with very slight error for other pairs of closely related liquids

In order to calculate the boiling-points of all mixtures of two such liquids under a given pressure, p, the vapour pressures of each must be known at all temperatures between their respective boiling-points under that pressure The percentage molecular composition of mixtures which would exert the vapour pressure p must then be calculated at a series of temperatures between these limits by means of the for-

mula  $M=100\frac{p_B-p}{p_B-p_A}$ . Lastly, the values of M must be plotted against the temperatures, when the curve drawn through the points will give the required relation between boiling-point and molecular composition. In the cases examined, the agreement between the observed and calculated results is quite satisfactory.

The relation between the composition of a liquid mixture and that of its vapour (distillate) has been the subject of many experimental investigations (Brown, Chem Soc Trans 35, 547; 39, 304, Lehfeldt, Phil. Mag. (v.) 46, 42, Zawidski, Zeitsch physikal Chem 35, 129, Carveth, J Phys Chem 3, 193; Winkelmann, Wied Ann 39, 1; Linebarger, J Amer Chem Soc 17, 615; Gahl, Zeitsch physikal Chem 33, 179; Rosanoff, Lamb, and Breithut, ibid 66, 349; Rosanoff and Easley, J Amer Chem. Soc. 31, 953, Rosanoff, Bacon and White, ibid 36, 1803; Rosanoff, Bacon and Schulze, *ibid* 36, 1993; Rosanoff and Bacon, *ibid* 37, 301 and 1072) Special attention may be directed to the last four of these papers. Unfortunately, however, it is only in a very few cases that the mixtures investigated consisted of closely related liquids (Young, Sci Proc Roy Dubl Soc 15, NS, 667) In the discussion of their results, Lehfeldt and Zawidski made use of formulæ which they derived from a general equation proposed independently by Duhem and by Margulès, and it is to be noted that both formulæ, in the simplest cases, can be reduced to one originally given by Brown,  $\frac{m'_{A}}{m'_{B}} = c \frac{m_{A}}{m_{B}}$ , where  $m'_{A}$  and  $m'_{B}$  are the relative weights of the two substances in the vapour,  $m_A$  and  $m_B$  the relative weights in the liquid, and c is a constant. From

Zawidski's formula it would follow that  $c = \frac{p_A}{p_B}$ . So far as experimental evidence is available, it would appear that Brown's formula is applicable to mixtures of liquids for which  $a_{AB} = \sqrt{a_A a_B}$ .

and that for closely related liquids  $c = \frac{p_A}{p_B}$ .

Another formula, which gives good results, is proposed by Rosanoff, Bacon and Schulze (loc. cit.)

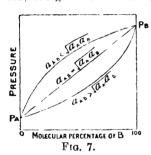

When the components of a liquid mixture are not chemically closely related, the relation between vapour pressure and molecular composition is not, as a rule, represented by a straight

line, but by a curve, and, in all probability, the form of the curve depends on the relation between  $a_{\rm AB}$  and  $\sqrt{a_{\rm A}}\,a_{\rm B}$ , as shown in Fig. 7. That is to say, when

$$a_{AB} < \sqrt{a_A a_B}$$
,  $100p > Mp_A + (100 - M)p_B$ , and vice versa

The greater the difference between  $a_{A \ B}$  and  $\sqrt{a_A} \, a_B$  the greater will be the curvature, and it will be seen that, for any given values of  $p_A$  and  $p_B$ , if the deviation from straightness exceeds a certain limit, there must be a point of maximum or minimum pressure on the curve. It is obvious, also, that the smaller the difference between  $p_A$  and  $p_B$ , the smaller will be the deviation required to give a maximum or minimum pressure. If  $a_{A \ B}$  is so much smaller than  $\sqrt{a_A} \, a_B$  that the two liquids are only partially miscible, the maximum pressure will not be represented by a single point, but by a horizontal line forming part of the curve

The influence of chemical relationship is well seen by the behaviour of the monhydric aliphatic alcohols towards water. These alcohols may be regarded as derivatives of water, formed

by the replacement of a hydrogen atom by the group  $C_nH_{2n+1}$ , the smaller the alkyl group, the closer is the relationship of the alcohol to water At the ordinary temperature methyl alcohol is miscible with water in all proportions, as also

are ethyl and propyl alcohols, normal butyl and isobutyl alcohol are only partially miscible with water, and the solubility of the higher alcohols in water diminishes with rise of molecular weight, cetyl alcohol, for example, being practically insoluble. The volume and heat changes on admixture with water similarly indicate that the attraction of the unlike molecules diminishes as the molecular weight of the alcohol increases. Lastly, the deviation of the vapour pressure curves from straightness increases (Konowalow, Wied Ann. 14, 34), as may be seen from Fig. 8

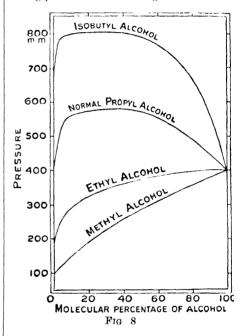

(The temperatures are such that the vapour pressure of each pure alcohol is 400 mm)

The boiling-points of liquids which are not closely related cannot, as a rule, be calculated by means of the formula  $M=100 \frac{p_B-p}{m_B-p}$  If,

as is usually the case, the vapour pressures of the mixtures are higher than are given by the formula  $100p = Mp_A + (100 - M)p_B$ , the observed boiling-points will be lower than the calculated; if the vapour pressures are lower, the boiling-points will be higher. Moreover, when there is a point of maximum pressure on the curve which shows the relation between vapour pressure and molecular composition, there must be a point of minimum temperature

on the boiling-point—molecular compositic curve, the composition of the mixture whice exerts a maximum vapour pressure, p, at being the same as that of the mixture which has the minimum boiling-point,  $t^{\circ}$ , under the pressure p So, also, two substances capabof forming a mixture of minimum vapour pressure can also form a mixture of maximum boiling-point

Such mixtures of either minimum or maximum boiling-point, when distilled, boil at a constant temperature without change of composition like pure substances, and they have frequently been mistaken for chemical compounds. The composition, however, depends on the pressur which would not be the ease with a definition compound, and, moreover, mixtures of minimum boiling-point are formed owing to the relatively

small attraction of the unlike molecules for each other A very striking example of th influence of pressure on the composition of th mixture of constant boiling-point has bee observed by Wade (Chem Soc Trans 99, 997 in the case of ethyl alcohol and water normal pressure the mixture of minimum boiling point contains 4 43 pc of water At highe pressures the percentage of water is slightly higher, at lower pressures it is smaller, an it is remarkable that the diminution in th percentage of water becomes more and mor rapid as the pressure falls, so that below 80 mm no mixture of minimum boiling-point is forme at all V also Merriman, ibid. 103, 628 and 1790.

In the case of three liquids, if each of th three possible pairs is able to form a mixture of minimum boiling-point, it may happen that particular mixture of all three liquids will be constantly at a lower tem perature than will an of the pairs or single liquids. Thus benzene an water form such ternary mixtures of minimum boiling-point with ethyl, n-propyl, isopropyl, and tertiary butyl alcohols (Young, Chem. Soc Trans. 81, 707, Fortey and Young, ibid 81, 739)

A table of mixtures of constant boiling-point is given in Young's Fractional Distillation, Other mixtures have since been discovered by Wade (Chem Soc Trans 85, 938, 87, 1656, v also 95, 1842), and by other observers The subject has been exhaustively studied by Lecat, La Tension de Vapeur des Mélanges de Liquides, l'Azéotropisme (Brussels, Lecat has collected the data published by other chemists, and has himself investigated more than 2000 mixtures, and has discovered and tabulated avery great number of binary mixtures of minimum boiling-point, and a moderate number of binary mixtures of maximum boiling-point, and of ternary mixtures of minimum boilingpoint. He has also observed the dependence of the composition of the azeotropic mixtures on the pressure in a considerable number of cases.

The composition of the vapour from a

The composition of the vapour from a mixture of liquids which are not closely related, cannot, as a rule, be calculated from the vapour pressures of the components and the composition of the liquid, but for purposes of interpolation the formulæ of Lehfeldt, Zawidski or Rosanoff may be found useful (lc) Rosanoff, Bacon and Schulze (lc) have discovered a simple and very useful solution between the partial pressures (number of molecules) of the components in the vapour and the vapour pressures of the mixture and of the two pure substances. They give a formula which is applicable even when mixtures of maximum or minimum vapour pressure are formed

Fractional distillation. It has been stated that Brown's formula,  $\frac{m'_A}{m'_B} = c \frac{m_A}{m_B}$ , is applicable to mixtures of all closely related liquids so far investigated, and that, in all probability  $c = \frac{p_A}{p_B}$ . The value of c is necessarily such that the vapour is richer than the liquid in the more volatile component. The first portion of distillate obtained by condensation of the vapour will, therefore, be richer, and the

residual liquid will be slightly poorer in that component. Continuing the distillation, the vapour evolved from the residual liquid will again be richer than the liquid in contact with it in the more volatile component, though poorer than the first portion of vapour. If successive portions of vapour be condensed, the percentage of the more volatile component in the distillates or fractions will steadily diminish, until, if the constant of differs greatly from unity, the residue will consist of the less volatile liquid in a pure or very nearly pure state. As the distillation proceeds, the temperature will, therefore, rise until, if c has a high value, the boiling-point of the less volatile component is reached

If the fractions obtained in the first distillation were redistilled, each of them could be separated into smaller fractions, the first richer and the last poorer in the more volatile component, and by a process of systematic fractional distillation it should, theoretically, be possible to effect a separation of both components

A mathematical and experimental investigation (Barrell, Thomas, and Young, Phil Mag (v) 37, 8) of the behaviour on distillation of mixed liquids which follow Brown's law, showed that with two components it is the liquid of higher boiling-point which is the easier to separate; and that if there are three or more components boiling at fairly equal intervals of temperature, the substances of intermediate boiling-point are the most difficult to separate, and the least volatile substance is the easiest See also Loid Rayleigh, Phil Mag [5] 4, 527, and Rosanoff, Baker and Schulze, J. Amer. Chem. Soc. 36, 1993.

The method employed for the fractional distillation of a mixture of two highest can best be explained by taking a concrete example. A mixture of 100 grams of benzene (b.p. 80.2°) and 100 grams of toluene (b.p. 110.6°) was slowly distilled, and the distillate was collected in a convenient number of fractions, the receivers being changed when the boiling-point reached certain definite previously arranged temperatures, the actual readings being corrected for barometric pressure and for criois in the thermometer scale. The results of the first four fractionations, and also of the ninth, are given in Table I

TABLE 1.

	'		l		ł	1	

In the first distillation the temperature rose almost at once to 86° (corr), and the first portion of distillate was therefore collected in receiver 4 On the other hand, the temperature reached 110 6° before the whole of the liquid had come over; the residue, therefore, consisted of pure toluene

The distillate in receiver 4 was now placed in a smaller flask and distilled, fractions being collected in receivers 2, 3, and 4 When the temperature reached 89 2°, the flame was removed, and the contents of receiver b were added to the residue in the still The distillation was recommenced, and fractions were collected in receivers 3, 4, and 5, the flame being removed when the temperature reached 92 2° The distillation was continued in a similar manner until, after addition of the contents of receiver 12, the temperature rose to 1106°, when the residue of pure toluene was added to that from the first fractionation. The third and fourth fractionations were carried out like the second In the subsequent fractionations the temperature ranges of the middle fractions were gradually increased and those of the lowest and highest fractions diminished. It was not until the minth fractionation that pure benzene began to be collected Eventually 81 4 grams of pure benzene and 88 8 grams of pure toluene were recovered.

Full details of the systematic fractional distillation of mixtures of two liquids and three liquids, and of more complex mixtures, are given

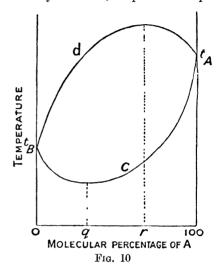

'Fractional Distillation,' 114-143
If the components of a mixture are not closely related, the composition of the vapour cannot, as a rule, be calculated by Brown's formula, but even in such cases the percentage of the more volatile component in the vapour will be greater than in the liquid, and the separation by fractional distillation is theoretically possible, unless the deviation of the vapour pressure-composition curve from straight-

ness is so great that a mixture of maximum or mınımum vapour pressure is formed.

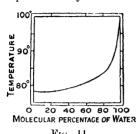

For mixtures to which Brown's law is applicable, it may be stated quite generally that the greater the difference between the boiling-points of the compounds, the more readily can a separation be effected by fractional distillation, but for other mixtures the form of the curve representing the relation between boiling-point and molecular composition, if known, must be taken into account. If the curve for two components were of the form a

(Fig. 9), the substance of higher boiling-point could be separated very easily, but the more volatile component only with great difficulty, if at all On the other hand, if the curve were of the form b, nearly horizontal at the higher temperature, the more volatile component would be comparatively easy, and the less volatile difficult to separate. The first case is frequently met with, the second seldom. With curves of the form c and d (Fig. 10) it would not, under any conditions, be possible to separate

both components by distillation of any given mixture, but it would be possible to separate the mixture of minimum of maximum boilingpoint from that component which was in excess In a case represented by curve c, where the minimum temperature corresponds to the molecular composition q, the distillation might proceed in either of three ways (1) If the liquid mixture had the composition q, it would distil unchanged in composition at the constant minimum temperature, (2) if the molecular percentage of A were less than q, the liquid would tend to separate into two components, the more volatile of which would be the mixture of minimum boiling-point, and the less volatile the substance B, (3) if the molecular percentage of A were greater than q, the components separable by distillation would be, first, the mixture of minimum boiling-point, and, second, A well-known case of this kind the liquid A is that of normal propyl alcohol and water; the boiling-points under normal pressure are: water, 100°; n-propyl alcohol, 97.2°; mixture of minimum b p. 87.7°. This mixture contains 43.2 molecules p.c. of the alcohol; it was described for many years as a hydrate of propyl alcohol. If the curve had the form d, the mixture would distil like a pure liquid if it had the composition r, or it would tend to separate into two components, the first being either A or B, according as the molecular percentage of A in the original mixture was greater or less than r, and the second the mixture of maximum boiling-point. Formic acid and water behave in this manner, as shown by Roscoe (Chem. Soc. Trans. 13, 146; 15, 270). Boiling-points: water  $100^\circ$ ; formic acid,  $99.9^\circ$ ; mixture of maximum b.p.,  $107.1^\circ$ ; molecular percentage of acid in mixture,  $56.7^\circ$ .

If, as with ethyl alcohol and water (Fig. 11), the mixture of constant boiling-point distils at nearly the same temperature as one of the two pure liquids, it is impossible to separate that liquid in a pure state by distillation. In this

case, as the curve is exceedingly flat at the lower temperature (Noyes and Warfel, J Amer Chem Soc. 23, 463), it is practically impossible to separate the mixture of minimum boiling-point (containing 4 43 pc by weight of water) in a pure state even when water is in excess, although it is quite easy to separate pure water from dilute spirit.

The correct interpretation of the results of the fractional distillation of a complex mixture may be rendered very difficult by the following

causes. (1) the presence of two components boiling at nearly the same temperature; (2) the presence of one or more components in relatively very small quantity, (3) the formation of mixtures of constant boiling-point It is only by plotting the total weights of distillate against the temperatures, or by dividing the weight of each fraction,  $\Delta w$ , by its temperature range and tabulating the ratios  $\Delta w/\Delta t$ , that the results are likely to be understood, and in any case, the existence of a mixture of constant boiling-point may not be discovered, and it may be difficult to decide whether a distillate collected at a practically constant temperature consists of a single pure substance or of two liquids boiling at nearly the same temperature

All the above difficulties are met with in the fractional distillation of petroleum, which contains homologous and isomeric paraffins, polymethylenes and their alkyl derivatives (naphthenes) and aromatic hydrocarbons, Russian petroleum poor in naphthenes and aromatic hydrocarbons. When American petroleum was carefully distilled, it appeared at first as though the distillate coming over between the ordinary temperature and 40° contained only a single component, boiling at about 33°; but by systematic fractional distillation with a very

efficient still-head, it became evident (Fig. 12) that two components, isopentane, bp. 2795, and normal pentane, bp. 362°, were present (Young, Chem Soc Trans 71, 440) Again, in the early fractionations there appeared to be no indication of the presence of any component boiling between 40° and 60°, but by tabulating the values of  $\Delta w/\Delta t$ , it was seen that a very small quantity of a liquid boiling at about 50° was present, and a distillate coming over almost constantly at 495° was eventually obtained. A chemical and physical investigation of this distillate showed, however, that it was a mixture of pentamethylene and a hexane of low boilingpoint The presence of benzene in American petroleum is indicated by the formation of dinitrobenzene, when the distillate from, say, 60° to 80° is treated with nitric and sulphuric acids (Schorlemmer, Annalen, 127, 311) when the petroleum was carefully fractionated, it was found that the small fraction coming over at about 80° yielded no dinitrobenzene, the greater part being obtained from the fractions This anomaly is explained by the fact that benzene forms a mixture of constant boiling-point with n-hexane, coming over at almost the same temperature as the paraffin The amount of benzene being relatively small, the whole of it distils over at the low temperature In Russian petroleum the percentage of benzene is so much greater that some of it comes over at its true boiling-point, 80 2° (Young, Chem Soc Trans 73, 905)

(For a detailed discussion of the interpretation

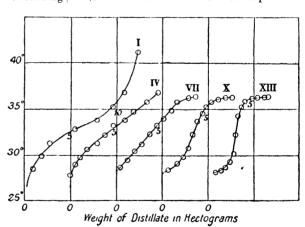

Fig. 12.

of the results of the fractionation of complex mixtures, v Fractional Distillation, chap 19)

Improved still-heads. It would be quite impossible to effect really difficult separations by means of the ordinary apparatus employed for distillation, and various modifications of the still-head have been devised in order to increase its efficiency. Even when the separation is an easy one, much time and material may be saved by the employment of efficient still-heads. Great progress was made in the improvement of the still-head in commerce—notably for the better sep\_ration of alcohol from weak spirit—before

any advance was made in the laboratory. It will, however, be more convenient to consider first those forms of apparatus which are suitable

for laboratory purposes

In choosing or constructing a still-head, the first point to be considered is its efficiency in separating the components of a mixture. It frequently happens, however, that the quantity of liquid available is small, and it is therefore important that the quantity of condensed liquid in the still-head at any moment shall be as small as possible. If the residual liquid is to value, it is also of importance that the condensed liquid in the still-head shall all return to the still after the source of heat is removed.

In comparing the efficiency and usefulness of different still-heads, it is necessary always to distil a mixture of the same composition, and the rate of distillation must always be the same, because the efficiency of any still-head is greatly diminished by increasing the rate. In the comparisons mentioned in this article, equal weights of pure benzene and pure toluene were employed, and the distillate was collected at the rate of one drop per second. Unless otherwise stated, 50 grams of the mixture were distilled

Of all possible forms, the plain vertical stillhead is the least efficient During distillation, as the vapour rises up the cylindrical tube, the outer part of it comes in contact with the con densed liquid flowing down the sides of the Since the tube is constantly losing heat by radiation and by conduction to the surrounding air, this liquid is constantly cooled and fresh condensation constantly goes on, the outermost layer of vapour probably condensing almost completely with little change of composition The central portion of vapour uses rapidly up the tube, and can only reach the liquid by diffusion or by convection currents, and much of it may pass through the still-head without reaching the liquid at all, the condensed liquid, on the other hand, flows rapidly back to the still In order, however, that a satisfactory separation of the components may take place, as much of the vapour as possible should come in contact with the hot condensed liquid, so that equilibrium, as regards composition, may be brought about all through the tube

The efficiency of a plan vertical still-head is, roughly, proportional to its length. For tubes of equal length, the efficiency is lowest when the internal diameter is about 14 mm. On the other hand, the quantity of liquid and vapour in the still-head increases regularly with the width of the tube; it is therefore better to use very narrow rather than very wide tubes.

wide tubing

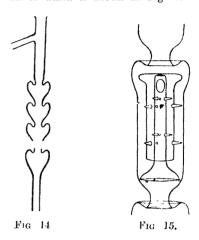

Fig 13

Better contact between liquid and vapour, and therefore greater efficiency, is ensured by sloping the middle part of the tube, the extremities being kept vertical, and the efficiency is further improved by bending the sloping portion so as to form a spiral In Young's 'rod and dise' still-head (Fig 13), the downflow of part of the condensed liquid is

greatly retarded by the discs on the central glass rod, and this liquid is protected from the cooling

action of the air, at the same time, eddies and cross-currents are produced in the vapour. The increase in efficiency caused by the introduction of the easily constructed rod with discs is very marked. Wurtz (Ann. Chim. Phys. iii. 42, 129) recommended a vertical tube with a series of bulbs blown on it, and Young has shown that the efficiency is somewhat increased and the amount of liquid in the still-head is greatly diminished by blowing pear-shaped instead of spherical bulbs on the tube (Fig. 14). The 'rod and disc' and 'pear' still-heads are specially suitable for liquids of high boiling-point.

Greater efficiency, combined with diminished condensation of liquid in the still-head, is attained in Young's 'evaporator' column, one section of which is shown in Fig. 15. The

vapour 118CS up the inner tube, passes down between the inner and middle tubes, and up again between the middle and outer tubes, and so reaches the section above. The liquid condensed in the upper part of the still-head falls in drops from the depression at the top of the section on to the flattened top of the inverted middle tube, and spreads itself over its surface, falling again in drops from the bottom of this tube. The temperature of the vapour passing through the inner tube of any section being higher than the boiling-point of the condensed liquid falling on to the inverted tube, re-evaporation takes place to some extent, and, if there is much difference between the boiling-points of the components of the mixture being distilled, buildition may actually occur. The quantity of condensed liquid in the still-head is thereby greatly reduced. The 'evaporator' still-head is specially suitable for accurate work where great efficiency is required (Chem. Soc. Trans. 75, 679. Wade and Meriuman, stud. 99, 984)

75, 679, Wade and Meruman, ibid 99, 984)

The 'Hempel' still-head (Zeitsch. anal. Chem. 20, 502) consists simply of a wide vertical tube, filled with glass beads of special construction, and constricted below to prevent the beads from falling out A short, narrower vertical tube with side delivery tube is fitted by means of a cork into the wider tube. The advantages of the Hempel apparatus are simplicity and efficiency, but the amount of liquid in the still-head is excessive. Raschig employs thin rings

glass beads, the depth of a ring being about equal to its diameter. Lessing uses split rings, the metal being also bent inwards across the These rings are easier to con- are given in Table II. ring, thus

of copper or some other metal in place of the | struct and give a larger surface; they give very good results Rings are much lighter than beads

The results obtained with various still-heads

In many of the still-heads employed on the large scale, for example in the Coffey still (Fig 28), the condensed liquid is caused, by means of suitable obstructions, to collect into shallow pools, and the ascending vapour has to force its way through these pools, very good contact is thus brought about between vapour and liquid at definite intervals. The excess of liquid is carried back from pool to pool, and finally to the still by suitable trapped reflux tubes. It is convenient to reserve the term 'dephlegmator for this class of still-head The Le Bel-Henninger' (Fig 16) and the Glinsky' (Fig 17) dephlegmators have been very frequently employed for laboratory work, but they do not give good results when small quantities of hquid are distilled; the dephlegmators of Brown (Chem Soc Trans. 37, 49) (Fig 18) and of Young and Thomas (ibid 75, 673) follow the principle of the Coffey still more closely, and are much better in this respect.

In a comparison of the Glinsky, Le Bel-Henninger, and Young and Thomas dephlegmators, each with three sections, it was found that when 400 grams of the mixture of benzene and toluene were distilled, there was not a great difference in efficiency, but the Glinsky

was the least satisfactory With 50 grams of the mixture the differences (Table II) were

quite noticeable, and with 25 grams they were greatly accentuated. With the Glinsky 1 Unnecessarily long

column the highest temperature reached was only 107.6°, and the residue, when distilled from a very small bulb, came over between 102.2° and 1104° No pure toluene was therefore obtained, and the residue left in the still was distinctly less pure than the last portion of distillate collected With the Le Bel-Henninger column the highest temperature was only  $107.25^{\circ}$ , and the residue began to boil at  $105.7^{\circ}$ with the Young and Thomas column the temperature just reached 110 6°, and the residue began to boil at 110 4°. The 'rod and disc,' the 'pear,' and the 'evaporator' still-heads gave better results when only 25 grams of the mixture were distilled, the residue in each case consisting of pure toluene. These results show consisting of pure toluene that for small quantities of liquid the Young and Thomas dephlegmator gives much better results than the Glinsky or Le Bel-Henninger, but that none of them is so satisfactory as the other still-heads.

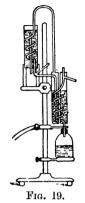

In order that a dephlegmator may give the best results, the following requirements should be fulfilled · 1 It should be possible to greatly increase the number of sections without seriously increasing the fragility of the apparatus the amount of condensed liquid flowing back at any level is greatest at the bottom and least at the top, it follows that, in order to form a pool, more complete obstruction is required at the top of the column than at the bottom 3 Since the amount of condensed liquid in the still-head should be as small as possible consistently with efficiency, the reflux tubes should not be widerin that part which is filled with liquid during distillation-than is necessary to carry back the liquid freely, and the traps should be no deeper than is required to prevent the ascending vapour from forcing its way through them. On the other hand, the upper part of the reflux tubes should be wide, so as to facilitate the entrance 4 There should be a rapid flow of the liquid of condensed liquid through the reflux tubes, otherwise the change in composition of the liquid in these tubes will lag behind that of the distillate 5 There should be a reflux tube connecting each section with the one below it, so that the change in composition may be regular from top to bottom of the column In this respect the Glinsky dephlegmator is entirely wrong in principle 6 When the distillation is completed, the residual liquid should return as completely as possible from the still-head to the still In this respect the dephlegmators as a class are less satisfactory than the other stillheads.

By surrounding the still-head with water or any other liquid, the temperature of which is kept as little above the boiling-point of the more volatile component as will allow of vapour passing through, a considerable improvement in the separation is effected. The temperature of the bath, however, requires very careful regulation if the boiling-points of the components are near together, or if one component is present in large excess, for in either case a fall of a fraction of a degree would cause complete-condensation of the vapour, while a slight rise of temperature would prevent any condensation from taking place, and there would be no fractionation whatever. In constructing a regulated tempera ure still-head, it is advisable to bend the tube into

the form of a spiral, because its effective length may thus be greatly increased without unduly adding to the height of the bath, and also because the spiral form is more efficient than the vertical But Rosanoff and Bacon (J. Amer. Chem Soc 37, 301) find that an annular form of regulated temperature still-head is far more efficient and quite as simple as the spiral tube

form This class of still-head was first recommended by Warren (Annalen, Suppl 4, 51) A better apparatus was described by Brown (Chem. Soc Trans. 37, 49; 39, 517) (Fig 19) A combination of a regulated temperature still-head and dephlegmator was employed by Young and Thomas (ibid. 71, 440) for the separation of normal and iso-pentane from petroleum.

Experiments to test the relative efficiency of these various forms of apparatus have been made by Kreis (Annalen, 224, 259, Claudon, Bull Soc chim 42, 613; Brown, Chem Soc Trans 37, 49; Young, ibid. 75,

679, Fractional Distillation, chaps. 10, 11, and 14; Friedrichs, Zeitschr Angew Chem, 32, 341)

Continuous distillation of wort has long been carried out on the large scale by means of the Coffey still (Fig. 28) In 1902 Carveth (J Phys Chem 6, 253) and Lord Rayleigh (Phil Mag. vi 4, 521) independently suggested apparatus intended for use in the laboratory The liquid to be distilled (or its vapour) is introduced continuously into the middle part of a long spiral or other still-head, the lower part of which is prevented, by means of a liquid or vapour-bath, from cooling below the boiling-point of the less volatile of the two components, while the temperature of the upper part is prevented, by means of a liquid bath, from rising above the boiling-point of the more volatile component. Lord Rayleigh obtained good results in the distillation of weak spirit. It is probable that the method might be made applicable to the distillation of mixtures of three components (Fractional Distillation, 189) See also Rosanoff, U S Pat 1171464 Constant temperature zones are utilised to obtain products of the desired composition

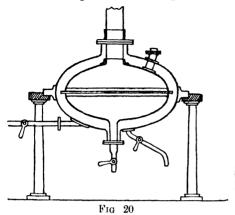

As many of the stills used in the arts are described under the headings Alcohol, Benzene, Paraffin, &c, it will be unnecessary here to give a minute description of all of them, but an account of the principles underlying the different methods will not be out of place

The still is usually made of copper or some other metal, but for special purposes other materials must be employed. Thus for the distillation of sulphuric acid, vessels of glass or platinum are used; for nitric acid, cast iron is found to be the best material; stoneware or glass stills are employed for bromine and iodine; and so on

The still may be heated by the free flame

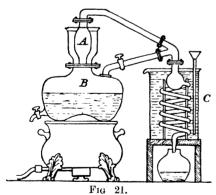

of a furnace or by steam. Fig. 20 shows an arrangement for heating a still with steam, which may be above the atmospheric pressure.

When only a rough separation of the constituents of a complex mixture is required, as in

the preliminary distillation of coal tar, dephlegmators or rectifiers are not employed, but the vapours pass directly from the still to the condenser

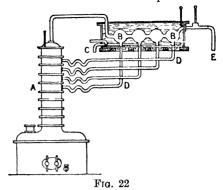

For the better separation of the components of a mixture, modified still-heads are employed A simple apparatus, devised by Mansfield for the distillation of tar oils, is shown in Fig 21, the vapours are partially condensed in the still-head a, which is cooled by water, and the condensed liquid flows back into the still B, the purified vapour passing on to the condenser c

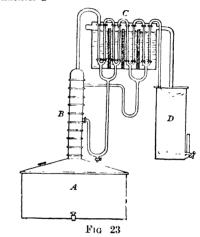

A more perfect separation is effected by Joupier's apparatus (Fig 22) In addition to the column a, there is a series of bulbs, B, B, placed in containing brine, which may be heated by steam by means of the pipe c. The vapour—of benzene, for example—partially freed from ess volatile substances in the column, is further purified by partial condensation in the bulbs, the ondensed liquid flowing back by the tubes D, D nto the column, while the purified vapour passes in to the condenser by the pipe E.

A very similar arrangement is seen in the rench column apparatus (Fig 23) The liquid heated by a steam coil in A; the vapour is

partially purified in the rectifier B; it is further freed from the less volatile components in the

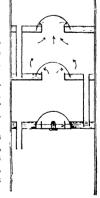

condensing apparatus c, and finally reaches the condenser p

In Savalle's apparatus also the vapours pass first through a dephlegmator or analysing

column, then through a  $\mathbf{or}$ multitubular condenser, which is provided with a water supply, regulated that its temperature is about that of the boiling-point of the liquid required, the liquid condensed in the regulatedtemperature still-head returns to the dephlegmator, and the purified vapour passes on to the cold condenser

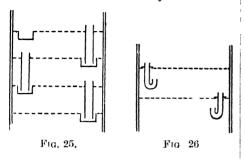

In most of the still-heads employed on the large scale, the vapour first passes through a dephlegmator, the construction of which varies considerably in different cases Dubrunfaut's dephlegmator, employed in

Frg. 24.

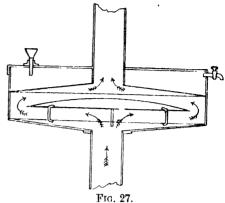

the French column apparatus, is shown in Fig 24. Two others, devised by Savalle, are represented in Figs. 25 and 26.

In the Ergot dephlegmator an arrangement somewhat similar to the dome (Fig 24) is used, but a large number of these domes are placed in each tray, and the condensed liquid is made to follow a zigzag course from the circumference to the centre of each tray

The principle of the still-head in the Pistorius still is quite different. The vapour, entering a section (Fig 27) of the still-head, is deflected from centre to cucumference by the flat dome, it then passes back to the centre above the dome, and is partially condensed by the water in the shallow vessel above—It may be pointed Kubierschky (Ger Pat 269995, 1913)—has out that if, in the Pistorius still-head, the 'roof' devised an excellent column in which the liquid

of the section were depressed at the centre instead of the circumference, the condensed liquid would drop on to the flat dome below, and the arrangement would then be somewhat

similar to that of the 'evaporator' still-head (Fig. 15). In all probability the efficiency of the still-head would thereby be greatly increased.

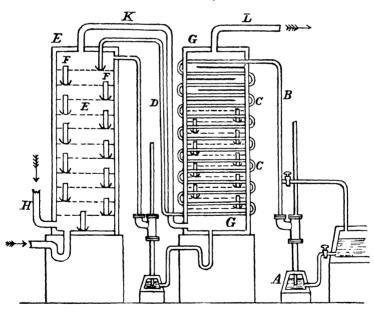

Fig 28

falls in drops through perforated plates, whilst | between two concentric cylinders. The vapour the vapour passes freely upwards and downwards, travelling from centre to circumference and from circumference to centre alternately, coming into intimate contact with the falling drops.

A simple and efficient still-head has been described by Foucar (Eng. Pat. 1999) of 1908) The column consists essentially of a helical

from the still passes up the long spiral passage before reaching the condenser. The inner cylinder can, if desired, be used as a thermostat, the column then acting as a regulated-temperature still-head Dutton (J. Soc. Chem Ind 38, 45 T) has described a still-head, suitable for laboratory work, somewhat similar in principle to Foucer's A spiral of ware is wound round an septum which traverses the annular space inner closed tube which fits quite loosely in the DIURETIN. 569

outer tube of the still-head. But excessive condensation, with consequent priming, must be prevented by covering the tube with a thick layer of cotton wool The still-head is stated to

give very good results

A Hirsch (J. Ind. Eng Chem 1910, 2, 409) recommends the use of a differential condenser in the still-head, in the form of a spiral of metal tubing, through which a current of water of regulated initial and final temperature is caused to flow. The apparatus works easily and well so long as the temperature of the vapour leaving the still-head is considerably lower than that of the vapour entering it, but the difficulty of regulation increases greatly as this temperaturedifference diminishes

For work on the large scale Hirsch recommends the introduction of a differential condenser between the lower and upper parts of

a rectifying column

In England, the Coffey still is largely used, it differs considerably from those described, inasmuch as there is no large boiler, and the heat is supplied, not from an outer fire or steamjacket, but by the condensation of steam in the wort, moreover, the process is continuous essential parts of the apparatus are shown in Fig. 28(p 568) The wort is pumped from a reservoir A, up the pipe B, and passes down the rigzag pipe cc, where it is heated by the ascending vapours. then up the pipe D, from which it is discharged into the column E It is prevented from falling through the perforated plates of the column or analyser by the ascending vapours, but falls through the pipes F, F, from one plate to another until it reaches the bottom, when it is allowed to escape Meanwhile, steam is passed into the analyser E by the pipe H, and causes the wort to boil, so that by the time it has reached the bottom it is completely deprived of alcohol The ascending vapours force their way through the perforated plates of the analyser, a portion of the aqueous vapour being condensed by each washing, and the descending wort being thereby On reaching the top of the column, the concentrated alcoholic vapour passes down the pipe k into the rectifier, and there ascends through similar perforated plates; but in the rectifier it is not washed by wort, but by the weak alcohol formed by the previous condensa-This dilute alcohol, on reaching tion of vapour the bottom of the rectifier, flows off into a reservoir, from which it is pumped into the top of the analyser, where it mixes with the descending In the upper part of the rectifier there are simply shelves, which compel the vapour to take the same zigzag course as the pipe which conveys the wort downwards The purified and concentrated vapour then passes through the pipe L to the condenser In modern continuous stills of the Coffey type there are special arrangements for the separation of (a) volatile impurities such as aldehyde, (b) pure rectified spirit, (c) fusel oil. For details the articles on ALCOHOL, etc., should be consulted S. Y.

**DISTYRENE** C<sub>18</sub>H<sub>18</sub>. Produced by heating styrene (q.v.) with hydrochloric acid at 170° (Erlenmeyer, Annalen, 135, 122) Also, together with distyrenic acid and carbon dioxide, by prolonged boiling of cinnamic acid with diluted sulphuric acid (Fittig Ber 12, 1739-1744; Erdmann, Annalen, 216, 179-199).

A colourless optically inactive oil, with a blue fluorescence, which gradually disappears; sp gr. 1016 at 15°; b.p. 311° On prolonged boiling yields toluene, isopropylbenzene, and some styrene; whereas metastyrene, produced from styrene on keeping, or heating in sealed tubes at 200° (Kovalevsky, Annalen, 120, 66), or with aqueous sodium bisulphite at 110° (Miller, *ibid.* 189, 341), passes almost quantitatively into styrene at 320° (Stobbe and Posjnak, ibid 371, 259-286)

Distyrene yields benzoic acid on oxidation with chromic acid; and a crystalline dibromide C<sub>16</sub>H<sub>16</sub>Br<sub>2</sub> (m p. 102°) on brominating in carbon disulphide solution

According to Stobbe and Posinak (Annalen, 371, 287-302), distyrene is  $\alpha \gamma$ -diphenyl- $\Delta^{\alpha}$ -butene

$$C_6H_5-CH=CH-CH(CH_3)-C_6H_5$$

Distyrene disulphonic acid (dicinnamene disulphonic acid) C16H14(SO3H)2, described by Lange as obtained on heating  $\gamma$ -truxillic acid with sulphuric acid (Ber 27, 1410-1415), is therefore not a derivative of distyrene

Solid distyrene; mp 124°; obtained by distilling cinnamic acid or its calcium salt (Engler and Leist, Ber 6, 256; Miller, Annalen, 189, 340), and by passing C<sub>6</sub>H<sub>5</sub>C<sub>2</sub>H<sub>3</sub>Br, over red-hot lime (Radziszewski, Ber 6, 494), has been shown by Erlenmeyer (Annalen, 372, 249-251) to be stilbene.

DISÚLPHO ACID S. Delta acid, 1-Naphthylamine-4 8-disulphonic acid v NAPHTHALENE.

DITA BARK. Satween (Ph J'Trans [3] 7, 110) The bark of Alstonia scholars (R Br), an apocynaceous tree found in India, the Philippines, Eastern Australia, and tropical Africa (Ber 11, 2234)

According to Harnack (ibid Chem Soc Trans [2] 36, 332), it contains only one base, ditaine, a basic glucoside, having the composition C<sub>22</sub>H<sub>30</sub>N<sub>2</sub>O<sub>4</sub>; but Hesse (Annalen, 203, 144; Ber 13, 1750, Pharm J [3] 11, 251, 331) found in it three bodies ditamine,  $C_{16}H_{19}NO_2$ ; echitamine (cchitammonium hydroxide),  $C_{22}H_{28}N_2O_4$ ,  $H_2O$ , melting with decomposition at 106° (this base is identical with Harnack's ditaine), and echitenine C<sub>20</sub>H<sub>27</sub>NO<sub>4</sub>, a brown amorphous mass, melting above 120°, soluble in chloroform, alcohol, and ether dissolves in nitric acid with the production of a purple-red colour which quickly passes through green into yellow

The milky juice of this tree has the same properties as guttapercha; when inspissated it softens in boiling water, is soluble in turpentine and chloroform, and receives and retains impres-A decoction of the bark is used as an sions astringent tonic.

DITAINE v DITA BARK
DITHION. Trade name for sodium dithiosalicylate: used as an antirheumatic.

DITTANY. The root of Dictamnus albus (Linn) (ord Rutacea, a native of the south of Europe It contains a volatile oil, and also resin, bitter extractive matter, and gum, and was formerly employed in medicine, especially for the treatment of epilepsy (Aldis, Lond. Med. Gaz 19, 142).

'Cretan Ditany' is the common name for Origarum dictamnus (Linn ), a native of the Levant DIURETIN. A compound of sodium 570 DIURETIN.

theobromine and sodium salicylate (v. Synthetic DRUGS)

DIVICINE v. VICINE.

DIVI-DIVI. Divi-divi consists of the dried pods of the Cæsalpınıa corıarıæ (Willd), a tree 20-30 feet high, found in the West Indies and Central America The pods are about 3 inches long and 3 inch broad, are very thin, and frequently resemble in shape the letter S From 40 to 45 pc of tannin is present, which consists of ellagitannin and probably also gallotannin. Extracts of this material have a somewhat unfortunate tendency to ferment, with simultaneous development of a deep-red colouring matter, but this can be prevented to some extent by the use of antiseptics Divi-divi is largely imported for the preparation of leather, and is also employed for black dyeing, but its use is far more limited in this latter respect than myrabolans

DOCIMACY or DOCIMASY. (Docimasie, Fr.) Originally the act or art of examining by test (δοκιμασία, a test), applied in metallurgy to experiments made to determine the nature and purity of a metal; in pharmacy, to the testing of medicines and poisons, in medical jurisprudence, to the different proofs to which the lungs of a new-born child are subjected, for the purpose of ascertaining whether it was born alive or dead (Dunglison) Usually employed in chemistry as synonymous with assaying

## n-DODĚCANĚDICÁRBOXYLIC ACÍD

CO2H(CH2)12CO2H

Prepared by hydrolysing the diethyl ester obtained by the electrolysis of an aqueous solution of the monoethyl ester of suberic acid (Brown and Walker, Annalen, 261, 123), or by the oxidation of chaulmoogric acid, obtained from chaulmoogra seeds (Barrowcliffe and Power, Chem Soc Trans 1907, 568), mp 123°.

DODECATOIC ACIDS C<sub>12</sub>H<sub>24</sub>O<sub>2</sub>.

1. Lauric acid, found by Marsson in laurel fat, a glyceride obtained from Laurus nobilis (Linn) (Marsson, Annalen, 41, 330), also present in cocoa-nut oil (Gorgey, ibid 66, 295), in pichurin beans, in Dika bread, and in the fruit of Cylicodaphne sebifera (Oudemans, Zeitsch 1867, 256); mp 435, (mp 475°-48°, Levene and West); spgr 0883/20° and 0875/436°; bp 2255°(100 mm)

2 Horderc acid is found among the products of the distillation of dried barley with dilute sulphuric acid; forms crystalline plates; m p 60° (Beckmann, J. 1855, 513). DOG-TOOTH SPAR. The scalenohedral form

of calcspar (v Calcite or Calcspar) **DOLERITE.** An igneous rock composed essentially of plagioclase-felspar (labradorite to anorthite) and augite, and of the same general chemical and mineral composition as the coarsegrained plutonic gabbros and the fine-grained volcanic basalts, but intermediate in texture between these two extreme types. Other minerals may also be present, especially olivine, giving the varieties olivine-dolerite, enstatite-dolerite, hornblende-dolerite, mica-dolerite, and quartz-dolerite. Accessory minerals, usually present, are magnetite and ilmenite, and secondary minerals, produced by alteration, include quartz, calcite, epidote, chlorite, ind serpentine. Dolerites occur as intrusive veins,

dykes, and sills; and very often they pass imperceptibly into basalts. The texture may be coarse enough for the individual mineral to be distinguishable to the unaided eye, or it may be so fine that these can only be distinguished in thin sections under the microscope In the latter case the rock is compact and dark greenish-black or black in colour. Often, owing to the presence of secondary minerals, the colour is distinctly green, and the rock is then frequently included under the general term 'greenstone.' The specific gravity ranges from 2 8 to 3 0, and the crushing strength is about 1500 tons per square foot The following analyses are of dolerite from I, Rowley Regis, Staffordshire; II, Clee Hill, Shropshire; III, quartz-dolerite from the Whin Sill, Co Durham (including MnO 0·16, CO<sub>2</sub> 0·19, P<sub>2</sub>O<sub>5</sub> 0·25, FeS<sub>2</sub> 0·49), IV, olivine-dolerite from Skye (including MnO 0 17, BaO 0 06, P<sub>2</sub>O<sub>5</sub> 0 17)

	I.	II.	III.	IV.
SiO,	490	48 4	$51\ 22$	$50 \ 33$

Na <sub>2</sub> O	25	3 1	2.55	4 30
$H_2O$	3 3	2 2	1 28	1.86

Dolerites are of wide distribution and are much quarried for road-metal and paving-setts. Being difficult to work and of a dull colour, they are not much used as building stones (v DIABASE) L J. S

This term includes both dolo-DOLOMITE. mite-spar and dolomite-rock, both of which are often referred to simply as dolomite They bear the same relation to one another as calcite (calcspar) to limestone, and as quartz to quartzite; these being cases in which a single mineral species builds up a rock-mass. The name dolomite, after the French geologist, D. G. Dolomieu (1750-1801), was first applied to the rock, being later extended to the crystallised mineral The rock is now often referred to as dolomitic limestone or magnesium limestone.

The pure mineral (Dolomite-spar) is a double salt of calcium and magnesium carbonates, CaMg(CO<sub>3</sub>)<sub>2</sub>; containing CaCO<sub>3</sub> 54·28, MgCO<sub>3</sub> 45·72 p.e., or CaO 30·42, MgO 21·86 p.e. It is a member of the isomorphous series of rhombohedral carbonates (calcite group), and has an angle of 73° 45' between the surfaces of the perfect rhombohedral cleavages It, however, differs from the other members of the group in the degree of symmetry of its crystals, which are hemihedral with parallel faces. It further differs from calcite in the fact that it never shows lamellar twinning on the obtuse negative f The mostusual form of rhombohedron crystal is the primary rhombohedron, the faces of which are parallel to the cleavage directions (this being an unusual form in calcite, except in combination with other forms). The faces are frequently curved, sometimes to such an extent that the crystals are saddle-shaped. The most perfect crystais, such as those found 11 the crystalline dolomite rock of the Binnenthal DOLOMITE.

in Switzerland, are colourless and transparent with a vitreous lustre. More often the crystals are white or creamy-white and opaque with a pearly lustre; hence the popular name pearl-spar The mineral is harder (H. 3½-4) and denser (sp gr 2 85) than calcite 1t may be readily distinguished from the more commonly-occurring calcite by the fact that it is only slightly attacked by cold dilute acid; in hot acid it dissolves with a brisk effervescence Dolomite is much less soluble in water containing carbon dioxide (3 parts in 10,000 at 18°) than is calcite Various micro-chemical tests have been devised for the purpose of distinguishing dolomite and calcite, especially in thin sections of rocks Lemberg's solution contains aluminium chloride and a staining material (haematoxylin or an aniline dye); a stained film of aluminium hydroxide deposits on calcite, but not on dolomite composition of dolomite may be varied somewhat by isomorphous replacement Iron and manganese may replace magnesium, forming a passage through brown spar to ankerite (qv) Zinc or cobalt is also sometimes present in small amount. Any excess of calcium over the double salt ratio may perhaps to some extent be present in isomorphous mixture, but more often it is probably present as mechanically admixed calcite Simple ratios of CaCO<sub>3</sub> MgCO<sub>3</sub> other than the 1·1 of 'normal dolomite,' probably do not exist Several trivial names have been applied to varieties of dolomite showing pecuharities of structure or supposed differences in composition, the analyses have not, however, always been made on well-crystallised material

The best crystallised specimens of dolomite are met with in mineral veins and other metalliferous deposits. For example, with iron ores at Traversella in Piedmont, and Cleator Moor in Cumberland; with lead and zinc ores at Laxey in the Isle of Man, and Jophin in Missouri, with silver ores at Schemnitz in Hungary, and Guanaxuato in Mexico Crystalline masses occur in serpentine, tale-schist, and other magnesian silicate rocks. As a rule, only quite small crystals are found in dolomite rocks, but occasionally good crystals are found in cavities.

Dolomite rock, dolomitic or magnesian limestone, is, as a rule, more indefinite in its characters and composition, since here the dolomite mineral is mixed with other mineral substances, such as calcite, carbonates of iron and manganese, oxide and hydroxides of iron, argillaceous matter, quartz, etc. With increasing calcite the rock may pass into ordinary limestone, and some authors restrict the term 'magnesian limestone' to rocks intermediate between 'normal dolomite' and ordinary limestone. The presence of calcite in a magnesian limestone containing a molecular excess of calcium over magnesium may be demonstrated by etching a polished surface or a thin section with cold dilute acid, when the calcite will be readily dissolved out leaving pits; or by means of the staining test with Lomberg's solution mentioned above

The purest dolomite rocks are the snow-white crystalline dolomite marbles of the Swiss Alps, Norway, &c, which have sometimes the character of a statuary marble and can be used for ornamental purposes More often, however, the rock is yellowish, grey, creamy, or brown, and very often cavernous in texture. It is

usually minutely crystalline, consisting of an aggregate of tiny rhombs of dolomite-spar more or less firmly held together, but at times quite loose and sandy Dolomite rock is of wide distribution and is met with in sedimentary strata of all geological periods In England a long narrow outcrop extends along the eastern slopes of the Pennines from Nottinghamshire to the Durham coast. This has long been extensively quarried as a building stone, the principal quarries being near Anston in Yorkshire, Bolsover Moor in Derbyshire, and Mansfield Woodhouse in Nottinghamshire Here the rock is of Permian age In the Dolomite mountains of southern Tyrol the rock is of Triassic age, whilst that of Swabia belongs to the Jurassic formation

571

The origin of dolomite rock has been a subject of much speculation and experimental work of a chemical character. A review is given in Doelter's Handbuch der Mineralchemie, 1912, vol 1 (here also 1s given a large collection of analyses, methods of analyses, &c) That of Permian age, which is usually associated with beds of gypsum and rock-salt, is supposed to have been deposited as the double carbonate by chemical precipitation from the salt waters of mland seas In some other cases the rock has been formed by the action of magnesium-bearing solutions on limestone, either contemporaneously and progressively with the formation of the limestone (as proved by the dolomitisation of coral-limestone-the magnesium in this case being derived from sea-water), or long subsequently by the action of subterranean mineralwaters percolating along the bedding and joint planes (as in the Carboniferous Limestones of Derbyshire and South Wales) Or again, it may have been formed by weathering and the solution of the more soluble calcium carbonate from limestones containing a small proportion

The following are analyses of dolomite rock I, from Bolsover, Derbyshire, II, Mansfield, Nottinghamshire, III, Anston, Yorkshire; IV, Southern Tyrol—

i			I	II	III	IV
CaO			28.6	29.0	30.7	31 4
Mg()			19.2	20 4	20 6	192
Fe,O,	, Al,	$_{2}O_{3}$	18		0.73	12
SiO			3 6	3 7	0.56	10
co,		. 4	43 5	44 9	46 7	46 l
H,Ö			3 3	2 1	0.75	

The economic applications of dolomite are confined to the rock, since this is much more plentiful and of wider distribution than the crystallised mineral Its principal use is as a building stone For this purpose it is more suitable than ordinary limestone, being harder and more resistant to solvents, but it needs to be carefully selected It is also used for paving and road-metal The Houses of Parliament are built of stone from the three English localities noted above (Anal I-III) The stones from these quarries have a crushing strength of 484-883 tons per square foot, absorption of 4.6-7.5 pc, and weigh 134-152 lbs per cubic foot Certain varieties of dolomite rock (dolomite marble) find an application as an ornamental Dolomite rock is also extensively used 8.one for the basic linings of Bessemer converters and

572 DOLOMITE

open-hearth furnaces in the manufacture of For this purpose the rock is calcined until it commences to sinter, crushed, mixed with gas-tar, and moulded in the furnaces or The best result is obtained shaped into bricks when the rock contains 3-4 p c of Fe<sub>2</sub>O<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub>, and about  $2\frac{1}{2}$  p c of SiO<sub>2</sub> (On British sources of dolomite rock for use as a refractory material, v Mineral Resources of Great Britain, Mem Geol Survey, 1918, vol v1) The rock is completely burnt or half burnt below a red heat (giving MgO-+CaCO<sub>3</sub>) for the preparation of cements and plasters, when it contains quite a small amount of argillaceous matter it gives a good hydraulic cement It is also burnt for agricultural purposes, and is said to be especially beneficial for leguminous crops It is a readily available source for the manufacture of magnesium compounds, eg Epsom salts, magnesium chloride, magnesia alba, but in this direction it was not able to compete with the large quantities of soluble magnesium salts obtained as by-products from the Prussian salt-deposits Various processes have been suggested for extracting the magnesia for use as a refractory material In one, the calcined dolomite is forming mixed with magnesium chloride, calcium chloride which is readily removed in In another, the calcined dolomite is treated with a solution of sugar, when the calcium passes into solution as saccharate, from which the sugar can be recovered by precipitating the calcium as carbonate with carbon dioxide When half burnt to  ${\rm MgO+CaCO_3}$ the magnesia can be extracted by carbonated water under pressure

The pure white dolomite marble is used for the manufacture of pure carbon dioxide for use in the manufacture of aerated waters LJS

**DOMEYKITE.** A copper arsende, Gu<sub>3</sub>As, corresponding to copper 71 7 and arsenic 28 3 p c It occurs in reniform, botryoidal, and compact masses, of white or grey colour, with metallic lustre, rapidly tarnishing H=3-3.5, sp.gi 7-7.5 Readily fusible before the blowpipe, with emission of arsenical vapours Soluble in nitrie acid, but not in hydrochlorie acid found at Coquimbo and Copiapo in Chile, at Cerro las Paracatas in Mexico, and at Zwickau in Saxony

Several other arsenides of copper, more or slike domeykite, are known The Algodonite less like domevkite, are known of F Field is Cu, As, and occurs at the Algodones mine, near Coquimbo. Whitneyite, from Houghton Co, Michigan, US, described by F A Genth, is Cu<sub>2</sub>As, and D. Forbes's Darwinte, named after Charles Darwin, is a similar mineral from near Copiapo Condurrite, from Condurrow mine, Cornwall, appears to be a mixture of arsemide of copper with various oxidised products derived from the alteration of tennanite or some kindred species The names Keweenawite, Mohawkite, and Ledouxite have been applied to various copper arsenides from Michigan, in which the copper is in part replaced by nickel and cobalt L J S.

**DONARITE.** An explosive consisting of a mixture of ammonium nitrate (80 pts), trinitrotoluene (12 pts), nitroglycerine (3 8 pts),

gun-cotton (0 2 pt, flour (4 pts)

DORMIGENE. A urea derivative of a-brome Used as a nervous sedative. isovalerianie wid

DORMIOL. A condensation product of chloral and tertiary amyl alcohol. V. SYNTHETIC

DOSS. Japanese name for a dyewood from an evergreen tree Ilex Mertensii (Maxim), found in the Ogasawara and Okinawa Islands. Contains a dyestuff, dossetin C<sub>15</sub>H<sub>9</sub>O<sub>5</sub>, crystallising in yellow needles; m p. 271 -272° (Ito, J Soc Chem Ind 1908, 440)

DOUBLE SCARLÉT, BRILLIANT SCARLET v Azo- colouring matters

DRACYL. An obsolete synonym for toluene DRAGON'S BLOOD. A resin used as a red pigment (v Pigments; also Resins)

DRIERS (in the United States also termed 'Japans') is the trade term for those metallic oxides, chiefly oxides of lead, manganese (litharge, red lead, manganese dioxide) and cobalt or their inorganic salts, which were formerly used exclusively in the process of oil boiling as 'driers.' More recently acetate, oxalate, and borate of manganese have been employed Since metallic salts of abietic acid have the same property, such salts are also manufactured as 'driers' They salts are also manufactured as 'driers' are obtained either by precipitating rosin soap solutions with solutions of metallic salts, or by fusing together a metallic oxide with colophony Hence these are distinguished in commerce as 'precipitated' driers, and 'fused' driers. The latter are readily discriminated from the former by their not containing any moisture salts of linseed oil fatty acids are now used as driers, they can be prepared either by precipitation or by the dry process, hence both 'precipitated' manganese linoleate, 'precipitated' lead linoleate, and 'fused' manganese linoleate, &c, are obtainable The driers prepared from linseed oil fatty acids, as also from rosin (colophony), are soluble in oil of turpentine, ether, chloroform, and linseed oil Hence they are also termed in commerce ıtself Solutions of these driers in soluble driers' linseed oil or in turpentine oil, or in a mixture of both, are obtainable in commerce under the name 'liquid driers,' 'terebene,' and other fancy names.

The function of these driers appears to be to absorb oxygen from the air and transfer it to the linseed oil, thus accelerating its drying to a flexible film when exposed to the air this assumption, the fact that litharge and manganese dioxide act as driers will be best explained by stating that at the high temperature at which linseed oil is 'boiled,' the oxides saponify the linseed oil, forming therewith lead or manganese soaps, which then act in their turn in the manner indicated above From experiments on the behaviour of cerium salts obtained from various drying oils, Morrell (Chem. Soc Trans 1918, 113, 111) concludes that a change occurs in the intra-molecular linkings when drying oils are polymerised by heat action of cerium a-eleostearate (from tung oil) as a drier may be represented by the following scheme :-

scheme :—
$$\begin{array}{c} \operatorname{CeX}_3 \text{ or } \operatorname{CeOX}_6 \Longrightarrow \operatorname{Ce}_2(\operatorname{XO}_2)_6 \\ \operatorname{CeO}(\operatorname{XO}_3)_6 + \operatorname{drying} \text{ oil} \\ \Longrightarrow & \operatorname{CeX}_3 + \operatorname{OCHY} \\ & | & | & | & | & | \\ \operatorname{OCHZ} \end{array}$$
This representation is also in accord with the

conclusions of Ingle (J Soc Chem Ind, 1917, 318) as to the behaviour of lead linolenate Cerium driers are less effective than cobalt or manganese linoleate in accelerating the drying of a varnish containing a lead drier. The following are the analytical data obtained by the author in the examination of a drier.

	Per cent.	•
Ash	18 6	
Fatty and rosin acids .	. 834	

The more detailed examination gave the following result -

		Per cent
Lead oxide		10.99
Manganous oxide		6 79
lron peroxide	•	0 47
Calcium oxide		0 56
Rosın acıds		$38\ 32$
Oxidised acids		4 24
Other fatty acids		40.86

It should, however, be understood that the results furnished by chemical analysis alone are not sufficient to supply the data on which to base an opinion as to the properties which a drier will impart to the oil. The colour and drying power of the boiled oil to be prepared and other conditions greatly influence the choice and the quantity of a drier to be employed on a large scale.

DROP GUM or GAMBOGE v PIGMENTS

DROSERA WHITTAKERI. Drosera whittakeri is found in Australia, and grows plentifully on the hills near Adelaide. The tuber of this plant consists of an inner solid but soft nucleus full of reddish sap or juice, and an outer series of easily detached thin, and more or less dry, layers of an almost black material. Between these layers are to be found small quantities of a brilliant red colouring matter, the amount varying in tubers of different size and age, but apparently more plentiful in the older plants (Rennie, Chem. Soc. Trans., 1887, 51, 371., 1893, 63, 1083)

63, 1083)

The colouring matter is extracted from the tubers by means of hot alcohol, the solution evaporated, and the residue, containing a little alcohol, is then mixed with water and allowed to stand. The product is dried, sublimed, and the billiant vermilion powder, which contains two substances, is fractionally crystallised from boiling alcohol, or acetic acid.

The more sparingly soluble compound  $C_{11}H_8O_5$  forms red plates, melts at 192°-193°, dissolves in alkaline solutions with a deep red violet colour, and gives a triactifi derivative,  $C_{11}H_5O_5(C_2H_4O)$ ,, melting-point 153°-154°

 $C_{11}H_5O_5(C_2H_3O)$ , melting-point  $153^\circ$ - $154^\circ$  The monosodium compound  $C_{11}H_1O_5Na_2H_2O$ , gives dark reddish-brown needles, the disodium compound  $C_{11}H_6O_5Na_22H_2O$ , brown needles, and the calcium compound  $(C_{11}H_1O_5)_2Ca_3H_2O$ , dark brown crystals

By treatment with stannous chloride or hydrochloric acid, this substance  $C_{11}H_{10}O_{5}$  yields a reduction product  $C_{11}H_{10}O_{5}$ . yellow needles, melting-point  $215^{\circ}-217^{\circ}$ . When dry, this is stable in air, but if left in contact with alcohol or water, it soon becomes red owing to exidation According to Rennie it is probable that the original colouring matter is a trihydroxymethylmaphthogramme, in which case the substance  $C_{11}H_{10}O_{5}$  will consist of the corresponding

hydroquinone derivative. The more readily soluble compound contained in the tubers possesses the formula  $C_{11}H_8O_4$ . It crystallises in red needles, melting-point  $174^\circ-175^\circ$ , dissolves in alkaline solutions with a deep-red colouration, and gives a diacetyl derivative,  $C_{11}H_6O_4(C_2H_7O)_2$ , yellow needles, melting-point  $107^\circ-110^\circ$ .

**DRUMINE.** An alkaloid stated to be present in Euphorbia Drummondii (Ogston, Brit.

Med Jour 1887, 451)

DRY CLEANING. French or chemical cleaning, Nettoyage à Sec A process of removing dirt, grease, &c, from fabrics by solvents other than water, such as petroleum benzine, coal-tar benzene, carbon tetrachloride, &c. The substitution of such liquids for water seems to have been first made in France during the middle of the last century by the application of 'camphene,' a terpene used at that period for illuminating purposes

The process was introduced into the United Kingdom, in 1866, by Messrs Pullar & Sons, who greatly developed it, employing machinery to a large extent in place of the hand labour

formerly used

The solvents mainly used at the present time are 'benzines,' usually obtained from American and Borneo petroleum, of sp gr 0 78; boiling between 80° and 120° The benzols employed are what are known commercially as 90's and They may contain sensible quantities of carbon disulphide, thiophen, and possibly other sulphur products, which are apt to impart a disagreeable smell to the fabric Carbon tetrachloride, on account of its relatively high price, is only used to a limited extent It has the great advantage over the hydrocarbons that it is uninflammable, and can be employed in particular cases where the use either of benzine or of benzol is madmissible (For a method of valuing benzine for the purpose of the dry cleaner, v Trotman, J Soc Chem Ind 1906)

Thiophen in benzol may be detected by the isatin and sulphuric acid reaction (v Thiophen).

(Cf Schwalbe, Chem Zeit 1905)

Carbon disulphide may be detected by the formation of a precipitate with phenylhydrazine, and determined quantitatively by conversion into potassium xanthate by means of alcoholic potash (v Carbon disulphide)

An admixture of paraffin hydrocarbons with the benzol may be recognised by nitrating the sample with nitrosulphuric acid and subsequent

steam distillation.

The carbon tetrachloride employed for degreasing should be free from hydrochloric acid or traces of free chlorine. It should also contain no chloroform or phosgene gas, which are apt to

act deleteriously upon the workpeople

Special soaps, soluble in benzine, are employed in dry cleaning. They not only assist the degreasing, but diminish the risk of fire. The soaps consist of practically anhydrous oleates or stearates of potash or soda made by melting together oleic acid and soap, or by dissolving the alkali in methylated spirit, and adding to the solution the requisite quantity of oleic acid or melted stearic acid. Strong ammonia solution may be employed instead of potash or soda.

(For a description of the methods and

machinery employed in modern processes of dry cleaning, and of the apparatus for the recovery and purification of the solvents used, v. Dyeing and Cleaning, by F J. Farrell, Griffin & Co, Ltd. 1910)

**DULCAMARA.** Buttersweet, Woody night-de. (Douce amère, Fr , Buttersuss, Ger) shade. (Douce amère, Fr, The young branches of the Solanum dulcamara (Linn), were formerly administered as a decoction in rheumatism and skin diseases contain an amorphous glucoside dulcamarin C<sub>22</sub>H<sub>34</sub>O<sub>10</sub> (Geissler, Arch Pharm [iii.] 6, 1010); 

DULCIN. p-Phenetol-carbamide

C2H5O C6H4 NH CO NH2

Used as a substitute for A sweet substance saccharın

**DURENOL** v PHENOL AND ITS HOMOLOGUES DUTCH PINK or ITALIAN PINK v Pig-

DUTCH ULTRAMARINE. Cobalt blue v COBALT AND PIGMENTS

**DURINE.** A preparation of formaldehyde **DYEING.** The art of dyeing consists in imparting colour to the substance of various

materials, usually textile fabrics, in such a manner that it is not readily removed or altered by those influences to which the dyed material is subsequently exposed Tinting is essentially the same as dyeing, but the term is applied to the production of light shades only. In staining, the colour is not so permanently fixed as in dyeing, but in all these processes the colouring substance is presented to the material in a dissolved condition. In textile printing, the colour is applied to portions of the material only, thus producing a pattern, but in other respects, many printing operations are, in principle, similar to dyeing. In some processes of textile printing, as in painting, on the other hand, a more or less opaque pigment is applied to the surface of the material by means of adhesives, thus partially or entirely obscuring the true surface.

Dyeing is of chief importance in connection

with the textile industries, but many other materials are coloured by dyeing processes, such, for example, as leather, feathers, horn, ivory, bone, straw, and wood.

The various materials above enumerated remarkable differences in behaviour towards any particular dyestuff. Wool, silk, leather, feathers, horn, and animal skin products in general, behave somewhat similarly towards colouring matters, but the dyeing properties of cotton, linen, and other vegetable products are quite different.

Differences quite as marked are to be noted in the behaviour of various colouring matters towards one and the same material, and thus, in dyeing operations, both the nature of the material to be dyed and of the colouring matter

employed, have to be taken into account

The theory of dyeing. The precise cause or causes of the different behaviour of the textile fibres in dyeing is still a matter of uncertainty, but there is little doubt that the chemical and physical properties both of the fibre and of the dyestuff are all factors of the complicated phenomena of dyeing

The earliest theory with regard to the fixation of dyes was that the action is purely mechanical, and it is still urged by many that rarely in dyeing processes is there direct evidence of chemical combination between fibre and dye-Both bodies, as a rule, retain their individual chemical and physical properties unchanged, and the dye can frequently be removed from a fibre by means of alcohol or other solvent

In its earliest form, the mechanical theory was put forward by Hellot and d'Apligny in 1780 (See Hellot's L'Art de la Temture des Lames (1734), and d'Aphgny's L'Art de la Teinture des fils de Coton (1776)) They assumed that the particles of colouring matter became embedded in the minute pores permeating the fibre substance Crum (Chem Soc Trans. 16, 404) strongly supported this theory, while Muller-Jacobs (J Soc Dyers, 1885, 63) expressed much the same idea in attributing the fixation of dyes to membranous diffusion. It has, however, been shown by several investigators that dyeing processes do not obey the general laws of osmosis. v Georgievics (J Soc Chem Ind 1895 149) considers dyeing is chiefly due to surface attraction Witt (Farber-Zeit 1890) put forward a modification of the mechanical theory. He regards the fibres as solid solvents in which the dyestuffs dissolve, the latter being withdrawn from its aqueous solution in the same way as, eg. ether will extract many substances from their aqueous solution The degree to which a dye-bath can be exhausted will then depend upon the relative solubility of the dyestuff in the acid or neutral dye liquor and in the fibre substance under the conditions (concentration and temperature) used Krafft (Ber 1899, 1608) attributes dyeing phenomena to a separation of the dyestuff upon the fibre in a colloidal state, and this view has been supported by Biltz (ibid 1904, 1766), Linder and Picton (Chem. Soc. Trans 1905, 1931), and Dreaper (J Soc. Chem. Ind 1905, 223)

The chemical theory of dyeing was originally put forward by Macquer and Bergman in opposi-tion to the mechanical theory of Hellot and d'Apligny, and has received much experimental

support from Persoz, Berthollet, Chevreul, Kuhlmann, Vignon, Knecht, and many others It is mainly based on the following facts: wool and silk fibres contain amino-acids, and thus possess strongly marked acidic and basic functions Cellulose, the essential constituent of the vegetable fibres, is chemically much less active, and lyes much less readily than wool and silk, but under certain conditions it exhibits weakly acidic All dyestuffs (with few exceptions) possess either acidic or basic properties, or are in the form of salts, which dissociate in the dyebath, and chemical combination between fibre and dyestuff would thus, primâ jacie, be expected Moreover, lanuginic and sericinic acids, which are produced respectively by the hydrolysis of wool and silk, precipitate both acid and basic dyes from their aqueous solution (Knecht and Appleyard, J Soc Dyers, 1889, 72)

A full discussion of the evidence for and against the mechanical and chemical theories of dyeing cannot be here entered upon, but a general review indicates that the attempt to cover all dyeing phenomena by any one simple explanation must fail, and that many factors are concerned, the relative importance of which varies in different cases In the dyeing of wool or silk, with acid or basic dyes, it may be taken as established that chemical combination occurs, but prior to this some hydrolysis of the fibre, and more or less complete ionisation of the dye-Surface concentration of the stuff takes place dye on the fibre probably also occurs, and the coagulation and precipitation of the dissociated colloidal dyestuff also plays a part supported by the observation that the temperatuie of maximum absorption of dye does not (in the cases investigated) correspond with that of maximum fixation (Dreaper, Trans Faraday Soc 1910, pt 1 Haldane-Gee and Harrison, ibid); the former possibly coinciding with the point of maximum coagulation and precipitation, and the latter indicating the point of maximum degree of chemical combination. Whether the superficially precipitated dye penetrates the fibre by osmosis or by 'solid solution' is mainly a question of definition of terms

In the case of the dyeing of vegetable fibres, the same factors probably operate, but their relative importance is not the same, the physical factors—precipitation, surface attraction, and osmosis—predominating over the effect of direct chemical action

Classification of colouring matters. It has already been pointed out that dyestuffs vary in their behaviour If, e g separate pieces of wool are boiled in solutions containing,  $(\hat{a})$  logwood, (b) indigo, (c) magenta, and (d) pieric acid, the following results are obtained: (a) the wool acquires a brown stain; (b) the wool remains undyed, the indigo floating about in an insoluble condition (c) the wool is dyed a magenta colour; and (d) the wool is dyed a full yellow If the experiment is repeated on wool which has been previously boiled with a solution of potassium dichromate, the result will be that in (a) the wool is dyed black, whereas in (b), (c), and (d), similar results are obtained to those of the Logwood, therefore, previous experiments must be applied in conjunction with potassium dichromate or some similar substance, i.e. with a mordant; whereas magenta and picric

acid dye without such aid, and indigo requires a special process, the nature of which is not indicated by the results of the above-described experiments.

Colouring matters may be divided into three groups on the lines indicated above, viz. (1) those which must be applied in conjunction with a mordant, (2) those which dye direct from their solutions; and (3) those requiring special processes

As regards groups (1) and (2) this classifica-tion is practically identical with that of Bancroft (Philosophy of Permanent Colours, 1 118, London. 1794), who, upwards of a hundred years ago, divided colouring matters into substantive dyes and adjective dyes, the former class comprising those which dye directly from their solutions, and the latter being composed of those dyes which require mordants Nietski (Farber-Zeit 1889-90, 8) uses the terms direct dyes and mordant dyes in exactly the same sense, and both Bancroft's and Nietski's terms are still in use. Hummel (The Dyeing of Textile Fabrics, 1st ed. 1885, 147) also classifies dyestuffs into two groups. monogenetic dyes being such as are capable of producing one colour only, while polygenetic dyes produce distinct colours with different mordants The members of the first group are coloured bodies, and these merely require to be fixed upon the fibre, whereas the colouring principles comprising the second group as a rule only develop a colour when chemically combined with a mordant

It will be seen that these three systems of classification closely correspond, the terms substantive dyes, direct dyes, and monogenetic dyes being almost synonymous, as are adjective dyes, mordant dyes, and polygenetic dyes. It should, however, be pointed out that none of these classifications is absolute, magenta, for example, is a direct dye as applied to wool, but requires a mordant when used for cotton.

A distinct method of grouping dyestuffs is that of Benedikt (The Chemistry of the Coal-tar Colours, 1886, 29), who distinguishes between colour acids, colour bases, and neutral colouring Both colour acids and colour bases are fixed on the fibre in the form of salts, but whereas in the colour acids the essential colourproducing group resides in the acid portion of the compound, in the colour bases the reverse is Alizarin ied, dyed on wool, is a salt of which alumina forms the basic and alizarin the acidic constituent Alizarin is therefore a colour acid. Similarly, the red pigment formed on dyeing tannin-moidanted cotton with magenta is a combination of rosaniline base with tannic acid Magenta is therefore a colour base. Indigo and other vat dyes are neutral colouring

All the above schemes of classification are defective, either from the point of view of the practical dyer, or the chemist As regards practical application, the large number of dyestuffs now on the market may, however, be satisfactorily classified into the following groups: (1) mordant dyes, (2) acid-mordant dyes; (3) acid dyes; (4) direct dyes; (5) basic dyes; (6) sulphide dyes; (7) vat dyes; (8) ingrain dyes.

The classification of dyes according to chemical constitution is based upon the existence,

of a certain group of atoms, in all members of each class, upon the integrity of which their colouring power depends. This is termed the chromophorous group, the theory being first put forward by O N Witt, in 1876 The introduction of such a chromophor into a suitable colourless compound is accompanied by the development of colour, eq benzene  $(C_6H_6)$  is colourless, but azobenzene  $(C_8H_5-N=N-C_6H_5)$ is orange-coloured Many substances, however, such as azobenzene, although strongly coloured, are devoid of dyeing power Such bodies are termed chromogens, and in order to convert them into useful dyes, the introduction of a saltforming group is necessary, such groups, in this connection, being termed auxochromous groups Thus, whilst azobenzene is not a dyestuff, both amino azobenzene and hydroxy-azobenzene are useful dyes In these compounds, the azo- group (-N=N-) is the chromophor, and the amino- or hydroxyl- group is the auxochrome

The presence of both a chromophor and an auxochrome does not, however, necessarily indicate that a substance is a useful dye For example, trinitroaniline,  $C_0H_2(NO_2)_3NH_2$ , contains the chromophor  $(NO_2)$  and the salt-forming auxochrome group  $(NH_2)$ , but it is not a useful dyestuff, because the basic character of the auxochrome is neutralised by the strongly acidic chromophor. On the other hand, trimtrophenol  $C_0H_2(NO_2)_3OH$  is the useful dyestuff pieric acid.

Those dyestuffs which do not contain a salt-forming auxochrome cannot be applied by ordinary dyeing processes, and the fact that a special process is required,  $e \, q$  for indigo, is not primarily due to its insolubility, but to its neutral character.

The scheme of classification, based on the chromophor, distinguishes the following groups—

Typical dyes

Acridine yellow, orange, and

Meldola's blue, gallocyanin,

mine, hydhron blue

scarlet

Capri blue.

Methylene blue,

Chromophor

Group

7. Acridine

8 Oxazine

9. Thiazine

1. 180-Nitroso->C-O Resorein green, dioxine, gambine or oxime >с-й он 2 Nitro--NO. Pieric acid, naphthol vellow 3 Azo--N-N- (a) Basic-chrysoidine, Bismarck brown, Janus red Acid-azo- oranges and scarlets, naphthol black, diamond black
(c) Direct—benzopurpurin, diamine colours, direct blacks (d) Mordant—'acid mordant' or 'chrome colours methyl violet, blue, patent 4. Triphenyl Magenta, Victoria methane blue, malachite green 5. Oxyketone CO The alizarm dyes, indan-threne and algol vat dyes 6. Pyrone Rhodamine, violamine, cosins.

12. Quinoline —CH—CH Quinoline yellow, cyanine

N<sub>2</sub>CH

13. Flavone —O—C— Fustic, weld, logwood
Brazil wood

15. Miscellaneous

This classification of dyestuffs into chemical groups is of importance in the identification and testing of dyestuffs, as the constitution of the compound determines its behaviour towards reagents. It is not, however, a convenient one as regards the practical application of the dyestuffs.

Essential properties of a dyestuff. In order to rank as a useful dye, a substance must possess certain essential features A direct dye must not only possess a colour of considerable intensity and permanence, but must also be capable of easy fixation on textile fibres without mjury to fibre or dyestuff For example, both vermilion and azo-scarlet possess a brilliant colour, but the former is not a dyestuff, because it cannot be applied or produced by dyeing processes. A mordant dye, on the other hand. need not possess a strong colour, and may, in fact, be colourless. It must, however, be capable of producing strongly coloured and insoluble colour-lakes in combination with mordants. Vat dyes-e g indigo-are, as a rule, quite insoluble in water, and therefore cannot be applied by an ordinary process The essential feature of this group is that their reduction products are soluble in alkaline solutions, and on this fact the method of application depends

In order to constitute a dyestuff a body must, therefore, either be strongly coloured in itself or be capable of producing coloured lakes. It must also be of such a character that it can be fixed upon textile material from an aqueous solution, and it must produce a colour which possesses sufficient permanence and resistance to washing and other influences. (In so-called 'dry dying' alcohol or other volatile solvent is used)

Operations preliminary to dyeing processes. In any dyeing operation, the chief bodies concerned are the fibre to be dyed and the dyestuff. In their natural condition, all textile fibres contain impurities which not only detract from their appearance, but prevent their being satisfactorily dyed. The removal of these impurities is the object of the washing, scouring, and bleaching processes which the 'raw' fibres undergo.

A great bulk of manufactured textile material chiefly cotton and linen, is used in the undyed condition, but wool and silk are usually dyed

Dyeing processes. Dyeing may take place at various stages of the manufacture of textiles 'Piece dyeing' is generally employed when a plain-coloured material is required, being the most economical and convenient process. If a coloured pattern is required, the material must either be printed, or dyed before weaving, and

he process may then be carried out on the raw rool or cotton ('wool dyeing,' cotton dyeing'), t an intermediate process ('sliver' or 'slubbing yeing') or upon the spun yarn ('yarn dyeing,' hank dyeing,' 'cop dyeing,' 'cheese dyeing,' 'u arf

Wool is dyed in all these forms; silk, almost xclusively in the form of yain, and cotton,

hiefly as warps, cops, or pieces.

The dyeing of wool. Wool may be dyed 71th a greater range of colouring matters than ny other textile fibre. All the various classes f colouring matters enumerated in the classifiation based on practical application (see p. 575) re used in the dyeing of wool, the most apportant groups being the mordant, the acid wordant, the acid and the direct dyes, as well as he *i at dye*, indigo. In boiling solutions, the ffinity of wool for dyestuffs is generally greater han that of silk, but at temperatures below 60° he relative affinity is frequently reversed. By suitable selection of dyestuffs and control of the rocess, it is therefore possible to dye the wool and ilk in a woven fabric either to different shades, r to produce a uniform colour on the two fibres s a general rule, dyeing processes which produce ood results on wool are entirely unsuited for otton, and it is an easy matter to dye one of the wo fibres when present in a mixed fabric and It both ave the other practically unstained bres are to be dyed the same or different colours, wo distinct processes are, as a rule, required

Different varieties of wool behave differently 1 dyeing, the finer wools, such as merino, 1euning a larger amount of dyestuff to produce a iven shade than the coarser qualities,  $e[\hat{q}]$  Lincoln r 'crossbred' wool The absorption of dye is, owever, by no means entirely governed by the nameter of the fibre, eg fine silky mohair is ery difficult to dye, probably on account of the lose texture of the external scales, Fibres aken from different portions of the same fleece lso vary somewhat in dyeing properties, and ool taken from the skin of animals slaughtered or meat, or from diseased animals, also differs om 'fleece' wool as regards its affinity for dyes Il these differences are shown to a much greater stent with some dyestuffs than with others

The affinity of wool for certain dyestuffs may e increased by suitable treatment with acids, lkahs, or oxidising agents (bleaching powder r hydrogen poroxide solution), or may be immished by a treatment with tannic acid olution and in other ways. Various colours may us be produced by a 'piece-dyeing' process y weaving together untreated wool and wool eated with one or other of the above-mentioned

The behaviour of wool towards solutions of netallic salts governs the use of these bodies as nordants. When boiled in solutions of salts f the heavy metals having an acid character g. sodium dichromate), a decomposition of ne salt takes place, and an insoluble basic salt r a hydrated oxide is fixed upon the fibre.

The dyeing of silk. In general behaviour wards colouring matters, silk resembles wool, ut, as a rule, dyes are fixed on silk in a less ermanent manner than on wool. The dyeing f silk appears to depend, to a greater extent, n absorption, and to a less extent on chemical ction. The acid, basic, and direct dyes are TTOT TT

chiefly used on silk, but other classes, eg. the mordant and vat dyes, are also employed, though they tend to detract somewhat from the brilliant lustre and suppleness on which the beauty of silk depends. The maximum absorption of dyes by silk usually takes place at 60°-80°, and

not at 100° as in the case of wool.

The so-called 'dry dyeing' process sometimes employed for silk consists in the use of benzine or other volatile liquid as a solvent for the colouring matter in place of water. The usual dyestuff salts are not soluble in benzine, but the fatty acid compounds or resinates of basic dyes are readily soluble.

The mordanting of silk with metallic salts is usually carried out in cold concentrated solutions of basic salts, chiefly basic aluminium sulphate for colours, and basic ferric sulphate or

ferrous acetate for blacks

The production of black upon silk is a matter of great importance, and is almost a trade to itself. The silk is first immersed in a solution of chestnut extract or other tannin matter, and then in a solution of basic ferious acetate (pyrolignite of non) or ferrie sulphate ('nitrate of iron') By successive alternate treatments in these liquors, the silk may be weighted to the extent of 400 p.c. It is then dyed with logwood extract There are a number of alternative processes for the black dyeing of

Wild silks, of which Tussur is the chief variety, are much more difficult to dve than ordinary silk, the fine fibrillæ of which the fibre is composed being very impervious. The bandlike flat surface of the fibre also reflects the light in such a manner that a white shiny appearance is liable to be produced instead of a rich, intense colour or black

Artificial silks, consisting essentially of cellulose, are more allied to cotton than to silk as regards dyeing properties. Those varieties produced from collodion (Chardonnet silk) dye more reaculy with the basic dyes than do cotton or the artificial silks obtained from a cuprammonium solution of cellulose (Pauly, Lehne, Thicle or 'glanzstofle' silk) or from cellulose xanthate ('viscose silk') There is, however, much individuality in the dycing properties of the various forms of artificial silk

The dyeing of cotton. Cotton is died chiefly in the form of hanks or warps, less frequently as loose cotten or piece goods The dyeing of cotton on the spool, cop or beam is, however, now of

great importance

The dyeing properties of cotton differ greatly from those of wool, and therefore the processes and materials used also differ. Until the discovery of Congo red in 1881, there were three dyestuffs only which were capable of dyeing cotton directly from their aqueous solution turmeric, safflower, and annatto-but there are now a large number of synthetic substantive dyes by means of which any desired shade can be obtained. The very numerous class of acid dyes which are of such great importance in wool and silk dyeing do not produce reasonably fast colours on cotton.

Cotton has no affinity for metallic salts, and therefore does not become mordanted by boiling in their solutions. Indirect methods have therefore to be adopted in applying the

basic mordants required for the fixation of the mordant dvestuffs on cotton This fibre exhibits a remarkable affinity for tannic acid, which is withdrawn from dilute solution and concentrated on the fibre to a considerable extent The tannic acid may then serve for the fixation either of metallic mordants or of basic dyestuffs upon the fibre

The vat dues and sulphide dyes are now of first importance, since, by their use, extremely

fast colours are obtained upon cotton

The so-called *ingrain dyes* are used almost exclusively on cotton The term is applied to designate a class of dyes which are produced in

situ on the fibre by precipitation

Mercerised cotton is viitually a distinct textile fibre, and whilst its dyeing properties are essentially the same as those of ordinary cotton, its treatment requires special precautions on account of its great affinity for the direct dyes

The dyeing of linen. The behaviour of linen towards the respective classes of dyestuffs is similar to that of cotton, but it is more difficult to dye. The inferior dyeing affinity of linen is probably due to the different physical structure of the fibre

The dyeing of jute. Although a cellulose derivative, jute differs from cotton and linen, both in its chemical composition and properties As regards dyeing processes, it behaves, to a certain extent, like tannin mordanted cotton. and may be dyed not only with direct, but with basic colouring matters without the aid of a mordant

The dyeing of leather. Leather resembles wool in dyeing properties, but the difficulty of dyeing it in fast colours is increased by the necessity of using lukewarm liquors only, since boiling water destroys ordinary leather Certain of the newer methods of producing leather, eq chrome tannage, yield a product which will withstand boiling solutions. It is very important as regards the permanence of the leather (when used eq for bookbinding or furniture covering) that no mineral acid should be employed in the dyeing process. As a substitute, formic acid may be recommended The acid and basic colouring matters are chiefly employed, the mordant dyes being used to a less extent

The dyeing of feathers. The chief cause of difficulty in the dyeing of feathers is their natural water-resisting property. This is due partially to their ultimate physical structure, and partially to the natural grease present The midrib is specially difficult to dye Apart from these special difficulties, feathers behave in dyeing, like wool, and may be dyed with acid, basic, direct, or mordant dyes Reds, browns, blues, and other colours are usually dyed with acid dves, but the most satisfactory blacks are obtained by successive and repeated treatments with logwood extract, and ferrous sulphate with potassium binoxalate Dyeing must proceed for a considerable period at the boil, in order to ensure penetration

The dyeing of horn. Horn is dyed in strong solutions of acid dyes by steeping for a long period in the cold or slightly warm baths, which are acidified with acetic or formic acid it contains sulphur, horn may be dyed brown

by steeping in a solution of sodium plumbite, which results in the formation of lead sulphide Black is also produced by alternate steepings in solutions of mercuric nitrate and potassium sulphide

The dveing of ivory. Both acid and basic dyes may be employed in the dyeing of ivory, the former being used with addition of acetic or formic acid in hot solutions. Alcoholic solutions of colouring matters may also be em-Red is frequently dyed by the cochineal ployed single-bath process used for wool (see p. 500)

Black is produced either by the logwood and iron or aniline black process, as used in cotton

dyeing, or by means of silver nitrate

The dveing of wood. The method of dveing wood in bulk is to boil or steam it to remove the resins, and then treat it in an apparatus similar to that employed in creosoting. The wood is placed in a closed vessel which is exhausted by a vacuum pump, and when the air has been sucked out from the pores as completely as possible, the hot dye liquor is admitted into the vessel and put under pressure by a force The direct and basic dyes may be employed Wood is usually dyed black by alternate treatments with logwood extract and sodium dichiomate solution

The dyeing of straw. Straw is largely dyed for use in the manufacture of hats and baskets There are two commercial varieties, distinguished as chip and straw Chip is readily dyed by means of the direct cotton dies or the sulphide dies, and many basic and acid dyes in neutral solution may also be employed. The process must be continued for 2 to 3 hours at the boil

'Straw' is more difficult to dye than 'chip,' on account of the highly silicious character of the surface The straw should be steeped for several hours in warm water before dyeing Blacks are usually obtained with logwood and iron, but for colours the direct cotton and the basic dyes are chiefly used

MATERIALS USED IN DYEING OPERATIONS.

A great variety of chemical substances are used in dveing processes- acids, alkalis, oxidising and reducing agents, metallic salts, and a wide range of organic bodies Two groups only need be here considered, viz (a) mordants, and b) colouring matters

Mordants. The function of a mordant is to chemically combine with the dyestuff employed. and fix the latter upon the fibre It has already been mentioned that many colouring matters do not require the aid of mordants, but dye direct from their solutions This applies to the acid, direct, basic, and vat dyes when used for wool and silk, and the direct, sulphide, and vat dyes On the other hand, the when used for cotton mordant and acid-mordant dyes (as their name implies) demand the use of mordants on wool, as do the mordant and the basic dyes on cotton

It is evident that the chemical properties of the dyestuff will govern the character of the mordant required for its fixation, and two types of mordants may thus be distinguished: (1) the metallic or basic mordants, used for the mordant' dyes; and (2) the acid mordants, required in applying the basic dyes to cotton or other vegetable fibre.

Basic mordants are employed for fixing on

animal and vegetable fibres those colouring matters which are of an acidic character, ie either true acids or bodies containing hydroxylgroups, of which the hydrogen is replaceable by metals They are metallic salts, of which the most important are certain compounds of chromium, aluminium, iron, and tin

Wool is mordanted by boiling it with dilute solutions of these metallic salts, usually with the addition of certain acids or acid salts, e.g. cream of tartar, sulphune acid, formic acid, oxalic acid, &c. During this operation, the wool assists in the dissociation of the metallic salt; an insoluble basic salt being fixed within and upon the fibre, while a more acid salt remains in solution acids or acid salts, which are added along with the metallic salt, possibly assist the dissociation of the latter by forming more sensitive salts (tartrates, exalates, &c), and are conveniently termed assistants

As a rule, the mordanting operation precedes that of dyeing, not infrequently, however, the two operations take place simultaneously, and the dyeing is thus effected by the so-called 'single-bath' or 'one-dip' method, as, for example, in producing cochineal scarlet on wool In such cases, the wool is boiled in a solution containing colouring matter, metallic salt, and assistant, in certain accurately determined relative proportions Combination takes place between the colouring matter and the mordant, but the pigment which would otherwise be precipitated, is retained in solution by the liberated acid of the mordant or the assistant present, and is only gradually withdrawn from solution by the fibre, which thus becomes dyed

In the case of the 'acid-mordant' dyestuffs, the application of the mordant follows

that of the colouring matter

Silk may be mordanted in the same manner as wool, by boiling with metallic salt solutions, but, more usually, it is steeped for about 12 hours in cold solutions of the mordants previously rendered more or less basic and sensitive subsequently washing with (calcareous) water, the metallic salt absorbed by the silk is dissociated, and an insoluble basic salt is precipitated within the fibre

Cotton is mordanted with metallic salts by processes very different from those adopted for wool and silk, since it has not the property of causing the dissociation of the metallic salts when boiled or steeped in their solutions The methods adopted also vary according to the form of the material, ie whether it be cotton-wool, yarn,

or cloth.

With calico, it is usual to impregnate the fabric with solutions of metallic acetates, then to dry it, and expose for several hours to a moist During this so-called 'agewarm atmosphere ing' process, dissociation of the salt takes place, acetic acid escapes, and a more or less basic salt remains fixed upon the fibre

Sometimes the 'ageing' is replaced by a 'steaming process,' in which the fabric is exposed from 1 to 1 hour to the action of high or low pressure steam in a closed chamber This method is adopted by the printer of textile fabrics in the so-called 'steam style,' in which a mixture of colouring matter and metallic salt (usually acetate) is printed upon the fabric, which is then dried and steamed. The metallic salt is decom-

posed, a basic salt is precipitated upon the fibre, and at the same time the mordant combines with the colouring matter and produces the coloured pigment. This method is analogous to the single-bath process of the woollen dyer

Cotton may also be mordanted by imprognating it with a metallic salt solution, drying, and then passing through a solution of an alkaline substance,  $e\,g\,$  ammonia, chalk, sodium carbonate, &c , to neutralise the acid and precipitate upon the fibre a basic salt or metallic oxide. Solutions of an alkali salt, the acid of which forms an insoluble compound with the base of the mordant,  $e\,g$  sodium phosphate, silicate, arsenate, &c, are also employed. The substances used in this manner for fixing the mordant upon the fibre are termed fixing agents

In some cases of mordanting, the cotton is first impregnated with the fixing agent (eg tannic acid, sulphated oil, &c ), then dried and afterwards passed through the mordant solution,

as for example, in Turkey-red dyeing

Special methods of mordanting cotton are occasionally adopted, in accordance with the properties of the metallic salt employed Stannic oxide, for example, may be fixed on cotton by passing the fabric through a solution of sodium stannate, and then through dilute sulphuric acid, and finally washing Alumina is precipitated on the fibre by the mere exposure to an of cotton impregnated with sodium aluminate, in which case atmospheric carbonic acid is the active fixing agent

The chromium mordants are of the first importance, since, with different colouring matters, they yield a considerable range of colours which are remarkable for their permanence The most important chromium mordants are potassium and sodium dichromates, and they are more largely used as mordants in wool dyeing than all other metallic In cotton dyeing they are not used as mordants, but are frequently employed as oxidising agents, eg to develop the colour in dyeing catechu brown or aniline black Dichromates are also used in producing 'chrome yellow' and 'orange' (chromates of lead) on cotton Chromrum fluoride (CrF<sub>3</sub>,4H<sub>2</sub>O) is also used to a limited extent as a mordant for wool Other chromium salts employed as mordants, chiefly for cotton, are chrome alum, chromium acetate, and various chromates of chromium. Chrome alum is obtained in large quantities as a byproduct during the manufacture of alizarin; chromium acetate is prepared by mixing together solutions of chrome alum and lead acetate

Wool is mordanted with chromium by boiling for  $1-1\frac{1}{2}$  hours in a solution containing 3 p c potassium (or sodium) dichromate calculated on the weight of wool. In many cases it is beneficial to add 1 p c sulphuric acid (sp gr. 184) or 15 pc hydrochloric acid (sp gr 116), or 6 pc tartaric acid, or 1 to 2 pc. formic acid, whereby fuller or brighter colours are ultimately obtained When potassium dichromate alone is employed, partial decomposition of the salt occurs, accompanied by some reduction, the wool absorbing some chromic acid and chromium chromate as well as potassium di-When an addition of sulphuric chromate. acid is made, the wool absorbs only chromic acid. In both cases the mordant d wool

has a yellow or buff colour, and only in the dye-bath does the reduction to the real mordanting body, chromic oxide, take place within the fibre through the interaction of the colouring When formie or tartarie acid is the assistant employed, the mordanted wool has a green colour, reduction of the chromic acid taking place already in the mordanting bath, and chromic hydrate being deposited within the wool substance If large amounts of potassium dichromate are employed in mordanting, especially if sulphuric acid is also added to the bath, bad results may be obtained through the colouring matter being oxidised and destroyed by the excess of chromic acid present in the wool This In certain defect is known as 'over-chroming.' cases, potassium dichromate may be usefully applied in the same bath with the colouring matter (eg with alizarin), or by an after process (eg in the case of camwood)

Silk is not usually mordanted with chromium It becomes mordanted, however, if boiled with a solution of potassium dichromate and tarterie acid after the manner of wool, but not if potassium dichromate alone, or with the addition of sulphune acid, is employed. The fibre is

somewhat injured by this process

Cotton may be mordanted with chromium by impregnating it with a moderately concentrated solution of chrome alum, drying, and passing through a boiling solution of sodium carbonate or caustic soda. Better results are obtained by the use of 'chromium mordant G A I' or 'G A II' (M L & B), which are solutions of chromium chromates. Other satisfactory mordants for cotton are chromium bisulphite (Knecht) and sodium chromite (Koechlin). A method in vogue with the printer is to implicance (pad) or print the cotton with a mixture of colouring matter and chromium acetate, dry and steam ('steam colours')

The chief aluminium mordants employed for wool are aluminium sulphate and alum. The best results are usually obtained by boiling the wool for 1-1½ hours with a solution of 8-10 p c of the aluminium salt calculated on the weight of the wool, with the addition of cream of tartar, in the proportion of 3 mols to 1 mol aluminium sulphate. Aluminium tartiate also gives excellent results, but it is cheaper to allow this salt to be formed in the mordanting bath itself in the manner described. With some colouring matters, exalts acid or potassium binoxalate are

to be preferred as assistants to cream of tartar Silk is mordanted by boiling with dilute aluminum sulphate solution, or by steeping 24 hours in a concentrated solution, and then washing in water, preferably calcarcous

washing in water, preferably calcareous

The methods of mordanting cotton with aluminium are various. It may be impregnated with a moderately concentrated solution of alum or aluminium sulphate, dried, and then passed for a few minutes into a hot solution of sodium phosphate, arsenate, or silicate, or ammonium carbonate. Or the cotton may be impregnated with a cold solution of neutralised sulphated oil, or of tannic acid, then dried, and steeped in a solution of aluminium acetate or basic aluminium sulphate. Another method consists in impregnating the cotton with a solution of sodium aluminate, drying and exposing to the a.r, or passing through a solution of am-

monium chloride. Normal and basic aluminium acetates are also employed, the cotton being impregnated with their solutions, then dried, and exposed to a moist warm atmosphere ('ageing'), and finally passed through a hot solution of, eg, sodium arsenate. The aluminium acetates employed are prepared by dissolving aluminium hydrate in acetic acid, or by decomposing a solution of aluminium sulphate with calcium or lead acetate ('red liquor'). The more basic the aluminium salts are, the more readily do their solutions precipitate by heating or on dilution with water, and the larger the quantity of alumina they yield to the fibre when used as mordants

The chief iron mordants employed are ferrous sulphate and acetate, and ferric sulphate, ace-

tate, and nitrate

The ferrous acetate employed is made by dissolving scrap iron in pyroligneous acid. The 'pyrolignite of non' or 'black iron liquor' thus obtained is preferable to that made by the mutual decomposition of ferrous sulphate and lead acetate solutions, being less liable to oxidise because of the presence of tarry matter and reducing agents, eg pyrocatechol, &c. Ferric sulphate is prepared by heating a mixture of definite proportions of ferrous sulphate, sulphuric acid, and nitric acid. Although the last-mentioned substance is only used as an oxidising agent, the final preparation is generally termed by dyers 'nitrate of iron' The socalled 'pure intrate of iron' (ferric intrate) is prepared by dissolving scrap iron in intricacid

Wool may be mordanted by boiling in a solution of 7 p c ferric sulphate [Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>] and 4 p c potassium binoxalate, calculated on the weight of the wool, but iron is now very little used as a mordant for wool

Silk may be mordanted by steeping for about 12 hours in a cold solution of pyrolignite of non (sp gr 1 025), and afterwards washing well. The most usual mordant, employed largely in black-silk dyeing, is the basic ferric sulphate  ${\rm Fe_4(SO_4)_5(OH)_2}$ . The silk is steeped in a somewhat concentrated solution of this salt (sp gr 1 25) for about 1 hour, then squeezed and well washed. The operations are repeated seven of eight times, after which the silk is boiled in an old soap-bath and finally washed. In this process, the very sensitive basic ferric sulphate absorbed by the fibre is decomposed during the several washings, a still more basic and insoluble salt being precipitated within the fibre.

Cotton is usually mordanted with iron by first impregnating it with a cold solution of tanin matter ( $e\,g$  myrobolans), and then, with or without drying, passing into a dilute solution of ferrous acetate, ferric sulphate, or nitrate (sp.gr  $1\,01-1\,02$ ) The cotton may alternatively be impregnated with ferrous or ferric acetate, dried, and exposed to a moist warm atmosphere ('ageing'), finally fixing the mordant by passing through a hot solution of,  $e\,g$ , sodium phosphate

Tin mordants are now rarely used, but if required the stannous salts are employed for wood and the stannous salts for cotton. The chief stannous mordant is stannous chloride or 'tin crystals' It is frequently sold as a somewhat acid solution under the names of 'single muriate of tin' (sp.gr. 1.3), or 'double muriate of

(sp.gr. 1.6). The general name 'tin spirits' en to a variety of solutions of tin in mixtures adrochloric, sulphuric and nitric acids.

Vool is mordanted by boiling in a solution aning 6 pc of the weight of wool of stanchloride, and 6-10 pc cream of tartar e proportions of stannous chloride should rictly avoided, otherwise the dyed wool feels 1 and its general properties are impaired

ilk may be mordanted in the same manner ool, or steeped several hours in a more is concentrated solution of stannic chloride,

hen well washed

otton is mordanted with stannic oxide by egnating the cotton with cold tannin solution sumach) for 3 hours, then squeezing, and, or usually without drying, steeping 1 in a dilute solution of stannic chloride · 102), and washing Cotton thus mored was much used formerly for fixing ant dyes-peachwood, logwood, &c, in i case the stannic oxide constituted the ant, the tannic acid acting as fixing agent that the basic coal-tar dyes are so much yed in dyeing cotton, although the same od of mordanting is employed, the roles of n salt and tannic acid are reveised, for it lly the tannic acid which is the essential ant, while the stannic chloride serves only · fixing agent

zid mordants are employed for fixing basic ing matters on cotton They are not used of or silk dyeing, since these fibres themact as acid mordants, and are dyed ly without the aid of any external mordant innic acid is the mordant par excellence ring the basic coal-tar colours on cotton ibre absorbs tannic acid from its cold soluand, when thus prepared, if immersed solution of a basic colouring matter, the · acid combines with the colour base, a ed lake is formed within the substance of ore, and the cotton becomes dyed yeing process, the acid originally in comon with the colour base is displaced, and in the free state it interferes with the comformation of the colour lake, it is found cial to add a small proportion of sodium nate or acctate to the dye-bath Since the tes of colour bases are somewhat soluble, in

of tannic acid or in alkaline (or soap) ons, it is necessary in practice to fix the acid on the fibre, previous to dyeing, in the of an insoluble metallic tannate This is by passing the tannic-acid-prepared cotton ha hot or cold solution of tartar emetic or c chloride, tannate of antimony or tin is ived on the fibre, and these salts have as in affinity for the colour base as free tannic as. Cotton thus mordanted and dyed is oly permeated with a very insoluble double e of antimony or tin and colour base; a compound which is insoluble in alkaline ns, and therefore fast to washing with ζC.

tannin mordants, chiefly used by the regall nuts and sumach, for light colours; nyrobolans, divi-divi, quebracho, and it extract, for dark colours and blacks already pointed out, tannic acid is somelised as a fixing agent for tin, iron, or ium mordants, and since its iron com-

pound is of a bluish-black colour, it sometimes serves as a useful colouring matter.

Tannic acid is not used as a mordant for wool, but for silk it is largely employed, partly for adding weight to the silk, and partly for the purpose of dyeing it black in conjunction with iron mordants. Its utility as a weighting agent is owing to the fact that under suitable conditions silk absorbs as much as 25 p c of its own weight of tannic acid from a hot solution, whereby the fibre gains not only in weight, but also in volume

Fatty acids are used as mordants, very much in the same way as tannic acid, for fixing the basic coal-tar colours on cotton. They are, however, not attracted by cotton from their solutions, but they form insoluble lakes with the colour bases. The method of procedure is to impregnate the cotton with a more or less concentrated solution of their alkali salts, viz soap, after drying, the fabric is passed through, or preferably steeped in, a cold solution of aluminium sulphate, and washed. Although the fatty acid is thus fixed on the fibre as an insoluble aluminium soap, it is still capable of combining with the colour base when the cotton is passed into a solution of a basic colouring matter Colours dyed by this method are brighter than, but not so fast to washing as those fixed by means of tannic acid.

Instead of ordinary soap, a more convenient fatty-acid mordant to employ is the so-called 'sulphated oil' This is prepared by mixing two parts by weight of castor oil with about one part of sulphuric acid (sp gr 184), and allowing the mixture to stand for 24 hours is then washed with a strong solution of common salt to free it from excess of acid, and is finally neutralised with ammonia or caustic soda product of the action of the acid upon the oil is somewhat complex, but its practical utility depends upon the fact that it behaves like a fafty acid and gives an extremely soluble soap with alkalis Ordinary easter-oil soap produced by boiling the oil with caustic soda is also very soluble, and may be used as a mordant Sulphated oil is frequently called 'Turkey-red oil,' 'alizarin oil,' and 'soluble oil,' since it is largely used in the modern short process of Turkey-red dyeing as the fixing agent for the necessary aluminium mordant, and it gives the characteristic brilliancy of colour obtained by the use of the oil preparations formerly employed Monopole oil is a similar product

Phenohe colouring principles, eg alizarin, and certain acid colouring matters derived from benzidene, stilbene, fluorene, &c (the direct cotton dyes) can also be fixed on cotton, and serve as mordants for basic colouring matters, but they are only occasionally used for this purpose for the production of compound shades

COLOURING MATTERS

(For Classification, see p 575)

GENERAL METHODS OF APPLICATION

CLASS I — Mordant dyes. This group of dyestuffs includes the majority of the natural dyes, also the namerous class of alizarin dyes, a number of derivatives of pyrogallol and other phenols, and certain azoquinone-oximes and nitroso-dyes. The following are the chief members of the group

Mordant dyes of natural origin—Logwood; limawood and other camwood and other cochineal; soluble redwoods' 'insoluble redwoods'; fustic; weld; querci-

tron bark and flavin.

Synthetic mordant dyes -Alizarin; anthrapurpurin, flavopurpurin, and purpurin; nitroalizarin (alizarin orange), alizarin maroon (aminoalizarin), alizarin bordeaux, anthracene brown, alizarin blues, alizarin cyanins, anthracene blues; alizarin greens, corulein, anthracene yellow; mordant yellow, galloflavin, &c; alizarın black; gallem; gallocyanın, cœlestine blue, naphthol green, dark green, gambine, &c

The mordant dyes are largely used in the dyeing of wool and in the dyeing and printing of cotton and silk Generally speaking, they yield colours which are of great fastness to light, soaping, acids, alkalis, bleaching agents, &c As regards cotton dyeing, they have largely been replaced by 'after-treated' direct dyes and the very fast vat and sulphide dyes recently intro-

duced

When a fabric, previously mordanted with a metallic salt, is dyed with a mordant dye, a chemical reaction takes place, resulting in the formation of a new compound which is the actual colouring substance, this compound being, at the same time, fixed upon the fibre, which thus becomes dyed. These colour lakes or pigments may, for the most part, be equally well produced by bringing together the mordant and the dyestuff under suitable conditions in the absence of the fibre Many colour lakes of this class are indeed manufactured in bulk for use in printing or painting.

There are three methods by which mordant dyes may be applied. (1) the mordant may be first applied to the fibre, and afterwards the dyestuff in a separate operation ('mordanting and dyeing method'), (2) the order of applica-tion of mordant and dye may be reversed ('dyeing and saddening method'), or (3) the mordant and dyestuff may be applied simultaneously ('single-bath method') All three methods are in use If equally good results can bo obtained, the 'single-bath' process is to be preferred, but usually the 'mordanting and

dyeing' process gives the maximum fastness

The dying of wool with mordant dies —

When potassium dichromate is comployed as mordant, the 'mordanting and dyeing' process is usually preferable, because, in the 'single-bath' process, the acid necessarily added to dissolve the colour lake formed in the dye-bath, converts the mordant into such a powerful oxidising agent by liberating chromic acid, that most dyestuffs are injuriously affected. In the two-bath process, the wool should be thoroughly washed after mordanting If this operation is omitted, a portion of the mordant passes from the wool into the dye-bath, and, combining with an equivalent amount of colouring matter, forms a precipitate which floats about in an insoluble condition. This not only leads to loss of dyestuff, but also tends, by superficial absorption, to cause the dye to 'rub off' The dyeing process consists in boiling the wool for from 1 to 2 hours with the colouring matter in aqueous The final washing, after dyeing, has for its object the removal of any colouring

matter which is imperfectly fixed; but, however thorough the washing may be, there is usually a small amount of colouring matter present on the dyed wool, which has merely been absorbed without combining with the mordant. This free colouring matter will dissolve out or 'bleed' during milling or scouring, because most mordant dves are readily soluble in alkaline solutions A slight supplementary mordanting ('afterchroming') is frequently used to fix this small amount of free dyestuff

The 'dyeing and saddening' method is not much used with the true mordant dyestuffs, but is the chief process used in applying the acid mor-Since the ultimate intensity of colour depends chiefly upon the amount of dyestuff which is fixed in the first bath, whilst the colour is only developed by the mordant in the second bath, it is obviously more difficult to exactly match a pattern when this process is used than

when the mordant is applied first

In the 'single-bath' method of dyeing, the bath is prepared with the necessary amount of mordant and dyestuff with an addition of sufficient acid (usually oxalic or acetic acid) to dissolve the colour lake formed. This process is therefore only suitable when the colour lake is soluble in dilute acid, and this is particularly characteristic of the tin and aluminium colour lakes, although the single-bath process is also frequently applicable in the case of ferrous sulphate or chromium fluoride mordants

The dyeing of silk with mordant dyes -The mordant dyes are not very largely used on silk, chiefly because they detract somewhat from the lustre of the fibre The degree of fastness of the acid dyes, if suitably selected, is, moreover, usually sufficient for the requirements of the silk dyer. The methods of mordanting have already been dealt with. Dyeing must take place at the boil for about an hour, and the silk is subsequently brightened by working in a warm dilute solution of acetic or tartaric acid,

and dried without washing

Dueing of cotton with mordant dies -The 'mordanting and dyeing' method is generally used in cotton dyeing Aluminium is the chief mordant employed, and, in conjunction with alizarin, it yields the important Turkey-ied dye This is a complex compound containing an alizarin-aluminium-calcium lake in combination with polymerised fat acids In the production of this colour, the cotton is first prepared with sulphated oil, then dued, mordanted with alum, and 'subsequently dyed with alizain complete process involves a large number of operations, for the details of which manuals of dyeing must be consulted. The dyeing of Turkey red is a very ancient process, having been carried out centuries ago in India by the aid of milk (as fatty matter) and munjeet, the Indian madder plant No alum was employed. but the plant with its earthy incrustations contained sufficient alumina to produce the alumina The art spread from the East through Persia and Turkey, and was first introduced into this country (Glasgow) in 1790 Madder has now been entirely replaced by synthetic alizarin in Turkey-red dyeing, and the substitution of 'sulphated oil' for olive oil or soap has also greatly simplified the process.

Another important mordant dye on cotton

is logwood black, which is obtained by dyeing with logwood on tannin-iron mordant. It is largely used in hank and warp dyeing. Catechu brown is produced by the 'dyeing and saddening' method, the cotton being first steeped in a strong solution of catechu, and subsequently treated with potassium dichromate. The latter acts essentially as an oxidising agent, producing the so-called paponic acid on the fibre

A great variety of permanent and bright colours may be obtained with mordant dyes on cotton mordanted with chromium or aluminium, but they are not very largely used, fast colours being chiefly produced by means of the sulphide, but, and margin dyes (Classes VI, VIII, VIII)

vat, and ingrain dyes (Classes VI, VII, VIII)

CLASS II—Acid-mordant dyes. These dyes are suitable only for wool and silk, and are largely used on wool They are now very numerous, and are chiefly azo-compounds containing salicylic acid or orthoaminophenol components. Some, however, are anthracene or pyrogallol derivatives. Unlike the mordant dyes, they usually contain sulphonic acid groups

Many of the acid-mordant dyes may be employed as ordinary acid dyes, since a mordant is not essential to the development of their colour. Usually, however, such dyestuffs produce faster colours when applied in conjunction

with a mordant

An exhaustive list of acid-mordant dyestuffs cannot be given, but the following will serve as They include dyes giving a complete examples acıd-alızarın, anthrarange of colours Redscene, chrome, cloth and milling reds and yellows cloth oranges and yellows, alizarin yellows (certain marks are mordant dyes), chrome yellows, milling orange and yellow, diamond, and mordant yellow Greens alizarin, chrome, diamond and milling greens Blues . acid-alizarin, brilliant-alizarin chrome blues, chromotropes (chromotropes dye red as acid dyes). Violets alizarin heliotropes, anthraquinone and chrome violets, fast violet Blacks and greys: acid-alizarin, acid-chrome, anthracene-acid, anthracene chrome, chrome, chromotrope and diamond blacks acid-alizarin, acid-anthracene, chrome, cloth, diamond, and palatine browns; chromogen

Dyeing of wool with acid-mordant dyestuffs The usual method of application of this class of dyestuffs is to prepare a bath containing the necessary amount of dyestuff along with 1 to 3 p.c sulphuric or 3 to 5 p.c acetic acid, and 5 to 10 pc sodium sulphate (Glauber's salt) (all calculated on the weight of wool) the solution has been brought gradually to the boiling-point, the boiling is continued until the colouring matter is entirely fixed, an additional amount of acid being added if necessary of acid, however, frequently retains the dyestuff The wool is then removed from in solution the bath, the metallic salt is added, and the wool is again boiled in the bath for half an hour. In most cases, petassium dichromate, to the extent of one-half the weight of the dyestuff, is the mordant employed

A modification of this process is used with the metachrome series of dyestuffs The metachrome mordant is a mixture of yellow potassium chromate and ammonium sulphate. The bath is prepared with 3 to 5 p c of this mordant together with the dyestuff. A prolonged boiling is necessary, during which the ammonium salt is decomposed, ammonia being evolved and the liberated sulphuric acid gradually converts the chromate into dichromate and as ists in the fixation of the dye and the formation of the colour lake.

The anthracene chromate dyes are applied in a bath containing colouring matter, dichromate, and sodium sulphate, this being another modification of the usual process.

The mercerol and autochrome dyes are also

applied by special processes

The acid-mordant dyes are of increasing importance in wool dyeing, but are little used on

silk, and not at all on cotton

CLASS III -Acid dyestuffs. The acid dyes constitute the most numerous class of synthetic The chief chemical groups colouring matters of acid dyes are azo- dyes, nitro- compounds, sulphonated basic dies, and phthaleins, greatest number being azo-dyes The azo-dyes contain few greens, blues, and violets, but the reds, oranges, yellows, browns, and blacks are very numerous The nitro- compounds are few in number and are all yellows, the chief being The greater pieric acid and naphthol yellow number of the sulphonated basic dyes, on the other hand, are greens, blues, and violets, but acid magenta belongs to this group. The resorcin or phthalein dyes are chiefly brilliant pinks or reds, the cosins being the most important group

So extremely numerous are the acid dyes, and their names are so varied, that no useful purpose would be served by the enumeration of

a small number of the products

The dyeing of wool with acid dyes—The commercial acid dyes are, in most cases, the sodium salts of sulphonic acids The introcompounds, however, owe their acid character to the presence of intro-groups in the molecule

The simplest and most usual method of dyeing acid colours on wool is to prepare a bath containing the requisite amount of dyestuff with 1 to 4 p c of sulphuric acid and 10 to 20 p c of sodium sulphate (Glauber's salt) wool is dyed in this solution for about an hour, boiling for the greater part of the time dyes require smaller, and some larger percentages The sodium sulphate has a levelling influence on the fixation of the dyestuff, probably by reason of the solvent action which it exerts, since acid dyes are readily removed ('stripped') from wool by boiling in a solution of sodium sulphate Another reason is to be found in the retarding action which it exerts in the liberation of the free colour acid by the sulphuric acid The equation, which may be expressed as

Colour salt + H<sub>2</sub>SO<sub>4</sub> ≥ colour acid + Na<sub>2</sub>SO<sub>4</sub>, is reversible (See also M Firt, Theory of the Acid Dyebath, J Soc Dyers, 1910, p. 33.)

Sodium bisulphate or 'nitre cake' may be used in place of the sulphuric acid and sodium sulphate, or the sulphuric acid may be entirely replaced by acetic or formic acid.

In the case of dyestuffs which do not readily produce level colours on the fabric, the acid may be added to the bath gradually in small portions at a time, or may be substituted by ar. ammonium salt, eg ammonium sulphate

The acid is then liberated very gradually as the ammonium salt is decomposed in the boiling bath, and the colouring matter is therefore converted very slowly from the condition of the soluble sodium salt to that of the more or less insoluble free sulphonic acid

The dyeing of silk with acid dyes —Acid dyes are very largely used in silk dyeing. They are applied in a bath containing a large quantity (up to 25 p.c. in volume) of 'boiled-off' liquor, the soapy solution of the silk gum obtained in the 'ungumming' of raw silk. The bath is rendered slightly and by means of sulphure, acetic, or formic and Dyeing usually takes place at about 80°, at which temperature silk has more affinity for acid dyes than in a boiling bath

After dyeing, the silk is washed and is then 'brightened' by working in a dilute (sulphuric, acetic, or tartaric) acid solution and dried

without washing

The dyeing of cotton with acid dies -There is no satisfactory method of fixing the acid dyes upon vegetable fibres, but for cheap work they are often applied by a 'padding' process
(LASS IV —The direct dyes. The direct dyes

have the special property of dyeing cotton without the aid of a mordant. Lake the acid dyes, they are for the most part azo- compounds, but contain the chromophor -N=N- twice in the molecule, and thus belong to the tetrazogroup of azo- dyes They further resemble the acid dyes in that they are alkali salts of sulphonic acids, but as regards dyeing properties, they differ greatly from the simpler azo-acid dyes Since the introduction, in 1884, of the first of the direct dyes, a very large number have been placed on the market, and the group contains dyes of all colours-reds, oranges, yellows, greens, blues, violets, browns, and blacks. As examples of these dyes may be mentioned the congo, benzo, diamine, mikado, titan, and chlorazol dyes

Primuline is an example of a direct dye which is not an azo- compound. It contains the

chromophor<S>C-

Turmeric is the only important natural direct dye for cotton

The direct dyes are largely used upon all No satisfactory explanation has been given of the fact that they readily dye cotton, whereas the acid dyes are entirely devoid of this property The further fact that the direct dyes dye wool in a neutral, or even slightly alkaline bath, whereas the acid dyes require the addition of acid, also requires explanation.

The dyeing of wool with direct dyes -I hese colouring matters are applied to wool in a neutral or feebly acid bath with or without the addition of sodium sulphate (Glauber's salt). In some cases, an after-treatment with a metallic salt gives improved fastness, the dyes then practically falling into the class of acid-mordant dyes.

As a class, the direct dyes on wool are much faster to milling than the ordinary acid dyes When fixed on wool, they are also faster to acids, washing, and light than when dyed on cotton In some cases, the colour produced by a direct dye on wool and cotton is identical, in other cases it differs considerably

The dyeing of silk with direct dyes -These

and also on account of their property of pe manent reduction to colourless bodies, in the s called 'foulard' style of printing. They a applied in a similar manner to the acid dybut smaller amounts of 'boiled-off liquor' a acid are required

The dying of cotton with direct dyes .- T application of the direct dyes to cotton is ve They are dyed either from a cold, lul warm, or boiling solution, to which is added small amount (up to 2 p c ) of sodium carbona and an amount of a neutral salt (up to 20 gra NaCl or Na SO<sub>4</sub> per litre), which is governed the solubility of the dyestuff employed At l temperatures more concentrated solutions colouring matter are required. Brighter color are obtained by passing the dyed mater through a solution of Turkey-red oil before d ing or by adding this substance to the dye-ba Mercerised cotton has a much grea affinity than ordinary cotton for the direct dy and in dyeing this fibre special precautions.

Many of the direct dyes produce on cott colours of great brilliance and richness, I they bleed out into hot water, and are s more readily attacked by soap. Most of th are also comparatively fugitive to light.

There are three processes by means of wh the fastness-properties of certain of the dir

dyes can be improved

1 The diazotising and developing process This process is applicable only in the case those dyestuffs in which amino- groups c stitute the auxochrome. The cotton is f dyed by the general process above describ then washed, and afterwards worked for a moments in a cold dilute solution of nitrous a (2 p.c. NaNO, and 4 p.c. HCl cn the wei of the cotton) This treatment diazotises The cotton is then well was amino- groups in cold water and entered immediately into developing bath, which contains a solution of phenolic or amino- compound; sufficient al or acid respectively being added to bring 'developer' into solution. The chief develop used are phenol, resorcinol, a- or \(\beta\)-napht aminonaphthol, aminodiphenvlamine, m-to enediamine, and certain of the napht sulphonic acids

Primuline is applied by the process described

A modification of this method is known the 'coupling process'. The cotton is first d with the direct dye, and, after rinsing, is wor in a diazotised solution of the 'coupler' chief body used as coupler is p-nitranil Ready prepared stable diazo- compounds of base are sold under the names 'nıtra: azophor red,' and 'nıtrosamine red'

2. After-treatment with metallic salts this process for improving the fastness of direct dyes on cotton, the fibre is first dyes the ordinary way, and then, after rinsing treated for half an hour in a warm slightly ac fied solution of a suitable metallic salt chiefly employed are copper sulphate, potass dichromate, and chromium quoride; from 1 pc with addition of 2 to 4 pc. of acetic: being used. A mixture of the two first-n tioned salts is frequently used. This process dyes are largely used on silk both for self shad a mainly employed in the case of blues, gre

browns, and blacks. The chromium salts exert the greatest influence in increasing the fastness to washing, and the copper salt in regard to the fastness to light

This process is only applicable to the case of dyestuffs containing free OH or COOH groups

3 After-treatment with formaldehyde -This process, which is chiefly used for navy blues and blacks, is carried out by working the dyed cotton for half an hour at 70° in a solution containing about 3 p c formaldehyde (on the weight of the The fastness against washing is concotton) siderably improved thereby.

Cotton dyed with direct dyes may be 'topped' with basic dyes, for which the direct

dyes act as mordants

CLASS V—The basic dyes. This group of colouring matters is numerically smaller than the mordant, acid, or direct dye groups includes, however, the most brilliant dyes known, rhodamine pink, auramine yellow, malachite green, methylene blue, and methyl violet being well-known examples.

The basic dyes are very diverse in their chemical constitution Many are derivatives of di- or tri-phenylmethane (magenta, malachite green, methyl violet), others are azo- compounds (chrysoidine, Bismarck brown), some are azinederivatives (safranine and induline), whilst the thia/ines contain sulphur as an essential constituent (methylene blue)

The commercial basic dyes are usually hydrochlorides of the colour bases, but some are acetates, oxalates, sulphates, or zinc chloride double salts. They are characterised by great tinetorial power, 1 p c being usually sufficient to produce a full rich colour As a class, they are not fast to light

Janus dyes. These occupy an intermediate position between the basic and the direct dyes. They are azo- dyes of strongly basic character, and possess an extraordinary affinity for both animal and vegetable fibres. They are only of

slight importance

The dyeing of wool with basic dyes -These dyes are little used on wool, the acid dyes being applied in an equally simple manner and producing faster colours Wool has a strong affinity for basic dyes, and readily becomes dyed if A small amount immersed in their solutions of sulphuric or acetic acid may usually be added with advantage Certain of the basic dyes, e g Victoria blue, are very fast to milling when dyed on wool, and such are still employed

The dyeing of silk with basic dyes—Members of this group of colouring matters are largely used by the silk dyer when fastness to light is not important. The silk yarn is dyed at 60°-80° in a slightly acidified solution of the dyestuff, to which is added some 'boiled-off liquor' After rinsing, the dyed silk is brightened in a dilute solution of acetic or tartaile acid

The dyeing of cotton with basic dyes.—Cotton has little affinity for basic dyes, which, on this fibre, must therefore be applied in conjunction with a mordant, and since the dyestuffs of this class are basic in character, the mordant must be of an acidic nature

Three types of acid mordants are available, tannin matters, fat acids, and colour acids

Tannın morde ils -As mentioned dealing with the mordants, cotton has a natu al

affinity for tannic acid, which it withdraws from solution Since tannic acid forms lakes with the basic colouring matters, cotton thus prepared may be dyed with basic dyes, but the colours produced in this manner are not fast against As previously explained, however, if after mordanting with tannin the cotton is treated with a salt of antimony, tin, or iron, an insoluble metallic tannate is formed on the fibre, which compound has the same affinity for basic dyes as tannic acid has The fastness properties of the double tannate of colour base and metal are much superior to those of the simpler tannates of the colour bases

For the production of pale or bright colours, commercial tannic acid, gall nuts, or sumac are the tannins employed. The cotton is saturated ('padded') with a solution of 2° to 3°Tw strength, or steeped for 2 to 3 hours in a solution containing 2 to 5 p c tannic acid or 10 to 30 p c ground gall nuts or sumac, the amount being calculated on the weight of cotton. The varn or fabric after squeezing is then at once passed into a 'fixing bath' containing I to 25 pe of tartar emetic or an equivalent amount of antimony oxalate or fluoride After well washing, the cotton is dyed with 0.1 to 1 p.c. of basic dye

Additions of acetic acid to the tannin bath, ammonium chloride and chalk to the fixing bath, and a little acid to the dye-bath, are frequently The mordanting and fixing baths may be used for several successive lots of material

If the brightest possible shades are not required, some cheaper tannin matter (myrobolans or quebracho) may be employed, and stannic chloride may replace tartar emetic as fixing agent For dark shades, ferrous acetate ('black iron liquor') is used as fixing agent, the blueblack tannate of non producing a composite colour with the basic dyestuff

2 Fatty mordants -If Turkey-red oil or soap is used as mordant, the colour produced with a given basic colour is brighter, but less fast, than when tannin mordant is used

The fat acids are fixed on the cotton as metallic salts, usually aluminium salts; the fibre being first saturated with a solution containing I lb of sulphated oil or soap per litre, then died and passed into a solution of aluminium acctate ('red liquor') of about 8°Tw.

3 Colour acids as mordants - Mention has already been made of the fact that the direct dyes act as mordants towards the basic dyes, compound shades being thus obtained Mordant, sulphide, and acid dyes also possess the property of attracting basic dyes, but these combinations

are not much employed.

The dyeing of jute with basic dyes -Although jute is a vegetable fibre, it does not consist of free cellulose, but of a bastose-cellulose compound, corchorobastose (Cross and Bevan) The dyeing properties of this substance differ materially from those of cellulose, jute, in fact, behaving in a very similar manner to tanninmordanted cotton, and dyeing direct with basic

CLASS VI -The sulphide dyes. The dyes of this group are numerous and important are chi fly employed for the production of fast blacks, blues, greens, browns, and yellows on cotton and other vegetable fibres. They come into the market in the form of powders, which

are usually insoluble in water, but soluble in solutions of sodium sulphide. They are also rendered soluble by other reducing agents, e g. sodium hydrosulphite or glucose in alkaline solution

The sulphide dyes are commercially known under such names as. sulphur, sulphurol, thiogene, thionol, thional, thioxine, cross-dye immedial, katigen, kryogen, pyrogen, pyrol rexoll, eclipse, vidal, or auronal dyes. They are produced by melting together under suitable conditions aromatic nitro-, amino-, or iminocompounds with sulphur and sodium sulphide. The constitution of the sulphide dyes is not known, but the commercial products are probably mixtures of polymers or homologues and not homogeneous bodies. They contain free sulphur in amount varying from I to as much as 12 p.c (Gardner and Hodgson, J Soc Chem Ind 1910, 672), and also contain very variable amounts of sodium sulphide and polysulphides

The dyeing of wool with sulphide dyes -Wool is rarely dyed with sulphide dyes, on account of the injurious action of sodium sulphide on the The wool may be protected to some extent against this action by the addition to the dye-bath of glucose, tannic acid, or ammonium salts. A previous treatment of the fibre with formaldehyde has also been recommended (R Kann, Eng Pat 3492, 1903), but this reduces the affinity of the wool for these dyestuffs

Greater success in the application of sulphide dyes to wool or union material has been attained by E Lodge (Eng Pats 19852, 1913, and 23386, 1914) by the use of sodium hydrosulphite and sodium sulphite as reducing agents, and ammonia as solvent for the reduced dyestuff (J. Soc. Dyers, 1915, 252)

The dyeing of silk with sulphide dyes -Owing to the harmful effect of their alkaline solutions upon the silk fibre, the sulphide dyes are not used

The dyerng of cotton with sulphide dyes -This group of dyestuffs is now of the greatest importance in cotton dyeing for the production of fast blacks, and to a less extent, fast blues, greens, browns, &c The necessary ingredients in the dye-bath, in addition to the dyestuff, are sodium sulphide, sodium sulphate, or other neutral salt, and an alkalı, usually sodium car-The actual and relative amounts of these substances vary considerably with different dyestuffs, depending upon the ease with which the colouring matter employed undergoes reduction and the solubility of the reduced product An addition of Turkey-red oil, monopole oil, or glue, tends to produce more level and brighter shades, glucose aids the reduction Dyeing takes place just below the boil, and it is usually desirable to keep the cotton completely immersed during the operation, in order to prevent irregular oxidation. The baths are used in a very concentrated condition, with the result that only a small proportion of the dyestuff is withdrawn, and for reasons of economy 'standing baths' are employed, that is, the baths are used continuously and replenished with dyestuff, &c. as required. The dyeing takes place in iron, wooden, or lead-lined wooden vessels, copper being nigidly excluded, on account of the ease with which it is attacked by sodium sulphide

Some of the sulphide dyes do not require any treatment subsequent to dyeing other than exposure to air, but with many dyes of the group an after-treatment greatly improves their fastness to light and other influences. object of the after-treatment is to ensure the complete oxidation of the colouring matter, and, as oxidising agents, chromium salts, or hydrogen peroxide are used Steaming the material in presence of air is employed in the case of immedial blue

After-treatment with potassium dichromate and acetic acid is now usually practised, since the use of copper salts has proved to be dangerous in regard to the subsequent tendering of the fibre on account of their catalytic action in inducing acid formation (Gardner and Hodgson,

J Soc Chem Ind 1910, 676)

The tendering of cotton dyed with sulphide blacks has greatly retarded the use of these dye-The defect does not usually develop for some weeks or months after the material has been dyed, and it has been shown to be due to the slow formation of sulphuric acid on the The development of acid arises mainly from the oxidation of free sulphur present on the dyed fibre, but even in the absence of free sulphur, acid development may take place by decomposition and oxidation of the colour molecule.

The risk of tendering, during storage, of cotton dyed with sulphide blacks is entirely eliminated by a final treatment of the material, before drying, with sodium acetate, but, of course, the protective influence of this salt disappears if the material is washed

CLASS VII—The vat dyes. Until comparatively recently, indigo was the sole representative of this group of dyestuffs synthetic production of indigo was, however, followed by that of a number of derivatives of this body Other series of vat dyes have also been produced, and by their use it is now possible to produce on cotton, and in a more limited degree on wool, many bright colours of a degree of fastness hitherto unattainable.

The essential features of a vat dye are its easy reduction to a form soluble in dilute alkali, its attraction in this condition by the fibre, and its ready reoxidation on the fibre to the original insoluble condition. The reduced solution is termed the 'vat,' the composition of the vats differing for wool and for cotton

The vat dyes are mainly derivatives of indigotin or anthracene They include the following . indigo (indigotin), mono-, di-, tri-, and tetra-halogen derivatives of indigotin, methyl and tolyl indigotins, ciba dyes (brom indigotins), thioindigo red and scarlet, helindone dyes (sulphur derivatives), algole dyes, cibanone dyes, and the indanthrene dyes The group includes dyes of all hues

Indigo is the oldest and by far the most important of the vat dyes It has been employed in India for at least 3500 years, by methods not differing essentially from some of those which are still employed. It is used upon all fibres,

but least commonly upon silk.

Various reducing agents are employed for the conversion of the insoluble indigo blue into indigo white, and they are always associated with an alkali to dissolve the latter substance. After saturating the fibre with the alkaline sclution, the indigo white is reconverted into

indigo blue upon the fibre by atmospheric oxidation

The dyeing of wool with indigo vat blue The two chief indigo vats used for wool are the fermentation vat and the hydrosulphite vat, the former being chiefly used for dark shades on woollen cloth (Army and Navy cloth, &c ), and the latter for light colours on slubbing, varn, &c There are several forms of fermentation vat, of which the woad vat is the most important in The precise composition and this country 'setting' of the vat is largely a matter of experience, the ingredients being somewhat as follows. finely ground indigo, 12 to 18 lbs woad, 300 lbs; bran, 10 lbs; madder, 12 to 18 lbs, lime, 12 lbs, water, 600 gallons After warming the liquor, various fermentations set in, the essential bacterium being the Desmobacterium hydrogeniferum The starchy matters present are first converted into glucose, which then splits up into lactic acid, the latter undergoing butyric fermentation with evolution of hydrogen.

Excessive fermentation is prevented by making suitable additions of lime, or it is accelerated, if necessary, by adding further quantities

of bran

In the so-called German or soda vat and the Indian or potash vat, the woad is replaced by bran with the addition of molasses, and the lime

by sodium or potassium carbonate

To avoid the derangements to which all fermentation vats are liable, Collin and Benoist (J Soc Chem Ind 1885, 493) proposed to employ a pure ferment and a completely fermentable food material, but this process has not come into practical use.

Natural indigo is still largely used in the fermentation vats, but in the hydrosulphite vat the synthetic product is generally employed The hydrosulphite vat may be prepared as lbs, caustic soda solution 42°Tw, 3 pints, sodium hydrosulphite solution 20°Tw, 7½ gallons, water, 50 gallons. The liquid is heated to 50° until it becomes clear greenish-yellow solution of indigo white thus obtained is diluted to 250 gallons with water at 50°, to which a little hydrosulphite has been previously added.

The hydrosulphite solution may be replaced by 3 lbs of solid sodium hydrosulphite, in which case the amount of caustic soda must be in-3½ lbs of natural indigo (60 pc indigotin) are about equivalent to 10 lbs synthetic indigo (20 p c paste) After working in the vat, the goods are well squeezed, and then exposed to the atmosphere to oxidise the indigo

white they are then well washed

Dark shades of indigo blue on wool are usually 'bottomed' with a red dye (alizarin, diamine fast red, or barwood) before vatting, and are frequently 'topped' after vatting with orchil or other dyestuff in order to add ' bloom ' to the colour.

In most respects indigo vat blue is an extremely fast colour, but has the defect of being liable to 'rub off'

The dycing of silk with vat indigo —This dye If used, the is not much employed on silk most suitable vat to employ is the hydrosulphite vat set with synthet c indigo.

The dyeing of cotton with vat indigo - . 'he

hydrosulphite vat is largely employed in cotton dyeing as well as in the dyeing of wool, but it is used cold in the case of cotton. Other cotton vats are the 'copperas vat' and the 'zincpowder 'vat.

A strong copperas vat contains, indigo (60 pc), 10 lbs ferrous sulphate, 30 lbs, and quicklime 35 lbs, in about 200 gallons of water The lime decomposes the ferrous sulphate, with the production of ferrous hydroxide, and this in the presence of lime and indigo decomposes water, yielding ferric hydroxide and hydrogen; the latter at once combines with the indigotin and produces indigo white, which dissolves by reason of the excess of lime present The normal colour of the vat liquor thus obtained is brownish-amber

The zinc-powder vat is made up with water, indigo, zinc-powder, and lime In the presence of the lime and indigo, the zinc decomposes water even at the ordinary temperature, and the liberated hydrogen effects the reduction of

the indigo

Vat dyes other than indigo -These may be divided into two groups (a) the indigoids, which may be considered as derivatives of indigotin, and (b) the anthracene derivatives all possess the common property of forming vats when treated with hydrosulphite of soda, but whereas the indigoids may be applied to the animal as well as to the vegetable fibres, the anthracene derivatives are only suitable for cotton on account of the large amount of caustic alkali required for their solution reduced anthracene vat dyes also do not appear to possess much affinity for wool

(a) Indigoids—Examples of dyes of this series are throundigo red and scarlet, helindone red and scarlet, ciba red and scarlet, vat red, helindone orange and yellow, ciba green; brom indigos, ciba blues and greys; ciba violets and heliotropes, helindone brown Some of the algole reds also probably belong to this group

(b) Anthracene vat dyes —Indanthrene red, algole reds, indanthrene yellows and oranges, algole yellows and oranges, cibanone yellows and oranges, indanthrene greens, algole greens; indanthrene, chloranthrene, duranthrene and caledon blues, algole blues, indanthrene grey, indanthrene blowns, algole browns, cibanone

The application of the indigoid vat dies to wool and silk —Vats suitable for the dyeing of wool and silk are obtained by reduction with sodium hydrosulphite in alkaline (caustic soda) Bright reds of excellent fastness are solution obtained with these dyes, and they are used in conjunction with indigo for producing bright purplish blues Separate vats are preferable for the indigo blue and the red dye, since the best conditions of dyeing do not coincide in the two

The application of indigoid vat dyes to cotton -Vegetable fibres are readily dyed with these dyes from a hydrosulphite vat, or alternatively they may be dyed from a sodium sulphide bath, as used for the sulphide dvestuffs. They may as used for the sulphide dyestuffs be mixed with most sulphide dyes and dyed from the same vat.

The application of the anthracene vat dyes -This group of dyes is also applied in the hydrosulphite vat, but usually requires such a strongly

caustic solution that its application to wool and silk is not practicable

By use of the vat dyes, it is now possible to produce a great variety of colours on cotton which are extremely fast to light, washing, bleaching, and other influences. The high cost of these dyes at present somewhat limits their application

Indophenol is a vat due of different type, being obtained by the action of nitroso-dimethyl amline on a-naphthol. On reduction, it is converted into indophenol white, a body sufficiently stable to be sold commercially. On oxidation with chromic acid, indophenol white is reconverted into indophenol blue

Indophenol has been employed in conjunction with, or as a substitute for indigo, but has the defect of being readily affected by acids.

Tyrian purple—As the result of an extremely interesting investigation, P Friedlander has shown (Ber. 1909, 765) that this ancient dyestuff is identical with one of the dibromingotins Tyrian purple, as described by Pliny, was obtained from various species of the mollusc mirrer, and from 12,000 of the species M brandaris Frieldander obtained 14 grams of the colouring matter

Under the law of the ancient Romans the use of Tyrian purple was confined to royalty, and the method of its production was a lost art for many centuries. At the beginning of the 18th century, it was investigated by Reaumur (Mem de l'Acad Royale des Sciences, 1711), but it never again assumed any importance as a dive stuff.

dye stuff
CLASS VIII—The ingrain dyes. The term
ingrain dye may be used to designate those
colouring matters other than mordant dyes
which are produced from their constituent
bodies upon the fibre. Three sub-groups may be
distinguished (a) aniline black, (b) the insoluble

azo- dyes, and (c) the metallic dyes.

(a) Anthre black—This term is applied to the insoluble black pigment which is produced by the oxidation of aniline in acid solution. In 1834 Runge noticed that a blue-black compound was produced by oxidising aniline with chromic acid, but Wilm, in 1860, first described the formation of the product on the cotton fibre. The first successful process for producing aniline black on the fibre was patented by Lightfoot, in 1863. He used potassium chlorate and cupric chloride as oxidising agents, and the black proved to be of such excellent fastness that innumerable modifications of the process have since been proposed, and the literature of the subject is very extensive.

Numerous oxidising agents have been employed in the production of aniline black, eq. chlorates, chromates, salts of copper, vanadium, tungsten, cerium, &c. Aniline black may also be produced by electrolytic (Goppelsroder, Jahresber 1876, 702) or by atmospheric (Green,

J. Soc Dyers, 1908, 231) oxidation

Pure aniline on oxidation yields a blue-black, the homologues and allied compounds giving somewhat different shades; e g orthotoluidine produces a brownish-black, paraphenylene diamine a deep black, and para-aminodiphenylamine (diphenyl base) a greenish black. The oxidation of a-naphthylamine on the fibre results in the formation of naphthylamine violet, but this colour is not of much importance.

The composition of aniline black has been the subject of much investigation (see Armand Muller, Chem. Zentr. 1871, 288; Goppelsroder, Jahresber. 1876, 702; Nietski, Ber. 1878, 1094; Caro Verhandt d Ges Deutscher Naturforchen u Arzte, 1896, 119; Willstatter and Moore, Ber. 1907, 2665; Marsden, J Soc. Dyers, 1908, 9; Willstatter and Moore, Ber 1909, 4118; Green and Woodhead, Chem. Soc. Trans. 1910, 223).

Three chief and successive products of the oxidation of aniline may be distinguished-emeraldine, nigraniline, and ungreenable black

Emerabline is produced by the limited oxidation of amline, several residues linking up to form a chain of 4 molecules (Willstatter and Moore) or a chain or ring of 8 molecules (A.G. Green). The aniline residues are in all probability linked by nitrogen atoms in para-position, since para-compounds only have been obtained on oxidation or reduction.

Emeraldine is a greyish-green body which is always formed during the early stages of the production of aniline black. By the action of oxidising agents, it is converted into nigraniline and by the action of reducing agents it forms first proto emeraldine by addition of two atoms, and then leuco-emeraldine by addition of four atoms of hydrogen (Green, Chem. Soc. Trans 1910, 223). More powerful reducing agents split the molecule and produce amino- and para diamino-compounds or quinone

Nigraniline, the second oxidation product of aniline, appears to contain eight aniline residues, and is said to be produced either by removal of two hydrogen atoms from the emeraldine molecule (Green) or by polymerisation with loss of hydrogen (Willstatter and Moore)

Nigraniline or aniline black is a violet-black body which is unaffected by alkalis, but which is turned green by mild reducing agents (sulphurous acid), owing to its reconversion into emeraldine. Dilute mineral acid also brings about indirectly the production of emeraldine from nigraniline. Oxidation of a portion of the latter substance probably takes place at the expense of the reduction of other molecules, since both quinone and emeraldine are formed in the reaction.

Ungreenable black, the final product in the technical formation of aniline black, is produced by the further oxidation of nigraniline in presence of aniline. It is a very stable body, and is not readily attacked by acids, alkalis, oxidising or reducing agents. Powerful oxidising agents, however, convert it almost quantitatively into quinone, and powerful reducing agents into a brown leuco-compound which is reoxidised to the original black on exposure to air. The presence of free aniline is essential to the production of ungreenable black, which suggests that it is a condensation product of emeraldine and aniline.

Technical production of aniline black—Of the large number of modifications of Lightfoot's original process which have been suggested, very few have withstood the test of practical experience The following technical methods may be distinguished (1) dyed blacks; (2) aged blacks; (3) steam blacks.

(1) Dyed blacks, also known as one-bath blacks, are used for the dyeing of cotton yarn, which is often previously dyed in a sulph de black

vat. The ingredients used are  $(e\ g)$  aniline (12 lbs.), hydrochloric acid (18 lbs.), sulphuric acid (24 lbs.), and sodium dichromate (24 lbs.), in 40 gallons of water. The use of hydrochloric acid alone produces a blush-black, and sulphuric acid alone a reddish-black, the mixed acids yielding a jet black

The yarn is worked in the solution whilst slowly heating to the boiling-point, and the bronzy black thus produced is steamed to convert it into a good black which is ungreenable. This process does not tender the cotton Many

modifications of the process are used

(2) Aged blacks are obtained by padding (saturating) the cotton with a solution containing aniline salt, some oxidising agent (sodium chlorate) and an oxygen carrier (copper sulphate, or vanadium chloride), after which the fabric is dried and 'aged'; the colour being developed by passing through an ageng chamber in which a moist atmosphere and a temperature of about 45° are maintained. The padded cotton has a green colour (emeraldine) which turns black (nigraniline) during ageng. The final change to ungreenable black is brought about by working the fabric in a solution of sodium dichromate

Copper aged blacks are very largely produced on cotton piece goods by a process which differs only in detail from Lightfoot's original process

Varadium blacks are chiefly used in calico printing Lightfoot (Bull Soc Ind de Mulhouse, 1871, 285) first noticed the special efficiency of vanadium salts as oxygen carriers in the production of aniline black, and Witz (Bull Soc Ind de Rouen, 1876, 310) showed that 1 part of vanadium chloride was sufficient to convert 40,000 parts aniline into aniline black

The production of aged blacks is liable to tender the cotton unless the process is very

carefully controlled

Air oxidation black—A G Green (J Soc Dyers, 1909, 191) has introduced an amline black process in which atmospheric oxygen is the oxidising agent, some carrier such as cuprous chloride being present. The mineral acid usually employed is also replaced by formic acid, and by these modifications the hability to tendering of the fibre is greatly reduced.

The process is based on the fact that amline oxidises much more rapidly in presence of a small quantity of a paradiamine or a para-amino-

phenol

After padding, the goods are dried, aged, and chromed as in the case of the ordinary aged black

(3) Steam blacks are more costly than aged blacks, but safer as regards tendering of the fibre. They are produced by padding with an aniline solution which contains sodium chlorate as oxidising agent, and sodium ferrocyanide as oxygen carrier. After padding, the goods are dried, steamed, and chromed Lightfoot's original steam black only differed from this in that it contained potassium ferricyanide in place of the less expensive sodium chlorate and ferrocyanide.

Anilne black, when successfully dyed on cotton, is the fastest and most intense black which it is possible to produce. Its chief drawbacks are the tendency to turn green and the liability to tendering of the fibre, unless great experience and close supervision are exercised

Application of an line black to wool and silk.

—The animal fibres are rarely dyed aniline black.

The black may be produced on silk by the same methods as on cotton, but the process is chiefly confined to the silk-cotton union material used as umbrella cloth.

Aniline black does not readily develop on wool, but if the wool is previously chlorinated (Lightfoot) or boiled with a mineral acid (Bethmann, Eng Pat 21236, 1901), the aged black may be produced—It is railly met with

(b) The insoluble azo-dyis—The sulphonated

(b) The insoluble azo- dyes—The sulphonated azo- dyes which are so largely used in the dyeing of wool and silk have little or no affinity for cotton. Azo- compounds, however, may be produced on cotton by impregnating the fibre with one of the constituents, and then passing it into a solution of the necessary combining body. The non-sulphonated compounds are used in this process, and the insoluble dyes thus obtained are, in many cases, useful colours

The constituent parts of an azo-dye are (a) a phenol or amine, and (b) a diazotised base, and the process (introduced by Holliday, in 1880) consists in saturating the cotton with an alkaline solution of a phenol, drying, and then developing

in a solution of the diazotised base

In calico printing (rarely in dyeing) the fibre may be impregnated with a paste containing the whole of the colour ingredients, and the colour developed by steaming

Substances employed in the process · Phenols—The only phenols practically employed in the padding operation are β-naphthol and β-oxynaphthoic acid anilid (naphthol AS)—Amines are not used

Aromatic bases—The following list gives the principal bases employed and the colours they produce when combined with \(\beta\)-naphthol.—

Colour produced with Base β-naphthol Orange yellow Anılıne Paranitraniline Red (with copper, brown) Paratoluidine Yellow orange Nitroparatoluidine Orange Xylıdıne Red Cumidine Bluish-scarlet Scarlet Phenetidine Blue shade of claret red a-Naphthylamine Ammoazobenzene Cumson Benzidine Purplish-brown Tolidine Reddish-brown Dianisidine Blue (with copper) Azo-black base Black

Padding or grounding —The intensity of the ultimate colour depends entirely upon the concentration of the padding solution, which, for a shade of medium strength may contain, per litre, 25 grams  $\beta$ -naphthol, 45 grams sodium hydroxide solution 36°Tw, and 75 grams Turkey-red oil. Cotton is evenly saturated in the cold with this solution, then dried at a low temperature and developed

The developing process—The most important dye produced by this process is paranitraniline red, which is dyed on a very large scale and used as a substitute for Turkey-red. The diazosolution is prepared as follows. stir to a paste 10 lbs. paranitraniline with 2 gallons water; then redd 2 gallons hydrochloric acid (35°Tw) and 6 gallons water. After mixing well, add 5½ lbs sodium intrite dissolved in 2 gallons water. Dilute to 200 gallons, and add sodium

acctate to neutralise the excess of hydrochloric acid. The colour is produced instantaneously on passing the padded cotton into this solution, the cotton being subsequently washed, dried, and soaped.

Various stable forms of the diazotised base appear under the names azophor red, nitrazol,

and nitrosamine red.

Azo-oranges, yellows, crimsons, claret-reds, &c, are obtained in a similar manner by the use of the various bases given in the above table

Azo-browns are produced by adding an alkaline solution of copper to the  $\beta$ -naphthol prepare, and developing with paranitraniline or  $\beta$ -naphthylamine

Azo-blues are obtained by padding with β-naphthol, developing with dianisidine, and subsequently treating with cupric chloride and

chromic acid

(c) The metallic dyes. Iron buff and Nankin uellow.-These two colours, which differ only in depth of shade, are produced by precipitating They are hydrated ferric oxide on the fibre dyed chiefly on cotton, and produce yellow to light-brown colours which are fast to light, washing, or alkalis, but are readily attacked by The cotton is padded in a solution of a ferrous or ferric salt, and then passed into an alkaline solution. If the cotton is previously mordanted with tannin, more even shades are produced, the black tannate of iron being subsequently destroyed by a treatment with sodium peroxide (Knecht) or other oxidising agent Iron buff is only produced on wool or silk as an intermediate product in dyeing Prussian blue

Manganese bronze—This colour is produced on cotton by precipitating manganous hydroxide on the fibre, and oxidising this to the brown

manganic peroxide.

Chrome yellow is produced on cotton by impregnating with a solution of lead acctate, drying, and passing into a solution of potassium dichromate

Chrome orange —This compound is a mixture of normal lead chromate (chrome yellow) and basic chromate It is obtained by treating cotton dyed chrome yellow with lime water

Prussian blue is produced on cotton by first dyeing an iron buff, and then passing into an acid solution of potassium ferrocyamide. This colour is extremely fast to light, but is sensitive to alkalis. It is produced on silk in a similar manner as a constituent in dyeing that fibre black. Prussian blue is little used on wool, but is readily produced either by a process analogous to the above, or by making use of the fact that when heated in acid solution with wool, the prussiates undergo decomposition with formation of Prussian blue.

COLOURING MATTERS USED IN DYEING

Natural dyestuffs · Indigo —There are two distinct methods of applying indigo in dyeing, and the most important, the vat method, has already been described (v. Vat dyes, p 586) Indigo may also be used as an acid dyestuff by converting it into the disulphonic acid. This sulphonic acid is known as indigo carmine or indigo extract. It dies a brighter blue shade than vat indigo, but it is much less fast to light and washing. It is largely used on wool and silk, but is inapplicable to cotton.

Logwood is a mordant dyestuff and is used for all fibres On wool it is largely employed other dyestuffs for browns, olives, greys, &c

Potassium or sodium dichromate is the usual mordant, but a single-bath logwood black may be produced by using a mixture of logwood, ferrous sulphate, and oxalic acid Logwood is now chiefly employed in the form of unoxidised (for cotton) or oxidised (for wool) extract On silk and cotton, logwood is only used for black dyeing

Brazilwood, peachwood, and Limawood constitute the class of soluble red woods. They are now very little employed, the colours they produce being fugitive to light. They produce reds with aluminum, reddish-browns with chromium, and purples with iron mordants.

Cumwood, barwood, and sanderswood are known as the insoluble red woods. If wool is boiled with the ground wood, it acquires a leddish-brown colour, which is still employed as a 'bottom' for indigo vat blue. They are, however, mordant dyestuffs, producing brownish reds with chrome mordant.

Madder—This dyestuff, once of great importance, has now been almost entirely superseded by synthetic alizarin. It is still used to a limited extent in the dyeing of wool felt, since it penetrates through the material more readily than alizarin. With chromium mordant it gives a reddish-brown, with aluminium a red, and with non a purple shade. The use of madder in the wood vat has already been referred to (v. Vat dyes). This dyestuff is not now

used on cotton or silk

Cochineal —The use of this valuable dyestuff in dyeing is now confined to the production of scarlet shades on woollen cloth, for which purpose considerable quantities are still imported, Stannous chloride is the mordant employed, and the colour is produced by the one-bath method. The aluminium and tin lakes are used as pigments in painting and printing.

Lac-dye may be employed in the same way as cochineal, and gives similar shades. Since the commercial product contains a considerable amount of mineral matter, the ground dyestuff is treated with dilute hydrochloric acid before use

Cudbear and orchit (or archit) —These products are essentially the same dyestuff, the former in the solid and the latter in the condition of paste. It is one of the few natural colouring matters which die wool without a mordant. Wool and silk may be died in a neutral, slightly acid, or slightly alkaline, solution. It produces full, rich crimsons, and is still used to a considerable extent. The colouring matter is not applicable to cotton.

Safflower was formerly much used in dyeing bright pinks upon cotton, but is now obsolete as

a dyestuff

Annatto produces orange shades on silk without a mordant, it is applied in a hot soapbath. Annatto is still used in colouring cheese and butter.

Weld—This mordant dyestuff produces pure yellows in conjunction with aluminium mordant. When used as a 'topping' for indigo vat blue, a special shade of green, known as 'carriage green,' is obtained.

Fusic is the most important of the natural yellow dyewoods, and is still employed in

conjunction with chrome mordant on wool as the yellow constituent in compound browns, olives, greys, &c It is chiefly used in the form of fustic extract

Osage orange is closely alhed to fustic utilisation as a dyestuff is only of recent date and is confined to America.

Quercitron bark and flavin are also natural yellow mordant dyes, producing somewhat brighter shades than fustic, but are now obsolete

Persian berries -This mordant dyestuff is employed by the calico printer for producing

bright orange shades with tin mordant

Turmeric is the only representative of the natural colouring matters which acts as a direct dye towards cotton, silk, and wool It produces yellow shades, which are brighter if dyed in a bath acidified with alum.

Catechu, cutch, and gambier —These dvestuffs are still largely employed in cotton dyeing cotton is steeped in a strong solution of the dye, and attracts the colouring matter The cotton is then passed into a boiling solution of potassium dichromate, which, by oxidation, produces insoluble brown japonic acid upon the A little copper sulphate is frequently added to the catechu bath, whereby fuller and faster shades are produced

Silk is dyed in a similar manner for the production of weighted blacks, the chromium, fixed during the oxidising process, subsequently acting as a mordant for logwood

Other natural dyestuffs —Colouring matters are very widely distributed in the vegetable kingdom, and all countries where the textile arts have attained any great development (notably India, Persia, and Japan) had until recently each its own series of indigenous products which were used as dyestuffs In Donegal, Sutherland, and other localities, the homespun tweeds, &c , are still largely dyed by means of the various lichens, 100ts, barks, nuts, &c , found in the neighbourhood

Synthetic dyestuffs. The number of individual synethetic dyestuffs now at the dyer's disposal is very large, and includes dyes yielding all possible hues. There is infinite variety in the cháracteristics of the various artificial dyes, and in most cases it is not difficult to match a given shade or to comply with given conditions as regards properties Being, therefore, more convenient to use, and in very many cases cheaper and faster than the natural dyestuffs, the latter have been largely superseded

The dyeing properties and the characteristics of the dyed colours depend chiefly upon the chemical groups to which the dyes belong, but, as indicated in the section dealing with the classification of dyes, the chemical groups do not coincide with groups based on the method of application (v. Classification of colouring

matters, p 575).

(1) Nitroso colouring matters — This class includes fast-green or dark-green and naphtholgreen. In conjunction with iron mordants, both these dyestuffs give olive-green colours re-

markable for their fastness to light

Cotton is dyed with dark-green by mordanting with iron, and dyeing in a neutral bath. Wool is mordanted with ferrous sulphate and oxalic acid, and dyed in a neutral bath. Silk is dyed in a similar manner.

Naphthol green which contains non as a constituent is only applicable to the animal fibres. Wool is dyed with the addition of suiphuric acid.

(2) Nitro-colouring matters -- The most important members of this class are pieric acid, Victoria orange, aurantia, palatine orange, naphthalme yellow, naphthol yellow These colouring matters are only applicable to the animal fibres, which are dyed in a bath slightly acidified with sulphuric acid. The colours they yield are not fast to light Pierre acid yellow is remarkable for its extreme freedom from any trace of orange On exposure to light it rapidly becomes brownish, owing to reduction of the nitro groups

(3) The azo- group —These may be divided into monazo, disazo, trisazo, and tetrakisazodyes, according to the number of azo-groups they contain They may be further classified into aminoazo- (NH<sub>2</sub>) and oxyazo- (OH) dyes, and into other subdivisions based upon the state of combination of the azo- group A few of the azo- colours are basic dyes, a large number of the acid dyes, and acid-mordant dyes, belong to this group, and practically the whole of the direct dyes. The azo-dyes vary greatly in their degree of fastness to light, and in other properties.

(4) The di- and tri-phenylmethane group -This group includes most of the basic dyes, such as auramine, magenta, methyl violet, malachite These bodies, when sulphonated, green, &c form acid dyes, and therefore such dyestuffs as acid magenta, guinea green, &c., and also patent blue, Victoria blue, fall under this group As a class, these dyestuffs are fugitive to light

(5) The oxyketone group - This group includes most of the artificial mordant dyes, eg the alizarin fieds, yellows, blues, browns, &c Most of the dyestuffs of this group are extremely fast to light and other influences, which renders them of the greatest importance

(6) The pyronine group —This includes (1) the pyronines proper, a small class of basic dyes, of which pyronine red is an example, (2) the much more important group of the phthaleins latter includes both basic and acid rhodamines, the cosms and the mordant dyestuffs gallem and cœrulem

(7) The acridine group —This includes a few basic dyestuffs of which the chief is acridine

(8 and 9) The oxazine and thiazine group -This group also includes both acid (thiocarmine), basic (methylene blue), and mordant dyes (gallocyanın)

(10) The azine group includes the valuable basic dyes the safranines, and the basic and

acid indulines and nigrosines

The dyeing of mixed fabrics of cotton and wool may be carried out by selecting those colouring matters for which both fibres have an attraction, eg the benzidine dyes, &c., or by first dyeing the wool in the usual manner with an acid colouring matter, then mordanting the cotton with tannic acid and tartar emetic or stannic chloride, and dyeing in the cold with a basic colouring matter The so-called 'crossdyeing' process is carried out by first dyeing the cotton (usually with sulphide or other 'ast' dyes) in warp form, then weaving with a

wool weft and dyeing the latter by means of acid dyes. Logwood blacks on union are dyed by first mordanting the cotton in the cold with myrobolans and nitrate of iron, then the wool with a boiling solution of potassium dichromate, and finally dyeing both fibres thus mordanted in a hot decoction of logwood Mixtures of cotton and silk are dyed by methods similar to those employed for cotton and wool. Fabrics of wool and silk are dyed by methods similar to those usual for wool or silk alone

When dyeing compound shades, the main principle to be observed is to apply simultaneously only such colouring matters as are applicable, when used singly, by methods as similar as possible to each other Basic and acid colouring matters ought not to be applied together in the same dye-bath, since the one requires a neutral, the other an acid, bath in order to yield their full colouring power Basic colouring matters, however, may be quite well applied to mordanted cloth along with phenolic colouring matters, since both these classes usually dye in a neutral bath.

It is very irrational to produce compound shades by the application of a mixture of fast and fugitive colours, the best results are obtained by employing colouring matters of about equal fastness to various influences observed, the dyed colour is hable to change materially in shade under those influences to which it is subsequently submitted, eq. light,

The Analysis of Dyestuffs

A G Green DYESTUFFS, IDENTIFICATION OF, ON FABRICS. The recognition of the particular dyestuff which has been employed in dyeing a fabric is frequently a master of considerable difficulty. If one dyestuff only has been used, it may be possible to identify it with little trouble, but when, as is often the case, two or more dyes have been employed to produce a given colour, their separation and recognition

may be a very complex problem

In the identification of dyestuffs, the ordinary basis of qualitative analysis is as far as possible made use of, i e the group to which the colouring matter belongs is first determined, and then tests are applied to identify it as an individual substance. There are, however, such a large number of closely related compounds amongst the dyestuffs, many being isomeric, and differing only (eg) in the position of a sulpho-group, that with the small amount of substance frequently at disposal it is quite impossible to definitely identify a specific commercial pro-

duct This is, however, of minor importance
The recognition of a dyestuff is much facilitated by a knowledge of the dyeing properties of the various groups of colouring matters. In a given case this may greatly limit the possibilities For example, no one with a knowledge of dyeing processes would search for a cochineal scarlet on cotton or a paranitraniline red on wool - The presence or absence of certain metallic bases in the ash of the incinerated material is also a useful indication of the nature of the dyestuff under investigation, and an examination of this point should be made

What may be termed the 'dyeing groups' of colouring matters do not coincide with the 'chemical groups'. For example, the dyeing group of 'basic' dyes, the members of which are fixed on cotton by means of a tannin mordant, includes members of the triphenyl methane, azine, azo-, acridine, and other chemical groups

To determine the dyeing group to which a colouring matter present on a fabric belongs, acid and alkaline solvents are used as 'stripping agents. The following are the general reactions:

ACTION OF 'STRIPPING AGENTS.'

Dyeing group Mordant dyes Basic dyes on wool " on cotton

Acid dyes Direct cotton dyes

Stripping solution 50 c c HCl (conc ) per litre 5 pc acetic acid 3 p.c. sodium hydroxide

3 p.c. ammonia 0 880 s.g. A small piece of mer-cerised cotton is placed in the solution. In each case the fabric is boiled for 5 minutes in the solution.

With direct cotton dyes the small piece of white cotton placed in the solution becomes dyed. With acid dyes this does not occur

The action of the above stripping agents can only be considered as general in regard to a particular group, and many exceptions will be found in dealing with particular members of the group, e.g. some acid dyes are only slightly stripped by boiling in dilute ammonia, and a few of them stain mercerised cotton. Too much reliance must not, therefore, be placed on these stripping reactions.

The most satisfactory group reagents for classifying dyestuffs into the chemical groups are acid or alkaline reducing agents, on the use of which several schemes of identification have been based. Those reagents were first proposed by Witt, in 1886, whose scheme was extended by Weingaertner, in 1887; but the systematic development of the scheme of analysis is mainly due to A. G. Green.

The reactions of dyestuffs are considerably

influenced by the nature of the fibre upon which they have been fixed, which also determines the particular dyeing process necessary. For example, the basic colours dye wool and silk direct, whereas their fixation on cotton involves the use of a tannin mordant. It is convenient, therefore, to treat separately the identification of dyestuffs on animal and on vegetable fibres.

Identification of dyestuffs on wool—Tables for the identification of dyestuffs on wool have been published in Hummel's Dyeing of Textile Fabries; in Knecht, Rawson, and Loewenthal's Manual of Dyeing, in Lehne's Farber Zeitung, and by many other authors; but the most systematic and reliable scheme is that of Green (Analysis of Dyestuffs, 2nd edit 1915) In this scheme, which is now to be described, the dyeing groups are first distinguished by the action of suitable solvents, and then further differentiation is carried out by the use of reducing agents with subsequent reoxidation. The various groups of dyestuffs as dyed on animal fibres, show the following reactions—

Decol	lourised by hydrosul	phito		Not decolourised, but changed in	
Colour restored on exposure to air	Colour not restored by air, but re- stored on oxidation with persulphate	restored other by	Not altered by hydrosulphite	shade Original colour restored by air or persulphate	
Azines, oxazines, thiazines, indi- goids	ines, indi-		Pyrone, acridine, quinoline, and thiazol groups. Some members of the oxyketone group	Most dyestuffs of the oxyketone group	

In Green's scheme the following reagents are employed, and must be used of the strength indicated.—

Dilute ammonia (1 100) —1 cc conc ammonia; 100 cc distilled water

Aqueous-alcoholic ammonia—1 cc conc ammonia; 50 cc strong alcohol or methylated spirit; 50 cc water

Dilute acetic acid (5 p c ) —5 c c glacial acetic acid; 95 c c. water

Dilute alcohol (1:1)—50 cc strong alcohol or methylated spirit; 50 cc water

Dilute hydrochloric acid (1 · 10) —10 cc conc, hydrochloric acid; 90 cc. water.

Caustic soda (10 p c) —10 grams solid caustic soda in 100 c c of water.

Hydrosulphite AX —Dissolve 50 grams hydrosulphite NF cone or rongalite 6, ie the formaldehyde compound of sodium sulphoxylate, in 150 c.c. of hot water. Add to the solution at 80°-90° 0 25 gram of precipitated anthraquimone previously ground to a paste with a little of the solution, and dilute the whole to 500 c c with cold water. The solution should be slightly alkaline. It may become acid on keeping.

Hydrosulphite B.—Dissolve 50 grams hydrosulphite NF conc. or rongalite C in 500 c.c. water, and acidify with 2 c.c. of acetic acid. This is used only for yellows and oranges.

Vol. II.—T.

Persulphate —A cold saturated solution of potassium persulphate, or a 1 pc solution of ammonium persulphate. If alkaline, neutralise carefully with acetic acid.

Sodium acetate (5 p c)—5 grams crystallised

sodum acetate, 100 c c distilled water

Procedure—The reactions are carried out in test-tubes upon pieces of the material about 3-1 inch square, which are covered with about 1-11 inches of the reagent The tests should be carried out exactly as described. Except when specially stated, the reagents are to be applied in succession to fresh portions of the In making 'stripping tests,' the degree of stripping is judged by comparing the remaining depth of shade with that of the original pattern The colour of the stripping solution cannot be relied upon as a guide boiling with dilute acetic acid and dilute ammonia, it is found advantageous to repeat the extraction, as a better stripping is thereby obtained, and with acid dyestuffs any staining of the cotton by the first strong extract is removed during the second boil In testing removed during the second boil with dilute ammonia or sodium acetate, the material is placed in a test-tube with a piece of white mercensed cotton cloth, somewhat smaller in size, and boiled for the time preser bed. If the shade is a pale one, the size of the sample should be increased and that of the cotton

diminished The dilute ammonia is replaced by aqueous alcoholic ammonia in the case of the violet and black dyestuffs (Tables III. and VII), as in these cases the acid dyestuffs are less easily extracted, and the cotton is more liable to be stained by them In making reduction tests, the sample is boiled for from onequarter to one minute with the hydrosulphite, then rinsed well under the tap, and allowed to he on white paper With most dyestuffs which form air-oxidisable leuco- compounds, the colour ieturns immediately or in a few minutes, but with others a longer time is required. The reaction is accelerated by exposing the pattern to ammonia If the colour does not return, the pattern is boiled with a little water in a testtube, and potassium persulphate is added drop by drop, carefully avoiding an excess also fails to cause any return of colour, the dyestuff is to be regarded as a nitro-, nitroso-, or azo- compound The depth of the restored colour varies greatly in different cases, with some dyestuffs the colour reappears with nearly its original depth, but with others (probably on account of the greater solubility of their leucocompounds) only a pale shade may return Safranine and its azo- derivatives are peculiar in yielding a violet colour on reoxidation of the leuco- compound, this being due to the condensation of the leuco-safranine with the formaldehyde present in the hydrosulphite NF

The tables (I to VII, pp. 596-602) give the

scheme of analysis

These tables do not always differentiate between closely related individual dyes, for which purpose further tests must be made stage of the investigation it is very desirable to procure small pieces of material dyed with such known colouring matters as the group tests, combined with the colour of the sample, have indicated as probable Parallel individual tests should then be applied with these and with the sample under examination

The following series of reagents have been found by W M Gardner to be convenient for this purpose They should be applied in the

order given, and used as follows -

Application of cold reagents - Steep a piece of the material 1 by 1 inch in (say) 5 cc of reagent for 5 minutes in a small porcelain

Application of reagents by boiling —In a testtube place 10 cc of reagent and a piece of material 1 by 1 inch Boil gently for 3 minutes

Application of nitric acid test - On a white glazed porcelain plate, spot the material by dipping a glass rod into the acid and then pressing it on to the cloth Note the changes in colour which occur during the formation of the spot, and re-examine after several hours, noting any further change

Reagents for identifying individual dyestuffs

1. Boiling water Use small pieces 2. 5 p c. acetic acid, boiling of white wool,

3. 3 p c. ammonia, boiling. silk, and cotton 4 3 pc soap, boiling along with the 5 Boiling alcohol dyed sample

Concentrated sulphuric acid, cold 3 p c ammonium persulphate, cold.

8 Bleaching powder solution, 5°Tw., cold

9. 50 grams SnCl<sub>2</sub>,2H<sub>2</sub>O+100 cc HC

 $32^{\circ}$ Tw per litre, cold 10. 5 c c. NaNO<sub>2</sub> (5 grams per litre), an

5 c.c. H<sub>2</sub>SO<sub>4</sub> (3 5 grams per litre) boiling.

11. Apply test 10 cold, then wash an steep the material in a solution of sodiu β-naphtholate 5 grams per litre

12 Concentrated nitric acid (spot test)

If the sample under examination shows tl same reactions as any one of the control sample with each of the above reagents, its identif may be considered as clearly established

Knecht (J Soc Dyers, 1904, 98) states the titanous chloride possesses advantages ov both stannous chloride and sodium hydrosulphi as a test for dyestuffs The solution is prepare by boiling together 25 c c commercial titanoi chloride solution (20 pc) and 25 cc HC 32°Tw, and diluting to 1000 cc with water.

IDENTIFICATION OF DYESTUFFS ON COTTON.

Green (Analysis of Dyestuffs, 1915) he worked out an analytical scheme for the detetion of dyestuffs on cotton on the same lines a that previously described for wool

The reagents are as follows .-

1 Dilute ammonia -1 c c strong ammon to 100 c c distilled water

2 Dilute caustic soda -10 grams causti soda in 100 c c water

3 Saline vaustic soda -10 c c caustic sod solution (35-40 p c NaOH) to 100 c c saturate solution of salt

4 Formic acid 90 pc -- Concentrated con mercial acid

5 Dilute formic acid—1 ee formic aci

(90 pc) to 100 cc distilled water 6 Dilute hydrochloric acid -- 5 cc hydro

chloric acid (30 pc) to 100 cc of water 7 Soap solution -10 grams soap in 300 c.

of water 8 Tannin solution -10 grams tannic aci

and 10 grams sodium acetate in 100 cc o

9 Bleaching powder solution —Fresh solutio at 5°Tw

10 Hydrosulphite AX (same as for woo see p 593)

11 Hydrosulphite B (same as for wool, so p 593)

12 Hydrosulphite BX —Dissolve 50 gran of rongalite or hydrosulphite NF cone in 125 c of hot water. Grind I gram of anthraquinor (precipitated, not sublimed) to a fine powde and reduce to a smooth paste with a little of th rongalite solution. Add this paste to the remaining solution, and heat the whole for 1 or 2 minutes at about 90°. Then dilute wit cold water to 500 cc, and, after standing unt cold, add 1½ c c of glacial acetic acid a well-stoppered bottle with greased stopper The reagent should be tested occasionally k trying its effect on cotton dyed with a-naphthy amine bordeaux, which should be fully di charged after boiling for 1 or 2 minutes anthraquinone may be replaced by  $\beta$ -oxyanthr quinone, which can be employed in the san way or previously dissolved in a little alcoh before it is added to the hydrosulphite. the advantage of giving a clearer solution, by is not so generally available

13 Persulphate solution —A cold saturate

solution of potassium persulphate, or a 1 pc solution of ammonium persulphate.

14. Acid stannous chloride —100 grams stannous chloride to 100 c c. hydrochloric acid (30 pc) and 50 cc water. The hydrochloric acid must be free from arsenic. In testing for sulphide colours, this reagent may be replaced with advantage by a strong solution of titanous

15 Chromium fluoride reagent -A solution of 10 grams chromium fluoride and 5 grams sodium acetate in 100 c c water

Procedure: General -All the reactions are performed in test-tubes, with pieces of material about  $\frac{1}{3}$ —\frac{3}{2} of an inch square, which are covered to the depth of from  $1\frac{1}{2}$  to 2 inches with the reagent. The degree of stripping is judged by comparing the remaining shade with that of the original pattern, the colour of the stripping solution cannot be relied upon as a guide testing the colours of calico prints, the separate colours should be cut out and the reactions tried upon them separately With cotton and wool, or cotton and silk unions, the weft is separated from the cotton warp, and each submitted to Doubt may frequently exist as examination to how a particular shade should be classified, whether, for instance, a reddish-blue is to be regarded as a blue or a violet In such cases the tables referring to both colours should be employed, but since the same general scheme is adopted throughout the tables, this can scarcely give rise to confusion. The same remark applies to possible mixtures, thus in examining a certain green shade, both the yellow and the blue tables may have to be used

To distinguish between individual dyestuffs of the same group the same method should be adopted as in the case of wool (see p. 594)

It is obvious that in many instances the analytical procedure may be greatly simplified by exclusion of dyestuffs the presence of which is rendered improbable or impossible by the special circumstances of the case, eg by the material, shade, or mode of application of the colour

Stripping test -A few of the direct dyestuffs are partially stripped by dilute ammonia, and may thus give rise to the impression that they are acid colours To avoid this error, it is advisable to add a small piece of white cotton when carrying out the test With an acid dyestuff the cotton is either not tinted or becomes white on boiling a second time with dilute ammonia

Transference of basic dyes to wool -The tannin mordant is first removed, as in testing for a basic colour, by boiling the pattern for half a minute with saline caustic soda It is then well washed to remove all alkalı, and is boiled with a piece of white wool (half the size of the cotton or less) in a little water for 1 or 2 minutes. In most cases the dye base will leave the cotton almost entirely, and dye the wool a If the colour does not develop on full shade the wool, one or two drops of dilute formic acid (1:100) may be added. In the case of a few dyestuffs which are more difficult to strip (e.g. basic greys), it is necessary to extract the colour with dilute hydrochloric acid (1.20), carefully neutralising the extract with ammonia before adding the wool.

Tannin test for basic dyes -Add a few drops of tannin solution to the formic acid extract. Shake well, and if the precipitate does not form at once, allow to stand a few minutes Some colouring matters such as the rhodamines, gallocvanines, and chrome colours of the rosaniline series (which contain carboxylor hydroxyl- groups in addition to basic groups) only precipitate slowly, and the precipitate, being more finely divided, is sometimes difficult to see

Bleeding test for direct dyestuffs -In testing for direct dyestuffs by the bleeding test, the sample is placed in a test-tube together with a smaller piece of white mercensed cotton cloth, and boiled with soap solution for about a minute The soap solution may be replaced by a 5 p c.

solution of sodium carbonate

Lead acetate test for sulphide dyes—The sample is first boiled for two initutes with a 10 pc solution of sodium hydroxide to remove any adventitious sulphur compounds. It is then well washed and just covered with acid stannous chloride solution The mouth of the test tube is closed by a cap of filter paper closely wrapped round it, into the centre of which is placed, by means of a glass rod, one drop of lead acetate solution. The contents of the test-tube are slowly heated to the boiling-point, when a blackish-brown stain of lead sulphide appears if The brown spot a sulphide colour is present will again disappear on continued boiling on account of the decomposition of the lead sulphide by the hydrochloric acid evolved It is important to pay special attention to the cleanliness of the test-tubes employed for this test, as tubes which have been previously used for hydrosulphite reductions acquire a thin invisible deposit of sulphur upon their walls, which, on boiling with stannous chloride, gives rise to hydrogen sulphide, and thus may lead to error

Reduction and reoxidation tests —The reduction with hydrosulphite BX is carried out by boiling the sample with the reagent for from a The azmes, minute to a minute and a half thiazines, oxazines, &c., and most of the azo-dyestuffs are fully reduced in about half a minute, but the insoluble azo- colours and some direct dyestuffs require longer boiling to complete their reduction In testing the reoxidisability by air, the reduced sample may be exposed to the fumes of ammonia, which in many cases accelerates oxidation

Tests for vat dyestuffs—(See Green and Frank, J Soc Dyers, 1910, 83; and Grand-mougin, Tabellarische Uebersicht der Kupenfarbstoffe)

The analytical tables worked out by Green for the identification of dyestuffs on vegetable fibres, are given on pp 603-609, Tables VIII. to XÍV

ST Mulliken (Identification of the Commercial Dyestuffs, 1910) has published a systematic scheme of analysis, primarily intended for the examination of the dyestuffs in substance. The tables give the reactions of 1475 distinct dyestuffs, and are of great service in the identification of dyes on the fibre

Spectroscopic examination of dyestuffs.—The absorption spectra of dyestuffs may be used as an aid to their identification. In the second

edition of Vogel's 'Practische Spectralanalyse irdischer Stoffe' (1889), charts were given of the absorption bands of various dyestuff solutions. This work was greatly extended in 'Formânek's Spectralanalytischer Nachweis Kunstlicher organischen Farbstoffe' (1900), which contains a systematic scheme for the spectroscopic identification of upward of 350 distinct dyestuffs In a later publication (1905) entitled 'Qualitative Spectralanalyse anorganischen und organischen Korper,' Formânek has extended his data to include the natural colouring matters, and, in conjunction with E Grandmougin, has republished his tables as 'Untersuchung und Nachweis organischen Farbstoffe auf spectroscopischen Wege'

The value of spectroscopic tests for the identification of dyestuffs on the fibre is limited to those dyestuffs which can be removed without

change by suitable solvents

Spectroscopic examination of dyed fibres has not yielded useful results W = M = G

Note.—Green's scheme of identification of dyes and the annexed Tables are printed by permission of Prof A G Green and Messis Chas. Griffin & Co., Ltd

DYER'S BROOM. Genista tinctoria (Linn) (Dyer's broom, Dyer's greenweed, Genet, Genestrole, Trentanel, Fr ; Ginster, Ger ) is found in the pastures, thickets, and waste places throughout Central and Southern Europe, across Russian Asia to the Baikal, and northward to Southern It is frequent in the greater part of England, but rare in Ireland and Scotland The fact that it contains a yellow colouring matter is recorded by numerous writers, and the following embody the principal references to the dycing and general properties of the plant Bancroft (Philosophy of Permanent Colours, 1813, 2, 108), Gmelin (Handbook of Chemistry, 16, 517); Berthollet (On Dyeing, 1824, 2, 242), Gonfreville (L'Ait de la Teinture des Laines, 501), Leuchs (Farben u Farbekunde, 1846, 2, 309), and Schutzenberger (Traité des Matières Colorantes, 1867, 4, 422)

To isolate the colouring matters, a hot aqueous extract of the plant is treated with lead acetate solution, and the pale yellow viscous precipitate is collected and decomposed by means of boiling dilute sulphuric acid. The clear liquid decanted from the lead sulphate deposits on cooling a dull yellow powder, this the solution poured into a large volume of ether, causing the separation of a dark-coloured resinous impurity. The clear liquid is evaporated, yielding a yellow crystalline residue, which consists of two substances. To separate is filtered off, dissolved in a little alcohol, and these, advantage is taken of the fact that, with sulphuric acid in the presence of acetic acid, one only of these compounds gives an insoluble This is collected and decomposed with water and the product crystallised from It is obtained as yellow needles, dilute alcohol and was found to be identical with the luteolin of weld (Resela luteola) (Perkin and Newbury, Chem Soc Trans 1899, 75, 830).

Genistein C<sub>14</sub>H<sub>10</sub>O<sub>5</sub>, the second colouring matter of dyer's broom, is present in the mother liquors obtained during the purification of the luteolin, and also in considerable quantity in the filtrate from the lead precipitate, from which

it is most readily isolated. To the boiling liquid ammonia is added, causing the separation of a lemon-yellow precipitate, which is collected and decomposed with boiling dilute sulphuric acid. The clear liquid is extracted with ether, and the extract evaporated, leaving a brownish crystalline mass. It is purified by crystallisation from acetic acid, and by conversion into the acetyl derivative.

Ğenistein crystallises in long colourless needles, mp 291°–293° (Perkin and Horsfall, Chem Soc Trans. 1900, 77, 1312), soluble in alkalıs with a pale yellow colouration. Alcoholic ferric chloride gives a dull-red violet colouration, and alcoholic basic lead acetate a lemon-yellow precipitate

Tracetylgenistein C<sub>14</sub>H<sub>7</sub>O<sub>5</sub>(C<sub>2</sub>H<sub>3</sub>O)<sub>3</sub>, colourless needles, m p 197°-201°, and tetrabromgenistein C<sub>14</sub>H<sub>6</sub>Br<sub>4</sub>O<sub>5</sub>, colourless needles, m.p. above 290°, have been described

On digestion with boiling 50 p c potassium hydroxide, genistein gives phloroglucinol and p-hydroxyphenylacetic acid

By methylation with methyl iodide in the usual manner, genistein dimethyl ether and methylgenistein dimethyl ether are produced

Genistein dimethyl ether  $C_{14}H_1O_3(OCH_3)$ , forms colourless leaflets, melts at  $137^{\circ}$ – $139^{\circ}$ , and gives the monacetyl compound

$$C_{14}H_7O_3(C_2H_3O)(OCH_3)_2$$

minute colourless needles, mp 202°-204°. When decomposed with alcoholic potash, it forms methoxyphenylacetic acid and phloroglucinol-monomethyl ether (identified by means of its disazobenzene derivative)

Methylgenistein dimethyl ether

melts at 202°, and the acetyl derivative

forms colourless needles, mp 212°-214°. With alcoholic potash it gives methoxyphenylactic acid and probably methylphloroglucinol-monomethyl ether

Genustein diethyl ether  $C_{14}H_8O_3(OC_2H_5)_2$  forms colourless needles, m p  $132^{\circ}-134^{\circ}$ , whereas acetylgenistein diethyl ether

$$C_{14}H_7O_3(C_2H_3O)(OC_2H_5)_2$$

melts at 168°-170°. Alcoholic potash gives p-ethoxyphenylacetic acid

According to Perkin and Horsfall, genistein may be a trihydroxyphenylketocumaran—

Genistein is a feeble colouring matter, and upon woollen cloth gives, with chromium mordant, a pale greenish-yellow, with aluminium mordant, a very pale yellow; and with iron mordant, a chocolate-brown shade.

Dyeing Properties of Dyer's Broom—In this respect there is a close resemblance between dyer's broom and weld. The dyeing power of the former is distinctly the weaker of the two; otherwise the only point of difference worthy of mention is that shown by the iron mordant, which, in the case of dyer's broom, gives a duller and more drab-coloured shade.

ECGONINE 611

Luteolin is also present in the Digitalis purpurea | Chem Soc 1918, 40, 598) (Urbain and Demeni (digito-flavone) (Fleischer and Fromm, Ber 1899, 32, 1184; v Kostanecki and Diller, ibid. 1901, 34, 3577), and in the flowers of Antirrhinum majus (Wheldale and Bassett, Bio-Chem J lc)

A G P DYMAL. Trade name for 'didymium' salicylate [Nd Pr] [C<sub>6</sub>H<sub>4</sub>(OH) CO<sub>2</sub>]<sub>3</sub>. A reddishwhite substance, used as a dusting powder, having non-irritant and antiseptic properties

DYNAMAGNITE, DYNAMITE v. EXPLOSIVES **DYSANALYTE.** A cubic or pseudo-cubic mineral consisting of titano-columbate of calcium with some ferrous oxide, cerium earths (up to 5 pc), and sodium The amount of Cb<sub>2</sub>O<sub>5</sub> given in various analyses ranges from nil to 26 p c, and the mineral has sometimes been asserted to be identical with perofskite (CaTiO<sub>3</sub>), the difficulties presented in the analysis of this mineral are, however, implied by its name, from δυσανάλυτος, 'hard to undo' It occurs as small black cubes in contact-metamorphic limestone at Sasbach in the Kaiserstuhl Mountains, Baden, and in metamorphic sandstone at Magnet Cove, Arkansas L. J S

**DYSCRASITE** (antimonial silver) Antımonide of silver Ag<sub>6</sub>Sb (Ag 84 3 p c) to Ag<sub>3</sub>Sb (Ag 72 9 pc), occurring as silver-white masses with metallic lustre, but often with a dull yellowish or black tainish The material is  $H = 3\frac{1}{2} - 4$ Orthorhombic crystals, twinned to simulate hexagonal forms, are rare and not distinctly developed. According to T. Liebisch (1910), two compounds are represented, namely, cubic AgoSb, with sp gr 10 05, and orthorhombic Ag<sub>3</sub>Sb, with sp gr 9 63-9 82 The mineral is found in silver mines at Wolfach in Baden (where it is the chief ore), Andreasberg m the Harz, Allemont in France, and the Cobalt district in Ontario. L J S Cobalt district in Ontario.

DYSODILE. A soft laminated carbonaceous substance of a yellowish-grey or green colour burning with a luminous flame, and a smell resembling that of burning caoutchouc in Sicily and in Bavaria (Fricklinger, Jahrb Min 1875, 760; also Church, Chem News, 34,

155, Potonić, Chem Zentr 1907, n 555). **DYSPROSIUM.** Sym Dy At wt 162 5 (162 52 Kremers, Hopkins, and Engle, J. Amer.

troux, Compt rend 1906, 143, 598, Hinrichs, *ibul* 1143) From erbia—one of the fractions obtained from ytterbite—Cleve separated an earth which he called 'holmia', and from this material Lecoq de Boisbaudran isolated a simpler constituent, dysprosia, characterised by a well-marked absorption spectrum showing bands in the ultra-violet as well as in the visible region of the spectrum (Compt. rend. 1886, 102, This oxide, one of the most basic constituents of holmia, was concentrated by precipitations with potassium sulphate and ammonia. Further fractionation of the nitrates and double nitrates gave a product rich in terbium and dysprosium (Urbain, Compt acnd 1904, 139, 736, 1905, 141, 521) The latter is separated from terbium by fractional crystalli-ation of the ethyl sulphates, terbium and yttrium being concentrated in the least soluble fraction, whilst dysprosium accumulates in the middle fraction (Urbain, Ann Chim Phys 1900, [7] 19, 184. Compt rend 1906, 142, 785)
Dysprosium material of very high purity

may be obtained by fractional crystallisation of the rare-earth bromates, followed by fractional crystallisation of the ethyl sulphates (Engle and Balke)

Dysprosium is separated from yttiium by crystallisation of the intrate with the addition of bismuth nitrate

Dysprosium forms a white oxide Dy,O3, but no perovide Its salts have a faint greenish-yellow tint chloride DyCl<sub>3</sub>.6H<sub>2</sub>O, nitrate Dy(NO<sub>3</sub>)<sub>3</sub>,511<sub>2</sub>O, melting at 88° in its water of crystallisation, very similar to bismuth nitrate (Urbain and Jantsch, Compt. rend. 1908, 146, 127), sulphate  $\operatorname{Dy}_2(\mathrm{SO}_4)_2, \mathrm{8H}_2\mathrm{O}$ , builtant yellowish crystals, stable at 110°, and completely dehydrated at 360°. For other salts, vJantsch and Ohl, Ber 1911, 44, 1274

Dysprosium stands first in the list of paramagnetic elements, its oxide Dy<sub>2</sub>O<sub>3</sub> being 12 8 times more magnetic than ferric oxide. high values for the magnetic susceptibility of the rare earths (yttria, erbia, &c) fractionated by Cleve and Nilson are probably due to the presence of dysprosium (Urbain, Compt. rend. 1908, 146, 922) G., T. M

 $\mathbf{E}$ 

EARTHNUT OIL v ARACHIS OIL EAU DE COLOGNE v PERFUMES

EAU DE JAVELLE. Solution of sodium hypochlorite (v Bleach liquor, ait Chlorine)

EAU DE LUCE. Aqua luciæ A milky liquid containing oil of amber, alcohol, and ammonia (v. Amber, Oil of).

EBONITE. Sulphurised caoutchouc RUBBER

EBULLIOSCOPE. An instrument for determining the strength of spirits of wine by means of its boiling-point ECBOLINE v. ERGOT.

N-benzoylhydroxypropylnovec-ECCAINE,

A compound allied to cocaine gonidene ester and of the structure

A crystalline base, more active than cocaine in its an esthetic properties, is non-toxic and can be readily sterilised (Braun and Muller, Ber 1918, 235, Chem Werke Grenzbach, D. R. P. 301139).

ECGONINE v COCAINE AND THE COCA ALKA-LOIDS.

ECHITAMINE, ECHITENINE v DITA BARK. ECHUJIIN v. DIGITALIS

E. C. POWDER v EXPLOSIVES

EDESTIN. A crystalline proteid substance found in the seeds of hemp, sunflower, and easter-bean, capable of uniting with acids to form salts (Osborne, J. Amer. Chem. Soc. 24, 39)

EDIBLE OILS AND FATS. Under this term are compused those oils and fats which serve as food. Most of the edible oils and fats, such as olive oil, cod liver oil, suct, laid, butter-fat, cacao butter, goose fat, &c, are immediately fit for consumption, if 'rendered' with sufficient care Hence they rarely need undergo a process of technical punication, except simple filtration, before they are placed on the market This applies, however, only to the freshly ('first') rendered products, as contact with putrescible organic matter rapidly causes hydrolysis of the oils and fats, so that, e g, lard or olive oil which has been allowed to remain in contact for some little time with the organic tissues from which they have been derived, readily become rancid, and therefore unfit for food in their original state. This applies with especial force to cod liver oil

The large demand made on the market by the rapidly growing consumption of oils and fats has, however, led to the employment of second and even third 'renderings,' in the case of animal fats, and second or third 'expressions' in the case of vegetable oils and fats. Such products contain, as a rule, notable amounts of free fatty acids, and small quantities of extractive substances, all of which must be removed before the oils and fats become suitable for food purposes. The processes applied to the purification and decolourisation are treated as deep secrets. It may, however, be stated that most of the processes are based on physical methods of refining (see OILS AND FATS)

Chemicals involving the use of mineral acids must be altogether excluded from the purview of the refiner, since the mineral acids, however carefully they may be removed by subsequent washing, impart an objectionable flavour to the products, thus rendering them useless for edible purposes Alkalis or alkaline earths are not so objectionable, and are, therefore, used commercially for the removal of fice fatty acids (A notable example of this kind is furnished by the usual method of refining cotton-seed oil) The alkalis and alkaline salts chiefly employed in practice are caustic soda, sodium carbonate, sodium silicate, lime, and magnesia Baryta has also been proposed (and patented), but its poisonous properties would prohibit its use.

Whereas all animal oils and fats, when freshly prepared, are suitable for food, this holds good only in a somewhat restricted sense of vegetable oils and fats. If the vegetable oils and fats are free from objectionable substances they may hold in solution or may have dissolved from the vegetable matter from which they have been obtained by expression or boiling out, they are suitable for edible purposes, and are so used to a very considerable extent.

We know, however, a number of oils which contain non-fatty toxic or injurious sub-tances, such as tung oil, calophyllum oil, cureas oil, croton oil. In the case of castor oil, the fatty acids themselves are injurious to health; hence

castor oil is unusable as a foodstuff. Experience has also shown that the fats belonging to the Chaulmoogra group are injurious to health All these oils must, therefore, be excluded from the list of edible oils

Oils which are regarded as palatable in one part of the world are not used as food in other parts. Thus, whereas rape oil and linseed oil ind a ready market for edible purposes in India, these oils are at present used in exceptional cases only as table oils in Western Europe. They are replaced in richer countries by cotton-seed oil, sesamé oil, arachis oil, poppy-seed oil, and olive oil. The increased consumption of the available edible oils and fats has created, during the last decades, a new and growing industry.

Amongst the most important developments in this industry is the preparation of coco-nut oil and palm-kernel oils for edible purposes (see Coco-nut oil and Palm-kernel oil). Mixtures of several edible oils are now largely prepared as 'table oils' to replace olive oil Amongst these substitutes the most important arachis oil, sesamé oil, cotton-seed oil, and to some extent also soya-bean oil. Mixtures of edible vegetable and animal oils a .d fats are chiefly represented by the 'suet substitutes,' which are prepared by mixing tallow with cotton-seed oil, and by 'lard substitutes,' which represent a mixture of animal fats with cottonseed oil, maize oil, &c Until a few years ago, 'compound lard' contained frequently no lard whatever, but, according to legislation in the United States, 'lard compounds' or 'lard substitutes' must now contain at least 50 pc. of lard (see LARD SUBSTITUTES)

Another development of the industry has been the introduction of hardened or hydrogenated oils, which are now extensively used as constituents of margarine (see Hydrogenated oils)

The manufacture and sale of edible oils and fats has assumed such considerable importance that legislation has stepped in to protect the public against fraudulent practices both as regards the commercial description of a 'blended' fat and the absence of injurious substances (see Margarine)

The changes in the character of fats during cooking have been described by Masters and Smith (Analyst, 1914, 39, 347).

J. L.

EDINOL. Trade name for p-amino-saligenin hydrochloride Used as a photographic developer

**ÉDULCORATION.** The act of washing insoluble matter so as to remove any soluble impurity.

**EFFLORESCENCE.** This term is applied to two or three different phenomena, characterised by the formation of a loose pulverulent deposit on the surface of a solid body

1 Crystallised salts are said to effloresce when they lose their water of crystallisation and fall to powder, e.g. normal sodium carbonate

fall to powder, eg normal sodium carbonate
2 The formation of a pulverulent crystalline deposit on the surface of a porous body, in consequence of the crystallisation of a salt existing in solution within its pores, or formed from materials existing therein, is also called efflorescence; e.g. the crystallisation of potassium nitrate on the surface of the earth or in caves, as

EGG. 613

in India, or on saltpetre plantations; of sodium sulphate and carbonate on walls; of alum on alum-slate; of ferrous sulphate on iron pyrites, &c In all these cases the solution of the salt is drawn by capillary action to the surface of the solid body, and there crystallises in consequence

of the evaporation of the water

3. The term 'efflorescence' is likewise applied to the effect which sometimes takes place when a saline solution is left to evaporate slowly in an open vessel The solid salt separates in dendritic crystals just where the surface of the liquid touches the side of the vessel, and the solution, rising by capillarity between these crystals, forms a fresh crystallisation just above the first layer; and this process is continually repeated till the crystallisation thus formed extends over the edge of the vessel, and sometimes down to the table on which it stands. Sal-ammoniac and other ammonia salts often effloresce in this The effect may be prevented to a certain extent by greasing the edge of the vessel, or better, by quickly boiling the solution, or evaporating it by heat from above EGG. The egg of the common fowl, Callus

EGG. The egg of the common fowl, Callus Bankva, consists of four principal parts the shell, the white, the yolk or vitellum, the white yolk or germinal cell, and the membranes separating these parts. The usual weight of an egg is 40-60 grams, of this the shell and shell membrane form 5-8 grams, the yolk, 12-18 grams: and the white, 23-34 grams.

The shell has the composition

The colouring matter of egg-shells is a bile

pigment (Liebermann, Ber 11, 606)

The shell membrane or membrana putaninis separating the white from the shell is double, the two parts being in contact over the greater part of the inner surface of the shell, but separated by an air-space at the broad end of the egg. These membranes are composed of a proteid substance allied to keratin (Liebermann)

Abderhalden and Strauss have examined the products of hydrolysis of ovokeratin, and find them to be, from 100 grams of substance 39 grams glycine, 35 grams alanine, 11 gram amino-valerie acid, 74 grams leucine, 40 grams proline, 81 grams glutamic acid, and 11 gram aspartic acid (Zeitsch physiol

Chem. 1906, 48, 530)

The white is a faintly yellow albuminous fluid enclosed in large cells of thin membrane. The fluid has sp. gr. 1045, and is really mobile, though it appears viscous because of its confinement by the cell walls. It has an alkaline reaction. Kojo (Zeitsch physiol Chem 1911, 75, 1) gives the following analysis:

Water		87 71 p c
Ash .		04,
Organic solids		11.89 ,,
Total nitrogen		1 75 ,,
Dextrose .		0 55 .,

The organic solids consist mainly of proteins, small amount of dextrose, and traces of fats, ecithin, and cholesterol Salkowski showed that glucosamine was also present (Biochem Zeitsch. 1911, 32, 335).

The protein substances of egg white are all gluco-proteids, and in their solution and precipitation properties are similar to globulins, albumins, or proteoses (v art PROTEINS)

Ovoglobulin separates from egg white partly on dilution with water, and completely if the solution be saturated with magnesium sulphate or ammonium sulphate By repeated solution in water and reprecipitation, part becomes insoluble (Langstein, Hofmeister's Beitrage, 1), and it is probably a mixture of several globulins (Corin and Beiard, Bull Acad Belg [3] 15, 643) The globulins form about 67 p c of the total proteids of egg white (Dillier, Hammarstein's Text-book Physiol Chem 430)

Ovalbumin is the chief proteid constituent of egg-white. It is obtained crystalline by precipitating the globulins with ammonium sulphate, as above, and allowing the filtrate to evaporate (For details of methods, see Hofmeister, Zeitsch. physiol Chem 16, 187, Osborne and Campbell, J. Amer. Chem. Soc. 1900, 22, 422, Rosenkrantz, J. Russ. Phys. Chem. Soc. 1906, 38, 2, and Mayer, Compt. rend. 1906,

143, 515)

Pure ovalbumin crystallises in large, well-formed needles A 2.5 p.c. solution in water becomes turbid at 60°, and at 64° yields a floculent coagulum. The addition of sodium of coagulation (Osborne and Campbell,  $l\,\epsilon$ , Starke, Pfluger's Archiv 12, 18)

The composition of ovalbumin is .

C H N S P () 52 75 7 10 15 51 1 62 0 12 22 90 p c

(Osborne and Campbell, lc 441, in agreement with Hopkins, J. Physiol 25, 306, and Hammarsten, Zeitsch physiol Chem 9, 304)

Many attempts have been made to assign a formula to ovalbumin Latham (Biochem J. 1908, 3, 207 et seq) gives it a molecular weight of 5473, and the formula  $\mathrm{C_{240}H_{397}N_{65}O_{76}S_3}$ , but this must be regarded as an approximation

It has been characterised by determining the various amino-acids yielded on hydrolysis with hydrochloric acid of sp gi 1 19 (v. art Proteins). 100 grams ovalbumin yield alanine, 21 grams, leucine, 200 grams, phenylalanine, 44 grams, tyrosine, 11 gram; cystine, 03 grams, proline, 23 grams; aspartic acid, 15 grams, and glutamic acid, 80 grams (Abderhalden and Piegl, Zeitsch physiol Chem. 1905, 46, 24, Osborne, Jones, and Leavenworth, Amer J Physiol 1909, 24, 252; Levene and Beatty, Biochem Zeitsch 1907, 4, 305)

The specific rotation of pure albumin is given as --31° (Willcock, J. Physiol. 1908, 37, 27), -30 70° (Hopkins, ibid. 25, 306), and

 $-29\,31^\circ$  (Osborne and Campbell,  $l\,c$  )

The precipitation of albumin by acids and salts is a completely reversible reaction (Galeotti, Zeitsch physiol Chem 1905, 44, 461), and follows the law of mass action (Ostwald, Chem Soc. Abstr 1908, 1 375, Gerrini, Zeitsch physiol Chem 1906, 47, 287)

Conalbumin Only about one-half of the proteid of egg white can be obtained as crystal-lised ovalbumin, the other fractions have a higher rotation and sulphur content By heating these fractions at 65°, conalbumin is

614 EGG

obtained as a coagulum, which, when dried at 110°, has the following composition:-

Its specific rotation is about  $-36^{\circ}$  (Osborne and Campbell, lc.; Panormoff, Chem Zentr 1898, 11, 487).

Ovomucoid is found in the residue after all proteids coagulated by heat have been removed from egg white (Neumeister, Zeitsch Biol 1890, 27, 369, Morner, Zeitsch physiol Chem 1893, It forms about 10 p c of the proteids 18, 525) of egg white It is not precipitated from solution by mineral acids or organic acids (except phosphotungstic and tannic acids) or by metallic salts.

The inorganic constituents of egg-white in 1000 parts are: Potash, 276-285 parts, soda, 235-239 parts, lime, 18-29 parts, magnesia, 16-32 parts; iron oxide, 4 4-5 5 parts, chlorine, 238-205 parts, phosphoric acid, 32-48 parts, sulphuric acid, 13-26 parts; silica, 3-20 parts, carbon dioxide, 97-116 parts (Poleck and Weber, Hammarsten's Physiol Chem 1904, 432). Traces of fluorine have also been found (Nickles, Compt rend 43, 885)

The yolk or yellow is contained within a membrane composed of a proteid allied to keratin (Liebermann, Pfluger's Archiv 43) It is a viscous, opaque, yellow, alkaline emulsion having a mild taste, and consists chiefly of water, fats, and colouring matter, together with vitellin, lecithin, cholesterol, &c Muller and Masuyama (Zeitsch f Biol 1900, 39, 542) have found a diastatic enzyme in the yolk, the presence of purme bases has been detected by Mesernitzki (Biochem Zentr 1, 739), and of

creatinin by Salkowski (lc).

1000 parts of the yolk contain approximately. water, 480 parts, fats, 228 4 parts proteid (vitellin), 1563 parts, lecithin, 1072 parts, cholesterol, 175 parts, insoluble salts,

6.12 parts, soluble salts, 3.53 parts

According to Poleck, the ash of yolk of eggs contains, in 1000 parts soda, 51 2-65 7 parts potash, 80 5-89 3 parts, lime, 122 1-132 1 parts, magnesia, 20 7-21 1 parts; iron oxide, 11 9-14 5 parts, phosphoric acid, 638 1-667 0 parts, silicic acid, 5 5-14 0 parts

The fat forms about 30 p c of the yolk, and may be extracted with ether. It is a mixture of solid and liquid fat, and contains 06 pc phosphorus, equivalent to 1504 pc. lecithin, 61 5 p c of neutral fat, and 23 2 p c free acids The neutral fat contains glycerol and acid in such proportions as prove it to consist of triglycerides only (Thorpe, Arch Nedér Sci Exact Nat 1901, 6, 155) On saponification On saponification it yields 40 pc oleic acid; 38 04 pc palmitte acid; and 15 21 p.c stearic acid (Paladino, Biochem Zeitsch 1909, 17, 356)

Barbieri, by extracting yolks with carbon disulphide, obtained tristearin and triolein (Compt rend 1907, 145, 133), besides cholesterol; while MacLean has isolated pure tripalmitin from egg-fat (Biochem. J 1909, 4, 168).

Lecithin (v Lecithin) is present both free and in combination with protein (Manasse, Biochem Zeitsch. 1906, 1, 246) Commercial Commercial lecithms are usually prepared from eggs, a d show a high choline content. Trier identified

B-aminoethyl alcohol in egg lecithin, isolating it as its gold chloride compound (Zeitsch physiol. Chem. 76, 496) Lecithin is best prepared from dried egg yolks by Bergell's method (Ber. 1900, 2584) The extract prepared by boiling with 96 p.c alcohol for 6 hours, is cooled to 0° and precipitated with an alcoholic solution of cadmium chloride The precipitate is filtered off, washed with 96 p c alcohol, dried in air, and extracted with ether The residue is boiled with eight times its volume of 80 p.c. alcohol, and a concentrated solution of ammonium carbonate is added until the solution is free from cadmium. The filtered solution is cooled to -10°, and the precipitate is dissolved in chloroform, precipitated with acetone, and dried in vacuô over sulphuric acid.

After hydrogenation of egg lecithin, Paul and Ochme isolated stearic and palmitic acids, and suggest that linolic and palmitic acids are originally present (Ber. 1913, 1297)

Barbieri (Gazz chim ital 1917, [1] 1) stands alone among a host of investigators in his failure to isolate lecithin from egg yolk affirms that the phosphorus of egg yolk is present as morganic phosphates, that the choline exists only as a degradation product of ovochromin, and that glycerol and fatty acids exist as constituents of fat, and not combined as lecithin

Cholesterol is present in the yolk to the extent of about 1 pc (Juckenack, Zeitsch. Nahr Genussm 1899, 1905; Benecke, Bied Zentr 1881, 568) According to Scrano and Palozzi (Chem Zentr 1911, 11 772), it occurs as its oleic and palmitic esters

Lutein, the colouring matter, was described by Maly (Chem Zenti 1881, 485) as a mixture two substances: vitello-lutein, which is yellow and soluble in petroleum, and vitello-rubrin, a red body soluble in carbon disulphide. The mixture is an orange-red amorphous substance, which is not affected by alkalis, and can therefore be isolated by hydrolysing the fats. C A. Schunk (Proc Roy Soc. 1904, 170), as the result of spectroscopic examination, identified the yellow pigment of the hen's yolk with the L xanthophyll, which he has isolated from The characteristic spectroscopic haviour of the lutein has been suggested as a test of the purity of commercial dried egg yolk (Lewin, Miethe, and Stenger, Pfluger's Archiv Willstatter and Escher (Zeitsch physiol Chem 76, 214) isolated the pigment from the yolks of 6000 eggs, and obtained it in crystalline form, and showed it belonged to the xanthophyll group of pigments; they showed also that a carotin-like pigment was present Palmer (J Biol Chem 23, 261) showed that the pigments of egg yolk were increased by feeding with rations rich in xanthophyll, yellow corn being particularly suitable for this purpose as a winter ration. The point is of importance to the poultry trade, since eggs with highly-coloured yolks are in great request.

Vitellin, the protein constituent of the yolk, is separated by mixing the yolks with brine, in which the protein is soluble, and extracting the fat, &c, with ether. It has the properties of a globulin, and, on dialysis or dilution of the solution, is precipitated as a white granular substance. A solution coagulates at 70°-75°. EGG. 615

Vitellin thus obtained is a mixture of compounds of protein matter with lecithin, containing from 15-30 p.c of the latter, called lecithin-nucleovitellins. The lecithin thus combined is not removed by ether, but is completely removed by alcohol, leaving an insoluble proteid, nucleovitellin, of constant composition, which, on digesting with pepsin, yields paranuclein.

It is probable that all these proteins are

compounds of vitellin with phosphoric acid H<sub>3</sub>PO<sub>4</sub>, or some very simple organo-phosphoric acid. The composition of vitellin, free from

phosphoric acid, is:

(Osborne and Campbell, J Amer Chem Soc 1900, 22, 413)

Plimmer states that another distinct protein 'livetin,' can be obtained from the yolk (Chem Soc Trans 1908, 1500)

Berthelot and André determined the heat of combustion of egg yolk to be 8124 calories per gram (('ompt rend 110, 925)

The germinal vesicle, or white yolk, forms a laver between the yolk and the yolk membrane, with a process extending to the centre of the It is enclosed in a membrane, and contains proteins, lecithin, and a nuclein rich in phosphoius (Meischer Chem Soc Trans 1871,

The space between the shell membranes at the broad end of the egg contains a mixture of oxygen, nitrogen, and carbon dioxide, richei in oxygen than the surrounding air (Hufner, Du Bois Reymond's Archiv de Physiol 1892, Phys Abth 54)

Eggs contain, on the average, about 4.6 mgms of ferric oxide This amount is increased by feeding the hens with foods rich in iron, and 'iron-eggs' thus obtained have been recommended for therapeutic use, but are very costly (Hartung, Zeitsch f Biol 1902, 43, 195, Hofmann, Zeitsch, anal Chem 1901, 40, 450)

Bertrand states that arsenic is normally present in the egg to the extent of  $\frac{1}{200}$  mgm (Compt rend. 1903, 136, 1083), and that 1 mgm boron occurs in 1 kgm dried egg (Compt rend

1913, 156, 2027)

Development —During incubation the egg respires, giving off carbon dioxide and water, and absorbing oxygen If this process be stopped by placing the egg in an ineit gas, or by rendering the shell impervious to gases, the development of the chick ceases The respiration is slight for the first four days of incubation, and then increases until, at the ninth day, the respiration of the egg is equal to that of a fowl, weight for weight. This respiration involves combustion of the fat of the egg, and a steady loss in weight (Pott, Landw Versuchs Stat 23, 203, Chem Soc Abstr. 1879, 474)

Levene states that the quantity of xanthine bases and nuclein compounds increases with the growth of the embryo (Amer J Physiol 1900,

3, x11)

In egg-white the ratio albumin: ovomucoid of egg is constant during incubation (Bywaters and Roue, J. Physiol 46, Proc 33) After 3 days α-lactic acid was found (Anno, Zeitsch. physiol. Chem. 80, 227) In new-laid eggs t'e cholesterol is free, but gradual esterification takes place, until at the time of hatching 40 p c. is in ester form (J. Biol Chem 21, 23)

All the phosphorus in the chick is derived from the yolk and white, and, until the last few days of incubation, no lime is taken from the shell (Voit, Zeitsch f Biol 13, 518, Pott, lc) At the end of incubation, the shell may supply some of the lime required (Carpiaux, Bull Acad Roy Belg 1908, 283, see also Plimmer and Scott, J. Physiol 1909, 38, 247)

The freezing-point of fresh eggs is 0 427°-0 480°, and rises slightly as incubation proceeds, corresponding to a rise of osmotic pressure from 55 atmospheres to 73 atmospheres (Atkins, Biochem J 1909, 480)

The chief uses of eggs are as an article of food and in the tanning industry As the supply of new-laid eggs varies with the season, recourse is had to some means of preserving a proportion of those that come into the market at the time

of greatest production

The following is a list of some processes for preserving whole eggs, which have been patented Saturating with carbon dioxide (Lake, Eng Pat 1653, 1888), treating with formaldehyde vapour (Loft, Eng. Pat 19721, 1915, Corden, Eng Pat 15206, 1914), wrapping air-tight in rubber-coated paper (Jessen, Eng Pat 15580, 1891), coating with gclatin (Mills, Eng. Pat 17717, 1891; Farquhar and North, Eng. Pat 15128, 1892, Coakley, Eng. Pat. 18816, 1899), with gelatinous starch solution (Schultz, Eng Pat 1328, 1902); with drying oils, wax, or varnish, with or without previous treatment with antiseptics (Stukes, U.S. Pat. 649899, Barlow, Eng. Pat. 11054, 1902, Lorne, Eng. Pat. 18439, 1901, and 9898, 1901; Davis and Metz, Eng Pat 105840, 1916), with boric acid (Markham, Eng Pat 3513, 1895), with lime (McArdle, Eng Pat 3592, 1892; Wilson and Wilson, Eng Pat 15461, 1899), with sulphuric acid (Reinhardt, Eng Pat 18130, 1898; Marks, Eng Pat 12867, 1903), with liquid petroleum (Henderson, Eng Pat 101337, 1916), and with water-glass (Stead, Eng Pat. 4910, 1882, Rylander, Eng Pat 23523, 1901)

The following methods (J Soc Arts 1898, 46, 390, J Soc Chem Ind 1898, 261) were found to keep over 90 p c of the eggs in good condition for 8 months. (1) varnishing with vaseline, (2) keeping in milk of lime, and (3) keeping in water-glass solution. Of these the last method is the one least open to objection, and is that chiefly used Eggs preserved in water-glass have a tendency to burst when boiled, but this can be prevented by piercing

the shell with a needle.

A Chinese preparation, 'Pidan,' is made from duck's eggs by coating them with a paste obtained by stirring into an infusion of 13 lbs. strong black tea, 9 lbs lime, 4½ lbs salt, and a bushel of wood ashes After 5 months they are The changes coated further with rice hulls which take place were investigated by Blunt and Wang (J Biol. Chem 28, 125), who deduced that decomposition of both the egg proteins and lipins had taken place. The values for ash, for total and organic phosphorus and especially for ammoniacal nitrogen, are high

The contents of eggs may be preserved by hating at 185°F with a strong solution of a sugar (glucose, maltose, dextrose, &c), until 616 EGG

readily miscible with water, milk, &c, and will keep for some months without deterioration (Fordred, Eng Pat. 15762, 1894, Goodlett, US Pat 692268)

An important method of preserving the whites and yolks of eggs consists in drying the mixture in a current of air at 37°-40° during 18 hours, powdering the product, and again exposing to dry an. The powder is packed in tins, or can be pressed into tablets, and is quite soluble in water (Foschi, Fr Pat 369967, 1906) A similar product is obtained by drying on a hot roller at a temperature above 212°F. (Hatmaker, Eng Pat 28, 1905, see also Eng Pat 8743, 1903, for apparatus)

Substitutes for eggs in baking are made from albumin and cascin obtained from skimmed milk, sometimes mixed with a proportion of dried egg, or from maize meal containing sodium bicarbonate and artificial colouring matter (Beythien and Waters, Zeitsch Nahi Genussm 1906, 11, 272, Bernstein, Eng Pat 14336 and 29189 of 1897) An emulsion of sunflower or other oil with blood serum and lecithin has been suggested (Eng. Pat. 100135, 1915)

The eggs used for the treatment of leather, especially the finer sorts of glove leather, are preserved in the liquid state by the addition of salt and borax (Jean, Mon Sci 1892, 6, 561) Analyses of this material, 'eggio,' show that it contains 2-5 pc more water and 31-6 pc less fatty acid than firsh egg yolk (Boyer, J Soc. Chem Ind 1892, 447) Bein has pointed Bein has pointed out that the addition of salt to yolks materially reduces the amount of fat (Bied Zentr 21, 138) Rotten eggs could well be used for this puipose, as Cech has found that the available oil is not much diminished in amount, and can be extracted by pressure (J pr Chem [2] 22, 338)

Oil of egg, obtained by extracting yolks with ether, or, better, chloroform, forms about 10 p c of the egg, and is used in pharmacy in the preparation of ointments and emulsions, in the leather industry and in tempera painting (Lupus, D. R P 187211) It has no medicinal value (Paladino and Toso, Analyst, 1896, 21, 161) It has the following properties mp 22°-22 5°, sp gr. at 15°, 0 9144, and number, 12, saponification number, 190 2; ether number, 189 0, indine number, 72 1; Hehner's number, 95 16, Reichert-Meissla Chem Zeit 1897, 21, 303). Reichert-Meissl number, 04 (Kitt,

Detection, estimation, and analysis —The presence or absence of egg yolk in pastry can be determined by examination of the fat, there being a great difference in composition and properties between the fat of wheat and of the egg (Spaeth, Zeitsch Nahr Genussm 1896, 10, 171) The phosphorus of the yolk being present chiefly as lecithin, the yolk may be estimated by igniting with sodium carbonate and nitre, determining the phosphoric acid in the residue 1·129 grams phosphoric acid represent 100 grams yolk (Bein, Ber 23, 423) The addition of alkalı is necessary to prevent loss of phosphoric acid during ignition (Juckenack, 7.c) The amount of egg present in pastry, &c, may be determined by the amount of cholesterol present (Cappenberg, Chem Zeit 1909, 33, 985) methods for the determination of the con-

the product contains 40-60 p.c of sugar. It is stituents of egg yolk for commercial purposes, see J Soc (hem Ind 1906, 829)
EGG ALBUMIN v PROTEINS

EGG ALBUMIN v PROTEINS 2 EGG FRUIT. The fruit of Solanum melongena (Linn) A plant of tropical and sub-tropical countries Konig gives, as the mean of three analyses--

Nitrogenous Soluble carbo-matter Fat hydrates Fibre 1 1 0 1 3 9 1 2 Water 93 2

An American analysis (Bull 28, US Dept of Agric ) shows a somewhat larger amount of carbohydrates (5 1 pc), but is similar in other respects

This plant is sometimes called Aubergine. The fruit is used in much the same way as the tomato

EGOLS. A class of antiseptics consisting of the potassium mercury salts of o-mitrophenolsulphonic acid, the individual members being termed 'phenegol,' 'cresegol,' &c, depending on the phenol from which they are derived They are reddish-brown powders, readily soluble in water, and are strongly bactericidal (Gautrelet, Compt rend 129, [2] 113, J Soc

Chem Ind 1899, 854) (v SYNTHETIC DRUGS)
EGYPTIAN BLUE. This is a blue colouring matter which was used by the Romans in the first few centuries of the Christian era, but ceased to be manufactured about the time of the invasion of the barbarians It figures in several beautiful frescoes in the Vatican, and has also been found at Pompen Fouqué discovered the composition to be that of a double silicate of calcium and copper CaO,CuO,4SiO<sub>2</sub>, devoid even of traces of alkali The substance is crystalline, and is hardly attacked by any chemical reagents, which explains the perfect state of its preservation in the paintings for which it was employed 1900 years ago. It may be prepared at a bright-red heat, but this temperature must not be exceeded, as it is then decomposed into cuprous oxide, wollastonite, and a clear light-green glass The higher the temperature, the more of the latter is formed, and, finally, wollastonite disappears entirely By the old method of preparation, described by Vitiuvius, fine sand and soda are intimately mixed with copper filings, then moistened with water, formed into cakes, and the latter dried. The cakes are then fused in an earthen pot until the blue colour is produced Fouqué found this method practicable, but used potassium sulphate in preference to soda as a flux It was not possible to replace chalk or lime by magnesia The ancient Romans employed a large excess of silica, whilst Fouqué employed more basic mixtures, finally purifying the product with hydrochloric acid exquisite colour of this mineral body, the fact that it is absolutely unaffected by moisture, light, and most chemical reagents, as well as the facility and the low price of production, render it desirable that its manufacture should be again resumed (F Fouqué, Compt rend 108, 325-327; and J Soc Chem Ind 8, 291)
The conditions of its production have been studied by Laurie, McLintock, and Miles (Proc. Roy Soc 1914, A, 89, 418) The French ultramarine works of Deschamps Frères reproduced Egyptian blue by fusing in an ultramarine furnace a mixture of quartz (50 parts),

chalk (21 parts), copper oxide (24 4 parts), and sodium carbonate (4 6 parts), all in the finest powder, and completely free from iron. The product, washed with hydrochloric acid and hot water, had the composition corresponding to Fouqué's analysis, and was in all respects similar to the material used by the Romans (Bock, Zeitsch angew Chem 1916, 29, 1 228) EIKONOGEN. Sodium salt of 1-anino-

8-naphthol-6-sulphonic acid Used as a photo-

graphic developer

EKSANTALAL (12H18O Obtained on oxidation by ozone of the sesquiterpene primary alcohol a-santalol (15H24O, which, together with the isomeric \(\beta\)-santalol, constitutes 'santalol,' the oil resulting from the hydrolysis of the hydrogen phthalate made from the oil obtained by distilling sandalwood with steam (Semmler, Ber 43, 1893)

It is dextro-rotatory ( $\alpha_D + 13.5^{\circ}$ ), bp 100°-110°, under 10 mm; spgr 0 9846 at 20°/20, n<sub>D</sub>, 1 48519.

It gives an oxime, which yields the corresponding nitrile and aminc, and gives eksantalol on reduction (Semmler, Ber 41, 1488)

Heated with acetic anhydride and sodium acctate, it forms enol-eksantalal acctate

which, on oxidation with potassium permanganate, yields noreksantahe acid C<sub>11</sub>H<sub>16</sub>O<sub>2</sub> (Semmler, Ber 43, 1722–1725), the methyl ester of which, on reduction by sodium and alcohol, yields noreksantalol<br/>  $\mathrm{C}_{11}\mathrm{H}_{18}\mathrm{O}\,,\,$  and this on oxidation in benzene solution with potassium dichromate and dilute sulphuric acid, gives noreksantalal C  $_{11}\rm{H}_{16}\rm{O},~b~p~92^{\circ}-94^{\circ}/11~mm~,~sp~gr~20^{\circ}/20^{\circ}~0~9964,~n_{_D}~1~48301,~\alpha_{_D}~-30~8^{\circ}$ The enol-noreksantalal acetate gives, on oxidation by potassium permanganate, teresantalic acid  $C_{10}H_{14}O_2$  (Semmler and Zaar, Ber 43,

In all three series, containing 10, 11, and 12 carbon atoms respectively, the same tricyclic system is present as exists in  $\alpha$ -santalol, and Semmler (Ber 43, 1893–1898) assigns to these bodies constitutions based upon the camphene or camphor type, and a santalol and eksantalal are structurally represented as below

$$\begin{array}{c|ccccc} H_2C & CH_2 & CH_2 \\ & \downarrow & CH_2 & \downarrow \\ & \downarrow & CH_2 & \downarrow \\ & \downarrow & CH_3 & CH \\ \hline CH_3 & CH & CH_2 \\ \hline CH_4 & CH_2 & CH_2 \\ \hline \rightarrow & & \downarrow & CH_2 \\ \hline \end{array}$$

EKTOGEN. Trade name for a mixture of zinc dioxide with zinc oxide and carbonate, used as a surgical dressing

ELÆOMARGARIC ACID C18 H32O2 An acid, melting at 48°, obtained by the saponifics tion of elaococoa oil (Japanese wood oil) with

alcoholic potash, and decomposing the trielaomargarin thus formed The glyceride when first formed is liquid, but on exposure to light gradually solidities. Isomeric with elaostearic acid, elaoleic acid, and linoleic acid. On exposing an alcoholic solution to light, plates of claostearic acid, m.p. 71°, are precipitated (Cloez, Bull Soc chim 1876, 26, 286; 1877, 28, 24); traces of iodine or sulphur also bring about this change (Maquenne, Compt. rend. 135, 696) Oxidation with potassium permanganate gives rise to azelaic acid, sativic acid, and dihydroxy-stearic acid (Kametaka, J Soc Chem Ind 1903, 1138, 1908, 1120, Kit, Chem Soc Abstr 1905, 10. Maquenne, lc) Linolic acid also on oxidation yields sativic acid, and on bromination, linolic acid and elaomargatic acid yield the same tetrabromide Elaostearic acid and linoleic acid yield the same diozomde (Majima, Ber 1900, 674) Elaomargane acid and elaosteame acid are converted into claoleic acid when heated at 180° m sealed tubes (Cloez, J. 1878, 38)

ELÆOPTENE. The volatile portion of an essential oil, used in contradistinction to the stearoptene or solid portion

ELAIDIC ACID C18H34O2 A solid stereoisomene modification of oleic acid, obtained by the action of nitrous acid upon olive oil, saponifying the glyceride (claidin) so formed, and decomposing the salt by hydrochloric or sulphuric acid May also be obtained by the action of nitrous acid or of intile acid (sp gr 12) (Edmed, Chem Soc Proc 1899, 190) upon oleic acid, or by decomposing barium oleate with furning nitric acid, m p  $52^{\circ}$  (Saytzeff, Chem Soc Abst 1893, 551), b p  $287.5^{\circ}-288^{\circ}$  at 100 mm (Krafft and Mordlinger, Ber 1889, 819) Soluble in alcohol and other Solutions have an acid reaction. The melted acid gradually absorbs oxygen from the air, and becomes permanently liquid. It may be distilled unchanged under diminished Heated with potassium hydroxide, it is converted into acetate and palmitate of potassium with evolution of hydrogen

Elaidic acid dissolved in benzene, toluene, ligioin, or chloroform, and mixed with caustic soda and shaken, gives a brilliant phosphorescence (Radziszewski, Annalen, 203, 305) Hydriodic acid forms an addition compound (nodostearic acid) with claidic acid (Farb vorm Fried Bayer & Co D R P 180087, Chem Soc Abstr 1907, 1 380), which, on treatment with alcoholic potash, yields oleic and 180-oleic acids (Lebedeff, ibid 1893, 550) On reduction with nickel or copper and hydrogen at 280°-300° elaidic acid is converted into stearic acid (Sabatier and Mailhe, Ann Chim Phys [8] 4, 319) Treated with dilute solution of potassium permanganate in presence of potash, it is converted into a dihydroxy acid, which differs from the corresponding compound obtained from oleic acid by its lower melting-point (995°), and its greater solubility in alcohol and other, and also into pelargonic, azelaic, and oxalic acids (Saytzeff, Ber 1886, 21, Edmed, Chem. Soc. Trans 1898, 627), oxidation with sulphuric acid, however, gives rise to the same dihydioxystearic acid as is obtained from oleic acid under the same conditions (Tscherbakoff and Saytzeff, pr Chem, 1898, 27).

Eluidin, a solid isomeride of clein, is obtained by the action of nitrous acid upon clein,

and is probably a triglyceride C57H104O6 melts at 36°; is nearly insoluble in alcohol. readily soluble in ether The Unquentum oxugenatum and U citrinum of the pharmacopœias, prepared by the action of nitric acid upon hog's lard, contain impure claidin.

ELAIDIN V ELAIDIC ACID

ELALDEHYDE v ALDEHYDE.

**ELARSON.** Trade name for strontium chloroarsenobehenolate

ELATERIN v ELATERIUM

ELATERITE. Elastic bitumen, Mineral caoutchouc A fossil resin, somewhat resembling asphalt, found at Castleton in Derbyshire, in France, Switzerland, &c It is a soft, flexible, elastic, and readily inflammable substance, with a resmous lustre and a dark-brown colour is mainly used as an insulator for electric cables It is rapidly decomposed by strong nitric acid When boiled with alcohol and alcoholic potassium hydroxide it behaves like beesway One sample gave an acid value of 49, and saponification value of 569, and contained 889 pc of unsaponifiable matter.

The sediment from the juice ELATERIUM. of the fruit of the Echallium elaterium (Richard), or squirting cucumber Elaterium is a drastic

purgative

It, and elaterm derived from it, were excluded from the BP in 1914 The latter substance is still official in the United States (Eluterinum, USP) Good specimens of elaterium when extracted with chloroform yield 25 pe of elaterin, which by recrystallisation is obtained in minute shining six-sided plates The dose of elaterin is  $\frac{1}{4}$  to  $\frac{1}{10}$  of a grain, and to it is ascribed the whole of the physiological activity Elaterin is a neutral bitter comof claterium pound, insoluble in hot or cold water leadily soluble in cold alcohol, sparingly in ether. If sulphuric acid be added to a solution of elaterin in melted phenol, a crimson colour is produced which changes to scarlet (Lindo, Chem News, 37, 35, Johannson, Zeitsch anal Chem 24, 154)

On hydrolysis with alcoholic potash, elaterin furnishes acetic acid and an amorphous compound, elateridin Further action of alkali gives clateric acid, also amorphous, and melting at 73°-75° (Berg, Bull Soc chim [m ] 35, 435)

Elaterium of English origin, examined by Power and Moore (Pharm J. [iv | 29, 501), was found to contain 5 3 p c of moisture and 6 7 p c of ash. By a suitable method of extraction, a colourless crystalline product, mp 217°-220°, was obtained, corresponding with the claterin of the pharmacopenas This was found to be non-homogeneous, consisting of at least two substances, one, a-elaterin, melting at 230° with decomposition, and lavo-rotatory, whilst the other, B-elaterin, has a lower melting-point, and is dextro-rotatory Both have the same empirical composition, but the former is physiologically mert, whilst the latter shows marked physiological activity. Examination of commercial elaterin showed that it consists mainly of varying proportions of these two substances, which probably accounts for the marked difference in medicinal value of different samples a-Elaterin has also been found in colocynth, the dried fruit of Citrullus colocynthis (Schraeder) (Power and Moore, Chem. Soc. Trans 97, 99), and has been further investigated by Moore (ibid. 97,

According to Berg (Bull. Soc. chim [ni] 17, 85; [iv ] 7, 385), elaterin does not exist readyformed in the fruit, but is produced after the rupture of the tissues by the action of an enzyme elaterase on a glucoside present. The latter consists of a brittle, amorphous powder, and gives the same leactions as elaterin with sulphuric acid and phenol Power and Moore (Chem Soc Trans 95, 1985), however, on examination of the fresh fruit, failed to confirm this

**ELBON.** Trade name for cinnamoyl-phydroxyphenylurea.

ELDERBERRY. The fruit of Sambucus nigra (Linn) The only analysis quoted by Konig gives, as the composition of the fruit-

> Water 81 9 Crude fibre Pentosans 66

The bernes are used for the preparation of a wine and of 'clderberry syrup,' an old-fashioned From the wine, a brandy is sometimes distilled, which according to analyses by Arnthor and Zink, quoted by Konig, contains 39 2 p c of alcohol (by weight) and has a sp gr of 0 836 According to de Sanctis (Gazz chim ital 1895, 25, 49), elder leaves and stems contain conine Malmejac (J Pharm Chim 1901, 14, 17) attributes the dimetic and purgative action of the bark of the elder to an alkaloid, sambucine, a deliquescent bitter substance, yielding the usual alkaloid reactions He also found elder bark to contain tannin, a resin resembling scammony and a yellowish-red oil possessing a strong odour of elder Elder pith contains both xylan and araban (Browne and Tollens, Ber 1902, 35, 1457) The oil extractable from the juice of red elderberries (S racemosa) by ether, is light yellow in colour, has a sp gr of 0.9072, solidifies at  $-8^{\circ}$ , and melts at  $0^{\circ}$ , contains 6 65 pc of free acid (as oleic acid), 0 66 p c of unsaponifiable matter, has a saponification number 2093, iodine number 814, and Reichert-Meissl value of 154 (Byers Hopkins, J Amer Chem Soc 1902, 24, 771)

The leaves of the elder contain a cyanogenetic glucoside, which, under the influence of emulsin, yields dextrose, benzaldehyde, and hydrogen cyanide; the yield of the last mentioned amounts to 0 126 gram per kilogram of fresh leaves (Guignard, Compt rend 1905, 141, 16; Bourquelot and Danjou, ibid 59) This glucoside, which has been named sambunigrin C14H17O6N, crystallises from ethyl acetate in long, colourless needles, melting at 151°-152°, is readily soluble in water or alcohol, but nearly insoluble in ether (Bourquelot and Danjou, Compt rend.

1905, 141, 598)

According to Ravenna and Tonegutti (Chem Zentr 1910, 1 544) the enzyme which decomposes the glucoside in the plant is not soluble in water The hydrocyanic acid is present in larger quantities than has hitherto been believed, and is most abundant in the stalks

ELECTRARGOL. Trade name for a form of colloidal silver.

ELECTRIRIDOL. Colloidal iridium.

ELECTRO-DEPOSITION and ELECTRO-I LATING. Electrolytic processes are now used to a considerable extent in the precipitation of metals in a reguline form, available for many commercial purposes. Thus the common and more easily corroded metals are coated with thin films of electro-deposited metal of a more permanent and less oxidisable character, in the process of electroplating; for the reproduction of engraved surfaces, type, &c, in electro-deposited copper, electrolysis is applied in electrotyping, and in the deposition of a pure metal from an impure form or a mixture of metals, the principles of electrolysis are applied in the process of electrolytic refining and in chemical analysis

An electric current passed through solutions of metallic salts brings about decomposition of a particular type, accompanied by the deposition or evolution of the products, or others which may have been formed as the result of secondary changes. When copper sulphate solution is electrolysed with a platinum anode, and any cathode, not ordinarily attacked by this salt, copper is deposited at the cathode, and oxygen and sulphune acid are formed at the anode, thus

Other metallic compounds follow a similar The primary products consist of charged atoms or radicals These are termed ions, and in the process of electrolysis migrate to the electrodes, those to the anode being called the anions, and those to the cathode cathions Anions consist of the acidic group of the salt, while the cathions comprise hydrogen, the metals, and basic radicals. At the electrodes, the electrical charges are neutralised, and the substance appears in the nascent form, subsequently being deposited or evolved Elementary amons, such as chlorine, bromine, and iodine may enter into subsequent secondary changes, while others, such as  $NO_3$ ,  $SO_4$ ,  $C_2H_3O_2$ , &c, react with water, giving generally the corresponding acid, and liberating oxygen With soluble anodes—those attacked by the anion—solution of the metal takes place, and thus, in a copper solution, a copper anode supplies metal under the best conditions as rapidly as metal is de-The strength of the solution is thus maintained, a condition necessary for continuous deposition as required for plating and refining

purposes
The deposition of metals follows the usual law of chemical equivalents as enunciated by Faraday in 1835. The ampere-hour is thus associated with a definite amount of metal, which cannot be exceeded, but may not be attained owing to failure in realising the best conditions. The quantities of metals deposited by the coulomb, ampere-hour, and 746 ampere-hours, are shown in the table on next column

These amounts, however, can only be deposited when the cathode is surrounded by a considerable amount of strong electrolyte, and only under this condition can the facts of electrolysis be applied, as in the voltameter, to the determination of the number of coulombs passing through a circuit While for most industrial purposes it is not necessary for the theoretical amount of metal to !e deposited per amperchour, yet the most satisfactory deposits are,

Metal	Chemical	Mgs per coulomb	Grams per ampere-hour	Oza (av ) per 746 ampere-hours
Copper (cupic) ,, (cupious) Gold (aurie) ,, (aurous) Iron Lead Nickel Silver Tin (stannous) ,, (stannie) Zine	31 8 63 6 65 7 197 0 28 0 103 5 29 3 108 0 59 0 29 5 32 5	0 329 0 658 0 680 2 040 0 290 1 070 0 302 1 118 0 610 0 305 0 336	1 182 2 364 2 440 7 320 1 040 3 870 1 085 4 025 2 190 1 095 1 210	31 0 62 0 58 6(Troy) 176 0 ,, 27 3 101 0 28 5 96 5(Troy) 57 5 28 7 31 8

in many cases, obtained when this condition is most nearly attained Failing the full amount of metal per ampere-hour, hydrogen is deposited, and this often leads to a dark powdery deposit unsuitable for most industrial purposes. Such deposits, caused usually by excessive current, are said to be 'burnt'. In some solutions—for example, those of copper, iron, or nickel sulphate this inferior deposit seems to result from the simultaneously deposited hydrogen due to a weak electrolyte In other examples, that of the alkaline or eyanide copper bath, it would seem (from the fact that much hydrogen may be deposited without 'burning') more probably due to the deposition of traces of basic compounds with the metal (Bancroft, Trans Amer Electrochem Soc vi [ii] 27) This view is supported by the fact that the presence of substances in the solution, which are good solvents for such basic compounds, prevents burning to a considerable extent. Thus, in the alkaline copper-bath, 'burning' is reduced, and the quality of the deposit improved by the addition of such salts as sodium bisulphite and potassium cyanide In other examples, notably those of tin and lead, the deposit is much improved by the addition of a trace of a colloid, such as glue or gelatine

Migration of ions. It is well known that ions migrate to their respective plates with definite speeds under unit potential gradient If deposition proceeds more rapidly than this rate of migration, the cathode liquid becomes impoverished of its metal, and this involves a falling off in the ampere-hour yield. The deficiency of metal around the cathode is counteracted to a limited extent by the ordinary process of diffusion, but there is a limit to the rate at which metal may be satisfactorily deposited, unless special steps are taken to make up for this slow migration Methods of circulation and stirring are based on this fact, and also on the further fact that the heavier solution formed around the anode falls to the bottom of the solution, and, owing to its superior conductance, gives rise to the conduction of an undue proportion of the current and consequently thicker deposits on the portion of the cathode in this heavier layer, hence a limit to the rate at which deposition may be safely allowed to proceed is se", and the time required to deposit a given amount of metal varies correspondingly.

E.M.F. for deposition. With an insoluble anode, a definite minimum E M.F is required to maintain electrolysis Thus, when copper sulphate is decomposed with a platinum anode, the total change is as follows:-

$$CuSO_4 + H_2O = Cu + O + H_2SO_4$$

This, as a chemical change, is endothermic, and electrolytically it demands a minimum EMF of about 1 25 volts for its continuance a copper anode is used, no change in the com-Energy changes position of the solution occurs at both electrodes are equal and of opposite character, and hence a much smaller E M F., viz. that required to overcome the ohmic resistance of the solution, is required With efficient anode solution and a good conducting electrolyte, such as is obtained in an acidified copper sulphate solution, a PD of about 03-05 volt will maintain a fair rate of deposition In the case of nickel, where there is usually inefficient anode solution and a poorly conducting electrolyte, a much higher PD is required, partly on account of the greater stability of nickel com-Figures given, therefore, for P D 's at bath terminals are of a very elastic character, depending upon the efficiency of anode solution, strength and temperature of the solution, distance between electrodes, presence or otherwise of conducting substances in the solution, and current density required, while the conditions controlling the allowable current density at the cathode are chiefly the strength of the electrolyte and its motion

The deposition of copper may be accomplished by simple immersion methods, resulting in a chemical exchange with the more positive

metal plated, thus

$$\frac{Zn}{Fe}$$
 +  $CuSO_4 = \frac{Zn}{Fe}$   $SO_4 + Cu$ 

The process is but little used, and then only for very cheap work Deposits on a surface which is undergoing simultaneous corrosion, cannot be sufficiently adherent to withstand the frictional processes of polishing and burnishing

The single-cell process, practised at one time, involves the generation of current and the deposition of metal in the same apparatus The process is illustrated in the Daniell cell, in which, if the copper cylinder is replaced by any conducting substance, copper is deposited

For the deposition of copper on biass and similar electro-negative metals, and on blackleaded or metallised non-conducting surfaces of wax, guttapercha, plaster, earthenware, &c, the following solution is of wide application

The composition is variable. Strong solutions admit of more rapid deposition without 'burning,' while the acid imparts conductance From such a solution deposition can be carried on at the rate of 40 amperes per square foot without stirring, while, with a properly stirred electrolyte, this current density may be increased up to 250 or 300 amperes per square foot

Previous to deposition, brass is cleaned first in potash (5-10 p.c) to remove grease. It is

of oxide, or tarnish, and, after rinsing, is scoured with pumice or ordinary sand or scratch-brushed. After finally rinsing, it is immersed in the solution, and should be covered immediately The deposit is pink, though dull When of sufficient thickness, the work is removed, rinsed, and the dull surface improved by scratchbrushing or polishing

For deposition upon non-conducting substances such as wax, guttapercha, &c, the following methods may be used .—

(1) Wax and guttapercha Thorough 'yet careful brushing with the finest plumbago causes sufficient to be retained to render the surface conductive Such surfaces when suspended in the copper solution, receive a deposit beginning at the metal connection, and gradually spreading over the whole surface, the thickness

of the deposit not being exactly uniform
(2) Plaster of Paris and unglazed earthenware may be rendered conductive by first seaking in linseed oil and allowing to dry They are thus linseed oil and allowing to dry rendered impervious to the solution, and the skin of dried oil will now retain blacklead, when this substance is applied by gentle brushing, sufficient to impart the necessary conductance

(3) Flowers, feathers, and other delicate objects which will not withstand the pressure of even gentle brushing, may be treated to produce a fine layer of some metal or sulphide on the surface by simple chemical means usual method is to paint them or immerse them in a weak solution of phosphorus in carbon disulphide, and, after drying, a brief immersion in silver nitrate solution leads to the precipitation of silver, which imparts the necessary conductance Again, the object to be treated may first be immersed in silver nitrate solution, and subsequently exposed to sulphuretted hydrogen, which produces a layer of silver sulphide, sufficient to cause the immediate deposition of copper at all points

A more successful method for wax and guttapercha involves covering these substances with copper by simple precipitation substance, usually as a mould or impression of a surface to be reproduced in electrotype copper, is first blackleaded and is then laid face upwards in a solution of copper sulphate filings are then spinkled on the surface filings in contact with the blackleaded surface produce innumerable voltaic couples, which bring about the deposition of copper quickly and completely The mould is then rinsed to detach the filings, and placed in the bath, when copper is at once deposited uniformly over the whole surface

On positive metals such as non, zinc, tin, Britannia metal, pewter, &c, copper cannot be successfully deposited from the acid sulphate solution on account of the ease with which these metals turn out the copper by simple immersion, and are, moreover, corroded by the acid more stable and more satisfactory compound for this class of work is the double eyanide of copper and potassium (CuCN KCN) Solutions of this compound are usually prepared by (1) dissolving the carbonate in a solution of potassium cyanide; (2) precipitating the sulphate with ammonia, dissolving the precipitate in creess of ammonia, and decolourising the blue then passed through aquafortis to remove scale solution with potassium cyanide. Many other methods are available and are in use The strength of such solutions may be varied between wide limits up to 4 ozs (or even more) of metal per gallon. An excess of potassium cyanide is essential, owing to the formation of insoluble single copper cyanide (CuCN) at the anode. The course of electrolysis in such double cyanide solutions (including those of zinc, silver, and gold) is very different from that of the salts of the mineral acids. In the case of copper, the reaction may be simply represented as follows.—

Anode CuCN KCN Cathode 
$$\left| \begin{array}{ccc} & & \text{Cathode} \\ & \leftarrow & \text{Cu(CN)}_2 \text{--} \text{K}^+ & \rightarrow \end{array} \right|$$
 then:

 $\begin{array}{ll} {\rm Cu(CN)_2 + Cu = 2CuCN} & {\rm K + CuCN \ KCN = Cu + 2KCN} \\ & {\rm (Insoluble)} & {\rm (deposited)} \end{array}$ 

The copper in the salt thus migrates as a complex ion to the anode, and there forms an insoluble compound This, unless removed, offers considerable resistance, and increases the difficulty of maintaining a normal current Sufficient potassium cyanide for its removal is formed at t'e cathode, and can be best brought to the anode by stirring, which facilitates the process of deposition by keeping the anode The solution of the anode deposit is more usually accomplished by using an excess of potassium cyanide called 'free cyanide' From such a solution copper is not deposited upon iron, tin, Britannia metal, pewter, &c, by simple immersion, and only very slightly on The solution is conveniently used warm, and yields a deposit of copper accompanied by hydrogen, which, as a rule, does not seriously interfere with the physical character of the deposit. The deposit is, under the best qualitative conditions, smoother than that from the sulphate solution, and once the positive metal has been coated in this solution, it may be removed, and, after thorough rinsing, introduced into the sulphate solution for a thicker deposit The cyanide solution, when strong, and used within certain limits of current density, yields twice as much copper per ampere-hour (viz 2 36 grams) as the sulphate, the cyanide compound being the monovalent cuprous salt.

Applications of copper deposition — The metal is most extensively deposited as a covering for more positive and more corrodible metals, and as a preliminary deposit before coating with the more expensive metals Deposits of copper on iron may then be burnished or polished and the surface improved by metal-colouring, when, by chemical processes, the surface is covered with a uniform film of oxide or sulphide by immersion in solutions producing these compounds, such as the salts of copper and soluble sulphides Uniform and pleasing effects are readily obtained, and may be rendered more permanent by subsequent lacquering metal is also deposited on a considerable scale in the electrotyping process, thin, but rigid reproductions of type, engraved plates and blocks being made in electro-deposited copper, and subsequently strengthened by 'backing with a lead-antimony alloy, which is then planed down to the required thickness.

Analytically, copper deposition is applied

The in the separation of this metal from more positive metals in an acid solution with a platinum anode From a solution of brass in nitric acid, the copper may be most completely deposited without interfering with the zinc The copper deposit made on a platinum dish or suitable electrode is then weighed, and the zinc obtained by either a chemical or a further electrolytic method (v Analysis) On a commercial scale, the deposition of copper has been applied by Cowper-Coles to the production of parabolic mirrors for lighthouse work, and to the production of sheet, wire, and tubes The manufacture of deposited tubes of large diameter has been successfully carried on by Elmore who arrange an agate burnisher to travel backwards and forwards along the tube during deposition, thereby producing a compact deposit of good mechanical properties. Tubes up to 16 feet long by 8 feet diameter, and weighing more than 3 tons, have been produced by this method More usually, however, tubes are of smaller dimensions, and are subsequently drawn down or opened longitudinally for the production of sheets Copper is deposited on a most extensive scale in the refining process, possibly as much as three-quarters of the total output of the metal annually being refined in this manner, using a solution of the sulphate with thick anodes of the crude metal The crude metal contains up to 10 p c of impurities deposited metal is almost entirely free from impurity Positive impurities pass into the solution, and are retained there by the application of the principle used in electrolytic analysis Electro-negative impurities, as silver and gold, pass as chloride and metal respectively into the mud at the bottom of the tank, from which they may be recovered Tin, antimony, arsenic, and bismuth are prevented from being deposited by a careful control of the conditions, and the sum-total of impurities in the refined metal is usually less than 0 05 p c

Deposition of silver. Silver, being an electronegative metal, is readily deposited by simple immersion. The process is applied commercially under the name of 'whitening' Solutions for this purpose contain a small proportion of a silver compound, such as chloride or cyanide, dissolved in cream of tartar, sodium chloride, or similar solvent. The deposition on properly prepared work is a case of simple replacement, and only very thin deposits are obtainable by this means. The same materials may also be used in the form of pastes, and rubbed on the prepared work with a wet rag, this method finding application in silvering clock and instrument dials.

Electro-deposition is most frequently practised. For this purpose the nitrate solution is unsuitable on account of its instability, being serviceable only as a voltameter electrolyte where the very electro-negative metal platinum is used. For silvering on more positive metals, those which usually require silver plating, a solution of the double cyanide of silver and potassium is used. This may be prepared from the metal as follows:—

(a) The metal is converted into intrate, and precipitated with potassium cyanide. When precipitation is just complete, the clear liquid is decanted and the precipitate washed and

subsequently dissolved in more cyanide solution, a further supply of cyanide being added for 'free cyanide'

(b) Precipitation may be effected by common salt, and the washed chloride dissolved in excess

of potassium cyanide

(c) A silver plate may be made the anode in a 5 p c solution of potassium cyanide, using a small copper or carbon cathode contained in some of the solution in a porous cell. The silver dissolves electrolytically, and the process can be continued until sufficient silver has passed into the solution and a good deposit is obtainable from it.

The solution is used cold, and yields a dull deposit of the metal, which may subsequently be scratch-brushed, burnished, and polished The addition of a small proportion of carbon disulphide (1 oz in 250 gallons) completely alters the character of the deposit from dull to bright. 'Bright plating' is, therefore, much practised The silver compound in the solution being somewhat unstable, special precautions are necessary before placing work in the solution for deposition Copper, brass, and nickel silver may be plated directly, though previous to deposition it is common practice to pass such work through a solution of mercury cyanide This solution can be prepared by treating a soluble mercuiic compound with excess of potassium cyanide, or by dissolving the oxide in cyanide A usual strength is 1 oz of metal per gallon From such a quicking, solution a bright deposit of mercury is obtained on brass, copper, and nickel silver by simple immersion, with the advantages that the more negative metal mercury is less oxidisable than copper, &c, and prevents simple immersion deposition of silver when the work is put into the bath, and possibly promotes the adhesion of the subsequently electrolytically deposited silver, by amalgamation More positive metals, like iron and zine, are first coppered in the alkaline bath, and subsequently treated as copper With the lead alloys it is usual to pass their straight from the cleansing processes through a separate silver solution, from which a rapid deposit is first made This is termed striking,' after which the work is transferred to the main solution to complete the deposition

The current density permissible is controlled largely by the metal content of the solution, Excessive current produces a light-grey, dark grey, or black deposit, which, being powdery, is unable to withstand the processes of burnishing

and polishing

Silver anodes should be of fine metal, preferably annealed, and, therefore, more susceptible to solution. Their behaviour is an indication of the condition of the solution. If a dull deposit collects upon them, with a falling off in the current, more free cyanide is required to dissolve the insoluble single cyanide which forms upon them. On the other hand, excessive free cyanide unduly promotes the solution of the anode, limits the permissible current density at the cathode, lowers the cathode efficiency, and promotes simple immersion deposition on work which is not 'quicked'. The amount of free cyanide present can easily be determined in this and other cyanide solutions by titration with standard silver intrate.

The deposition of gold is practised considerably on account of the pleasing colour and permanence of the deposit Deposition is easy owing to the strong electro-negative character of the metal, and for electro-gilding, as with electro-silvering, cyanide solutions are used. Gold may be applied to metallic surfaces by three methods, viz · (1) mercurial gilding; (2) simple immersion; and (3) the electrolytic method. Mercurial gilding is used for heavy deposits of gold. An amalgam of gold is first prepared by pouring mercury on to hot gold. Excess of mercury is squeezed through chamois leather, and the pasty amalgam preserved in balls under water—It is applied to the prepared metallic surface with a wire brush, which has first been wetted with a weak solution of mercuric This is rubbed on the amalgam and nitrate then on to the work, depositing a layer of amal-When a uniform coating is obtained, the mercury is expelled in a muffle, and the process repeated for thicker deposits The dull surface is improved by scratch-brushing. This process is still largely employed

Simple immersion methods are followed, for mere films of metal, in solutions of very varied composition. A moderately strong solution of sodium pyrophosphate is prepared (5-10 pc), and gold chloride added a little at a time. The warm solution at once gives up its metal, but the deposits can, in any case, only be very thin, though they may be thickened somewhat by 'quicking' in a mercury solution and re-

immersing in the gold solution

Gilding with the separate current is largely practised, using a solution prepared by the

following or similar methods.

(1) Making a gold sheet the anode in a cyanide solution (4 ozs per gallon), using a cathode contained in a porous cell. The process is continued until sufficient metal is lost from the anode or until the solution yields a good deposit.

(2) Precipitating gold chloride with ammonia, avoiding excess, and dissolving the washed pre-

cipitate in potassium cyanide solution

The metal content may vary from a few pennyweights to a few ounces per gallon solution is used warm with a gold anode, which is electrolytically corroded, or by a less desirable, though common, method of using an insoluble platinum anode and making frequent small The colour of the additions of gold chloride deposit varies considerably with the conditions, chiefly that of current Other conditions, such as temperature, size of anode, distance between electrodes, metal content, also apparently affect the colour; but these varying conditions primarily influence the current. Cold and weak solutions give a pale colour, which may be improved by warming. Excessive current produces darker and foxy deposits, which are, however, improved by scratch-brushing. More satisfactory deposition proceeds when work is kept in motion. The colour of The colour of the deposit is heightened somewhat by a preliminary coating of copper, while a deposit of silver has the reverse effect, though occasionally required. The colour is modified also by the addition of copper and silver cyanides to the solution Thick deposits are most satisfactorily obtained by occasional scratch-brushing and 'quicking.'

The deposition of nickel is now very largely applied on account of the hardness of the deposit and its permanence, together with the exceptional lustre which can be imparted to it by polishing. The solution most commonly employed is .

Nickel ammonium sulphate . 12 ozs Water . . . . 1 gallon

The conditions which affect the electro-deposition from this solution have been studied by Bennett, Kenny, and Dugliss (J. Phys Chem 1914, 18, 373, Bennet, Rose, and Tinkler, *ibid* 1915, 19, 564; Hammond, Trans. Amer. Electrochem Soc 1916, 30, 103) To this solution, additions are frequently made to increase the conductance, sal-ammoniae or common salt being used. Owing to the fact that no free mineral acid is permissible, and the tendency also to the formation of nickel hydroxide at the cathode, small additions of acids, such as citric, boric, or acetic, are made with varying success The only modification in the above solution which adds any appreciable advantage, is that of nickel sulphate, which is so much more soluble than the double salt, and from which, therefore, much stronger and therefore better, conducting solutions can be prepared thick deposits, Langbein recommends the use of 3 lbs of nickel sulphate per gallon, with the addition of ethyl sulphate or magnesium ethyl On account of the greater stability of nickel compounds and the poor solution of the anodes, and also the absence of free mineral acid, a distinctly higher EMF is required than for copper deposition, viz 5-6 volts for 'striking,' that is, rapidly coating the work with nickel, and then 2-3 volts for depositing the bulk of the metal The absence of free acid necessitates especial care in the preliminary cleansing processes, most work being finally passed through a weak solution of cyanide (5 pc), and quickly and thoroughly rinsed before being put into the vat. The nickelplating solution is usually worked cold, and is conveniently contained in lead-lined Anodes may be of east or rolled metal, the east being much superior, as its porosity assists its corrosion under the influence of the current Rolled metal is but little attacked by the amon SO<sub>4</sub>, and, failing the solution of the anode, sulphuric acid is produced and oxygen evolved; thus

## $SO_4 + H_2O = H_2SO_4 + O$

This acidity is to be avoided, and with it there is a diminution in the metal content of the solution which is similarly undesirable. Cast anodes are therefore much more largely used, more uniform conditions being maintained with them. On account of the high E.M.F. used, some hydrogen is evolved at the cathode, though the current efficiency should not ordinarily fall below 90 p.c. Occasional motion of the work is desirable in order to disengage any bubbles which may collect. Once deposition has commenced, the work should not be exposed more than momentarily, otherwise an imperceptibly thin film of oxide will form and almost entirely prevent the adhesion of further deposited metal. In fact, it is Toonsidered impossible to successfully deposit nickel on such

a surface or on a previous deposit. On this account, previously nickelled work should be entirely freed from its nickel, and, while this may be done by acid solutions, common practice follows the method of polishing, at the same time preparing the surface for the new deposit Copper and brass work is mckelled directly after the usual cleaning operations, whilst positive metals like zinc and Britannia metal require a previous deposit of copper from the cyanide According to Canac and Tasilly (Compt 1914, 158, 119), alummium is readily plated with a durable coating of nickel by first plunging the metal in a boiling potassium hydroxide solution, scrubbing it with milk of lime, followed by steeping in a 0.2 p.c solution of potassium cyanide for some minutes, after which it is transferred to a bath of 500 grams of hydrochlone acid and 1 gram of iron in 500 e.e. of water Between each bath it is well washed with water, and then plated electrolytically in a solution of nickel chloride The success of the plating apparently depends on the use of the ferruginous bath Iron and steel may be nickelled without coppering, the polished surface being first rendered somewhat dull by scouring with finest pumice. The deposit should be kept bright, and thus is attained by a current density not exceeding 5 ampeies per square Higher current densities produce dull deposits, tending to become powdery on the edges. The nickel deposit is very hard, and the final lustre is obtained by 'finishing' with Sheffield lime, which produces a highly lustrous surface—In addition to the extensive cycle and motor industry, nickel-plating is applied con siderably for small machine parts and instru-ment work and for 'facing' stereotypes, the deposit being much more durable than the stereotype metal

The deposition of iron is carried out on lines similar to those for nickel, solutions of ferrous sulphate or ferrous ammonium sulphate being used These must be entirely free from mineral acid, more so than in the case of nickel, and water should be well boiled before being used, to expel air and prevent the oxidation of ferrous to ferric compounds Ferric compounds under electrolysis yield little metal, being first reduced to ferrous at the cathode The process is not much used beyond the application in steel-The iron deposit facing? engraved plates obtained is free from carbon, but is very hard Anodes of the softest wrought iron containing a minimum of carbon are desirable, and require occasional scouring to remove the layer of insoluble carbon. The deposition of iron has also been used for thicker deposits, which have subsequently been removed and examined to investigate the properties of pure iron, and to more successfully determine the effect of impurities. For 'steel facing,' the engraved plates are cleaned, any scouring being done with only a light brush. The plate is then hung in the bath and covered quickly by 'striking. Deposition is then continued more slowly for 10-15 minutes. The deposit is very hard and withstands the printing process much better than copper. When the deposit shows signs of wear by the exposure of copper, the metal is simply and readily removed by immersion for a short time in a 5-10 pc sulphuric acid. By voltaic

action the iron is soon dissolved from the plate, and, after a light scouring with a fibre brush and subsequent rinsing, the plate is again immersed in the solution to receive a further coating of iron, thus considerably lengthening For a review of the work done in the its life commercial electro-deposition of cadmium, see Mathers and Marble, Trans Amer Electrochem Soc 1914, 25, 297 et seq

Of several cobalt solutions the following vield the best results. (1) crystallised cobalt ammonium sulphate, 200 grams per litre of water; (2) cobalt sulphate, 312 grams; sodium chloride, 196 grams; boric acid, nearly to saturation, water, 1000 cc. From these solutions, cobalt plates on brass, iron, steel, copper, tin, nickel-silver, lead, and Britannia metal, the coating being firm, adherent, hard, and uniform When polished, the surface, although brilliantly white, has a slight bluish tint Compared with nickel-plating, the plating with solution (1) is four times, and with solution (2) fifteen times, more rapid, but the voltage required is greater than that used for most nickel-plating baths Since cobalt is harder than nickel, a much thinner coating of cobalt will offer the same protective coating as a greater weight of nickel deposit, thick deposits of cobalt are superior in appearance and character to those of nickel (Kalmus, Harper, and Savell, J Ind Eng Chem 1915, 7, 379, Chem Soc Abst. 1915, 107, 11 465)

Deposition of alloys. (1) Brass. From mixed solutions of zinc and copper sulphates with the addition of acid, copper can be completely deposited free from zinc, this principle being applied in electrolytic analysis and also in With salts more alike in stability, this condition being attained in the double evanide olutions, the two metals are deposited simultaneously in proportions varying with conditions The cyanides are invariably used for this purpose, the zine and copper compounds being used in about the same quantity The mixed solution may be prepared in many ways, of which the following are in common use

(a) Treating solutions of the mixed sulphates with excess of ammonia and adding about 30 p c more cyanide (KCN) than is required to decolour-

ise the blue solution

(b) Preparing a solution of potassium cyanide (1-1½ lbs per gallon) and saturating about three-quarters of it with the mixed carbonates of zinc and copper, subsequently adding the remaining solution for 'free cyanide'

The solution may be used warm or cold If cold, a higher concentration is desirable, and also a smaller proportion of zinc compound If warm, the zine compound should be increased and the solution may be safely diluted Brass anodes are used, which, in a warm solution with a fair proportion of free cyanide, dissolve under the influence of the current. Lack of free evanide gives rise to the formation of a deposit of the two single compounds on the anode, adding resistance and reducing the current, and thus altering the colour of the deposit The colour and composition of the deposit vary with several conditions In general, the conditions which demand a higher E M.F. give rise to a lighter deposit containing more zinc, whilst those which reduce the resistance of the solution

tend to the production of redder deposits co taining more copper. Thus more yellow depos are produced in cold dilute solutions with lit free cyanide, whilst the copper in the depo is increased when the solution is strengthened warmed, or more free KCN added. The co position of the deposit is controlled also by t proportion of the two metals in the solution and the fact that from cyanide solutions copi and zinc are ordinarily deposited in the prop-tion of 63 6 of copper 32 5 of zinc accoun approximately for the 2 1 proportion in deposit yellow brass The colour of the deposit lightened by the addition of ammonia ammonium carbonate, these substances assisti the solution of the zinc compound, which is l soluble than the copper compound, and p venting the formation of basic compounds

The methods of deposition of brass foll on the same lines as those of copper from t

cyanide solution

(2) Other alloys are deposited to only The choice of solution very limited extent depends upon the ease of mixture of solution from which the constituents can be separate deposited Thus for bronze, the sulpha chloride and cyanide solutions, are unsuital A satisfactory mixture can be made from t double oxalates of the two metals with amn nium oxalate, the solution being worked wa with a bronze anode Similarly, a solut from which nickel silver may be deposit may be prepared by mixing the separate dou cyanides of copper, zinc, and nickel with pot sum cyanide, or by dissolving the alloy nitric acid, precipitating the mixed carbona and dissolving the mixture in evanide deposition of these alloys is subject to the sa conditions as for brass, attention being paid those conditions which facilitate the deposit of the more positive constituents, viz tin, 71 and nickel

The electrodeposition of zine has of late ve been extensively carried on As a protect coating for iron and steel an electro deposit ] great advantages over the ordinary process galvanising The sulphate solution is commo used In some cases zinc anodes are employ and these to a large extent maintain a consti composition of solution Other processes emp insoluble anodes, resulting in the formation sulphuric acid equivalent in quantity to the z The deposition of zinc from si deposited acid solutions demands special conditions, a for general plating purposes the free acid tl formed is neutralised by filtering the liq through zinc dust From neutral solution there is the tendency for the formation of ba compounds leading to the growth of mo deposits Such addition agents as gluc beta-naphthol, &c, lead to a considera improvement in the character of the deposit

Another extending application of z deposition is found in the recovery of z from liquors produced by treating certain z ores with weak sulphuric acid. The zinc ores with weak sulphuric acid usually present to the extent of 6-10 pc. electrolysis this is reduced considerably, the acid solution formed by the use of insolu anodes is then used for extracting the z compounds from a further quantity of ore process has been applied largely at Anaconda reguline deposits may be obtained from solutions of the stannite, stannate, or double exalate with ammonium, with ease. They are prepared as

(1) The hydrate is precipitated from stannous chloride with alkali, and the precipitate dissolved in excess of alkali

(2) By converting the metal to hydrated oxide with nitric acid, and dissolving the washed oxide in alkalı

(3) By adding a solution of ammonium ovalate to tin chloride A white precipitate first forms, and this is soluble in excess.

Solutions containing from 1 to 2 ozs of metal per gallon are of convenient strength these solutions tin may be obtained as a reguline deposit within certain limits of current density Excessive current produces a grey spongy deposit, which may, however, be considerably improved by the addition of a small amount of glue or gelatine, thereby extending the limit of allowable current Solutions of moderate strength yield metal quantitatively, and the anode suffer normal corrosion, maintaining the strength of the electrolyte The dull white deposit is improved by gentle scratch-brushing with a soft brush Tin may also be deposited without the current by using an oxalic acid solution to which tin chloride is added metal is deposited by simple immersion, and the process may be improved by the addition of grain tin with the work, which facilitates deposition by local voltage action, while tin The process is hastened passes into the solution by immersing the small work in zinc trays, the zine passing into the solution as an anode this case the solution must be replemshed with tin chloride, and rejected when any large amount of zinc has accumulated in it

The deposition of lead may be similarly offected from alkaline solutions, which yield reguline deposits, whilst the acetate produces the well-known crystalline deposit. The process has but little application, but more recently the deposition of the metal has been successfully applied by Betts to the refining of the metal The electrolyte is a solution of lead fluosilicide, which may be made by dissolving the oxide or carbonate in the acid With unrefined anodes the lead passes into solution, whilst silver is retained in the anode mud. Good reguline deposits are obtained by the addition of glue or gelatine in small amount

More recently, lead perchlorate has been successfully used Perchloric acid is prepared from the sodium salt with a slight excess of hydrochloric acid Insoluble sodium chloride is filtered off and the acid liquid evaporated down to 135° C until excess of hydrochloric acid is expelled The perchloric acid solution is diluted and neutralised with litharge, a small proportion of the acid being set aside to add to the lead perchlorate solution, so that lead and free acid are present to the extent of about 5 pc. each. Very satisfactory deposits are obtained from this solution, especially with the addition of peptone in the proportion of 0.05 p c, and deposits of considerable thickness may thus be produced. With moderate current Vol. II. -T.

Deposition of tin may be successfully carried densities deposition proceeds almost quantitaout from a number of solutions. The chloride | tively, and this with the high chemical equivalent yields a beautiful crystalline deposit, but of lead has suggested its use for voltmeter purposes

A feature of lead deposition is the production of lead peroxide at the anode. This has long been known, and the production of coloured rings and films was first observed by Nobili, in Thus in a solution of lead acetate, or of 1826litharge in alkali, and a polished anode of mickel or iron, coloured rings are obtained if a wire The colours cathode is held close to the anode are due to the gradually varying thickness of the film, which brings about interference in the light falling upon them With anodes of other shapes the colours follow the shape of the anode, though they pass off into a more or less rounded form These colours are called 'metallochromes' With excessive current a dull-brown deposit of lead peroxide is at once formed

Anodic deposition of lead peroxide is also applied in the estimation of small amounts of lead in certain alloys from solutions containing nitric acid

The deposition of platinum is carried out from a solution of the chloride in sodium phosphate A platinum anode is insoluble and the solution needs the addition of the platinum compound. A brown colour sometimes occurs owing to some of the metal passing into the colloidal form

Palladium may be successfully deposited from a solution of its double chloride, and the process has been applied by Cowper-Coles for producing a non-corrodible covering for electro lytically deposited parabolic mirrors in copper

Cobalt deposition follows on lines similar to those for nickel, mercury, which may be deposited from the nitrate solution, has been applied to the construction of electrolytic meters, in which a small and definite fraction of the total current is shunted through a cell in which mercury is deposited, the weight of the mercury deposit automatically recording the current passing through the meter, and at constant potential difference the energy absorbed in the S F. circuit

ELECTRUM v NICKEL **ELEMI** v Olfo-resins ELEMI, ESSENTIAL OILS OF, v OLYO-

**ELEMICIN** (3 4 5-trimethoxyallylbenzene) A constituent of the essential oil of elem has been synthesised by Mauthner (Annalen, 1917, 414, 250) by condensing allyl bromide and pyrogallol-2 6 dimethyl ether, which yields 2 6 dimethoxyphenyl allyl ether (I), which, by heating at 220° is converted into 2 6-dimethoxy-4-allyxphenol (II), this, on methylation, yields elemicin (III.).

626 ELEMOL.

**ELEMOL**, C<sub>15</sub>H<sub>26</sub>O, a naturally-occurring monocycle sesquiteipene alcohol found in Manilla elemi oil; b.p  $152^{\circ}-156^{\circ}/17$  mm; D<sup>20</sup> 0 9411;  $n_{\rm D}$  1 5030;  $\alpha_{\rm D}-5^{\circ}$ . Forms a benzoate; b p  $214^{\circ}-218^{\circ}/10$  mm, D<sup>20</sup> 1 0287;  $n_{\rm D}$  1 5378;  $\alpha_{\rm D}-6^{\circ}$  Elemol, when reduced by means of formic acid, sodium hydrogen sulphate, or zinc-dust, yields Elemene C15H24; bp 115°- $117^{\circ}/10 \text{ mm}$ ,  $D^{20} 0 8797$ ,  $n_{D} 1 4971$ .

Elemol is the first monocyclic sesquiterpene alcohol to be found in Nature or to be obtained artificially (Semmler and Liao, Ber 1916, 49, 794).

ELIQUATION or LIQUATION. A metallurgical term to denote the operation of separating substances by taking advantage of their different fusibilities

ELLAGIC ACID. Ellagic acid, C14H6O8, is obtained from numerous tannin matters which contain an ellagitannin by boiling the aqueous extract with dilute sulphuric acid. In many cases it is found in the free state, due probably to the hydrolysis, by fermentation, of the ellagitannin or ellagic acid glucoside originally present, and such a fermentation frequently occurs when aqueous extracts of the tannin matters are allowed to stand for some time

Divi-divi (Casalpinia coriaria [Willd]) (Lowe, Zeitsch anal Chem 1876, 14, 40), myrobalans (Terminalia chebula [Ratz]) (Lowe, ibid), algarobilla (Casalpinia brevifolia) (Zolffel, Beilstein, 2, 1085), and valonia (Quercus aegilops [Linn]) yield considerable quantities of ellagic acid, and are the best natural sources of this material It has also been isolated from oak galls (Chevreul, Ann Chim Phys. 1828, [2] 9, 329), oak bark (Etti, Montash 1880, 1, 226), the bark of Picca excelsa (Link) (Strohmer, ibid 1881, 2, 539), pomegianate ind (Rembold, Annalen, 1867, 143, 288), Quebracho colorado (Perkin and Gunnel, Chem Soc Trans 1896, 69, 1307), Arctostaphylos uva-ursi (Spreng) and Contaria myrtifolia (Linn) (Perkin, abid 1900, 77, 424), Hamatoxylon campeachranum (Linn) (Perkin, ibid 1897, 71, 1137), the fruit of Casalpinia digyna (Rottl) (Nierenstein, Chem Zeit 1909, 87), and the bank of Terminalia catappa (Linn) (ibid) In fact, ellagic acid probably always occurs, if only in minute quantity, in all plant products which contain gallotannin Most interesting are the Oriental bezoar stones, concretions which are found in the stomachs of goats and other animals, and consist largely of ellagic acid These originate, without doubt, from the fact that the animal has fed upon plants in which some quantity of an ellagitannin is present

Ellagic acid was first discovered by Chevreul (Ann. Chim. Phys l.c.) in oak galls, and more closely examined by Braconnot (ibid 9, 187) According to Pélouze, it possessed the composition C<sub>7</sub>H<sub>4</sub>O<sub>4</sub> (*ibid*. 54, 356), whereas Merklein and Wohler (Ann Chem. Pharm whereas 55, 129), who isolated it from bezoar stones and termed it 'bezoaric acid,' showed that its true formula is C<sub>14</sub>H<sub>6</sub>O<sub>8</sub>

The precipitate of crude ellagic acid, which is produced by boiling the tannin extract with dilute mineral acid, is purified by wasning with alcohol and subsequent recrystallisation. A (Barth and Goldschmiedt, Ber. 1878, 11, 846; similar procedure is also satisfactory with the Schiff, ibid. 1879, 12, 1534; Zolftel, Arch.

deposits so frequently produced by fermentation and alluded to above. Ellagic acid is most readily crystallised from pyridine (Perkin and Nierenstein, Chem Soc. Trans 87, 1416), and the product, which is either a pyridine compound or contains pyridine of crystallisation, is washed with alcohol.

Lowe (Zeitsch Chem 1868, 4, 653) was the first to prepare ellagic acid synthetically by oxidising gallic acid with arsenic acid, and this was subsequently accomplished by Ernst and Zwenger (Annalen, 1871, 159, 32) by heating ethyl gallate with sodium carbonate solution in the presence of air, and by Griessmayer (ibid 1871, 160, 55) by heating gallic acid with water and iodine. It is readily produced by oxidising gallic acid dissolved in acetic acid by means of potassium persulphate and sulphuric acid (Perkin and Nierenstein, lc), and together with flavellagic acid by the addition of potassium persulphate to a solution of gallic acid in sulphuric acid (Perkin, ibid 1906, 89, 251) Under similar conditions, gallotannin produces ellagic acid (Nierenstein, Ber 1908, 41, 3015, and 1909, 42, 353), and it can also be prepared by boiling the tannin with hydrogen peroxide solution (ibid 1907, 40, 917) Herzig and Bronneck obtained good results by passing air through an ammoniacal solution of gallie acid ethyl ester, and also of gallotannin (Monatsh 1908, 29), whereas Sisley (Bull Soc chim 1909, [4] 5, 727) prepared ellagic acid from tannin by means of alcoholic potassium hydroxide solution According to Rupe, a 60 p c yield is produced when gallie acid in sulphuric acid solution is oxidised with sodium nitrite (Chemie d naturl Farbstoffe, 1909, 2 162)

Ellagic acid crystallised from pyridine forms prismatic needles, which are converted by alcohol into a pale yellow crystalline powder, but when purified by means of its acetyl derivative, the product is almost colourless (Perkin and Nieren-It is very sparingly soluble in all the usual solvents, dissolves in alkaline solutions with a pale yellow colour, and from these liquids, when diluted with hot alcohol, is deposited on acidifying in a crystalline con-When heated it does not melt below 360°, and sublines at higher temperatures with considerable carbonisation. With nitrie acid containing nitious acid and subsequent dilution, it gives a blood-red colouration (Griessmayer's reaction), and this property, considered at one time to be characteristic, is known to be also possessed by flavellagic acid (Perkin)

According to Merklein and Wohler (lc), the alkaline solution of ellagic acid becomes reddishvellow on exposure to air, and deposits black crystals of potassium glaucomelanate

When boiled with phenylhydrazine in alcoholic solution, or when carefully heated with phenylhydrazine, ellagic acid forms the product  $C_6H_5NH\ NH_2,C_{14}H_6O_8$ , which crystallises in yellow needles, and is readily reconverted into ellagic acid Ellagic acid gives similar compounds with aniline and quinoline (Goldschmiedt, Monatsh 1905, 26, 1139)

Pharm. 229, 123), colourless needles, mp 343°–346° (Perkin and Nierenstein); tetrabenzoylellagic acid  $\rm C_{14}H_2O_8(C_7H_5O)_4$ , colourless needles (Goldschmiedt and Jahoda, Monatsh 1892, 13, 151), m p 332°-333° (Perkin), cllagic acid monomethyl ether (14H<sub>5</sub>O<sub>7</sub>(OCH<sub>3</sub>), yellow crystalline powder (Goldschmiedt, Monatsh 1905, 26, 1139); diacetylellagic acid monomethyl ether C<sub>14</sub>H<sub>3</sub>O<sub>7</sub>(OCH<sub>3</sub>)(C<sub>2</sub>H<sub>3</sub>O)<sub>2</sub>, crystalline powder (Goldschmiedt); ellagic acid dimethyl ether C<sub>14</sub>H<sub>4</sub>O<sub>6</sub>(OCH<sub>3</sub>)<sub>2</sub>, crystalline powder (Goldschmedt), and ellagic acid tetramethyl other C<sub>14</sub>H<sub>2</sub>O<sub>4</sub>(OCH<sub>3</sub>)<sub>4</sub>, colourless microscopic needles (Goldschmiedt, Herzig and Pollak, Monatsh 1908, 29, 263), have been described

Ellagic acid gives the following salts  $KC_{14}H_5O_8$ , minute yellow needles (Perkin and Wilson, Chem Soc Trans 1903, 83, 134); K<sub>2</sub>C<sub>14</sub>H<sub>4</sub>O<sub>8</sub>, prisms (Merklem and Wohler, Perkin and Wilson), K<sub>2</sub>C<sub>14</sub>H<sub>4</sub>O<sub>8</sub>, KOH, microscopic prisms (Merklem and Wohler),

crystalline powder, \*NaC<sub>14</sub>H<sub>5</sub>O<sub>8</sub>,H<sub>2</sub>O, yellow needles (Ernst and Zwenger, Annalen, 1871, 159, 32)

The tinctorial properties of ellagic acid are somewhat feeble, but in 1887 it was placed on the market by Messrs Meister, Lucius, and Bruning, under the name of 'Alizarin Yellow in paste,' and was recommended as yielding, with chromium mordants, greenish-yellow shades of considerable permanence

Rembold (Annalen, 1867, 143, 288) states that when ellagic acid is treated with sodium amalgam, it gives \gamma-hexahydroxydiphenyl

three distinct sufohydrocllagic acids C14H10O6.  $C_{14}H_{10}O_7$ ,  $C_{14}H_{10}O_9$ , and glaucohydrodluqic acid, but, according to Nierenstein (Ber 1908, 41, 1649), this latter compound is in reality the pentahydroxydiphenylmethylolid referred to later By the action of boiling potassium hydroxide solution (Barth and Goldschmiedt, Ber 1879, 12, 1242), ellagic acid gives herahydroxydiphenylencketone (\*) C<sub>1</sub>, H<sub>2</sub>O<sub>7</sub>, by fusion with potassium hydroxide *B-hexahydroxydiphenyl*, and by fusion with sodium hydroxide \gamma-hexahydroxydrphenyl, together with some of the  $\beta$ - compound

When ellagic acid is distilled with zinc-dust fluorene is produced (Rembold, Ber 8, 1494. Barth and Goldschmiedt, ibid 11, 846, cf also Graebe, *ibid* 1903, 36, 212)

As a result of their investigation, Barth and Goldschmiedt (ibid 1879, 12, 153) suggested that ellagic acid could be represented by one of the two following formulæ:

and of these the first was preferable

Whereas such a constitution requires the presence of five hydroxyl groups, Schiff (Ber 1879, 12, 1534) considered that acetylellagic acid was  $C_{14}H_{2}(C_{2}H_{3}O)_{4}O_{8}$ , and this was subsequently corroborated by Zolffel (Arch. ellagic acid.

Pharm, 229, 123) Schiff, at the same time, proposed two formulæ for ellagic acid

the latter of which is identical with that preferred by Graebe ( $l \epsilon$ ) In a later investigation, Goldschmiedt and Jahoda (Monatsh 13, 49), as the result of their preparation of tetrabenzoylellagic acid, were satisfied of the existence in ellagic acid of but four hydroxyls, and con-

Graebe (Ber 1903, 36, 214), among other criticisms, pointed out that a substance having this constitution, and which may be more clearly written as follows (1) -

$$\begin{array}{c|c} COOH & COOH \\ \hline (1) & OH & OH \\ \hline \end{array}$$

would yield, on distillation with zinc-dust, not fluorene, but an isomeric hydrocarbon (2), if this, indeed, were capable of existence. In the same paper this author announced the interesting fact that diphenylmethylolid

on distillation with zinc dust, gives not only diphenyl and methyldiphenyl, but also fluorene; and in a theoretical discussion of the subject, suggested that Schiff's second formula (given above) most probably represents the true constitution of this substance

The subject was remvestigated somewhat later by Perkin and Niercustein (le), who, on digesting ellagic acid with boiling potassium hydroxide solution, obtained Barth and Goldschmiedt's so-called hexahydroxydiphenyleneketone ('13H<sub>8</sub>O<sub>7</sub>) From this substance a penta-acetyl derivative ('13H<sub>1</sub>O<sub>7</sub>(('2H<sub>3</sub>O)<sub>5</sub>, piismatic needles, mp. 224°-226°, and a pentabenzoyl derivative, ('13H<sub>3</sub>O<sub>7</sub>(('7H<sub>5</sub>O)<sub>5</sub>, plates, mp. 257°-259°, were prepared. As, moreover, zinc-dust distillation gave fluorene, there could be little doubt that this compound was in reality pentahydroxydiphenylmethylolid, as, indeed, was surmised by Graebe.

From their results, together with a study of other similar compounds, Perkin and Nierenstein considered that Schiff's formula, and which can be more clearly written thus .

Finally, Herzig and Pollak (Monatsh 1908, 29, 263), by a study of the methylation products of ellagic acid, obtained results further corroborating this constitution.

When Goldschmiedt's tetramethylellagic acid is digested with alcoholic potash and methyl iodide, diphenyl-1 2.3:6.7 8-hexamethoxy-5 10-di-carboxylic methyl ester (mp. 109°-111°)

is obtained, together with a small quantity of diphenylmethyloid-2 3 6 7.8-pentamethoxy-5-carboxylic acid methyl ester (2), m.p. 187°-189°.

By means of alcoholic potash, these compounds (1) and (2) yield respectively diphenyl-1 2 3 6 7 8-hexamethoxy-5 10-dicarboxylic acid (3), mp 238°-240°, and diphenyl-2 3 6.7 8-pentamethoxy-1-hydroxy-5 10-dicarboxylic acid (4), m.p. 200°-203°:

(4) 
$$CH_3O$$
 $OCH_3$ 
 $COOH$ 
 $OCH_3$ 
 $OCH_3$ 

Ellagic acid is probably not a tanning material in the true sense of the term, but is of considerable importance nevertheless in the tanning process. Thus the ellagitannic acid absorbed by the hide is at least in part converted into ellagic acid, and the deposit thus formed adds weight and bloom to the finished article.

Other members of this group have been prepared from m-hydroxybenzoic acid, p-hydroxybenzoic acid, proto-catechuic acid, sym. dihydroxybenzoic acid, gallic acid, and from ellagic acid itself—An account of these is given below

## FLAVELLAGIC ACID

Flavellagic acid  $(^{\circ}_{14}\text{H}_{0}^{\circ})_{9}$  is obtained in conjunction with ellagic acid when gallic acid is oxidised with potassium persulphate and strong sulphuric acid. By the employment of a dilute acid, flavellagic acid almost free from cliagic acid can be produced, and for this purpose the following process is recommended (A. G. Perkin, Chem. Soc. Trans. 1906, 89, 251). 20 grams of gallic acid are treated with 160 c. c. of 96 p. c. sulphuric acid, 66 c. c. of water added, and the hot solution thus obtained is cooled to 50°, and maintained at this temperature during the gradual addition of 40 grams of potassium persulphate. A. G. Perkin and F. M. Perkin (Chem. Soc. Trans. 1908, 93, 1194) have obtained the same compound by the electrolytic oxidation of gallic acid in the presence of sulphuric acid,

and more recently Bleuler and Perkin (bid. 1916, 109, 530) have prepared it by heating gallic acid at 110°-120° with arsenic and sulphuric acids.

Flavellagic acid crystallises from pyridine in small yellow prismatic needles which contain pyridine, and do not melt below 360°. With nitric acid containing nitrous acid and subsequent dilution, it gives the blood-red colouration (Griessmayer reaction), which is also produced by ellagic acid. Dilute alkalis dissolve it with a yellowish-green colouration, and by distillation with zinc-dust fluorene is produced. Acetyl-flavellagic acid.  $C_{14}HO_{9}(C_{2}H_{4}O)_{5}$ , colourless needles, melts at  $317^{\circ}-319^{\circ}$ , and benzoyl-flavellagic acid.  $C_{14}HO_{9}(C_{14}H_{2}O)_{5}$ , prismatic needles, melts at  $287^{\circ}-289^{\circ}$ . Flavellagic acid dyes mordanted woollen cloth shades somewhat resembling but stronger than those produced by ellagic acid.

Chromium Aluminium Tin Iron.
Yellowish- Pale greenish- Pale Dark oliveolive yellow. yellow brown.

By the action of boiling 50 p.c. potassium hydroxide solution, flavellagic acid gives hexahydroxydiphenylmethylolid

colourless needles (mp above 300°). This compound dissolves in solutions of the alkali hydroxides with an orange-yellow tint, and this, on dilution with water and exposure to air, develops a strong bluish-violet colouration. The acetyl derivative  $C_{13}H_2O_8(C_2H_3O)_8$ , colourless prismatic needles, melts at  $232^\circ-234^\circ$ . Flavellagic acid is hydroxyellagic acid, and possesses the following constitution.

(cf Herzig and Tscherne, Monatsh 1908, 29, 281)

Flavellagic acid gives with diazomethane the methyl ether C<sub>14</sub>HO<sub>4</sub>(OMc)<sub>5</sub>, mp 245°, and this is converted by methyl iodide and potassium hydroxide into methyl-3 4 5 6 2'.3'.4'-heptamethoxy/liphenyl-2.6'-dicarboxy/late

 $C_{12}H(OMe)_7(CO_2Me)_2$ 

m p 83°-87°. The latter, on hydrolysis with potassium hydroxide, yields the acid

 $C_{12}H(OMe)_7(CO_2H)_2$ 

m p  $163^{\circ}$ - $167^{\circ}$ , in the anhydrous condition. From water it crystallises with  $1\rm{H}_2\rm{O}$  and then melts at  $95^{\circ}$ - $100^{\circ}$  (decomp ) (M. von Bronneck, Monatsh 1908, 29, 281)

When gallic acid 3 4-dimethylether, or gallic acid trimethylether is oxidised by means of potassium persulphate and sulphuric acid at 45° (Herzig and Schmidinger, Monatsh. 1910, 31, 918), flai ellagic acid tetramethylether

yellow needles, m.p. 270°-271°, is produced, the acetyl derivative of which melts at 270°-271° By means of methyl sulphate and potassium hydroxide, the heptamethoxy compound is obtained

## CERULEOEILAGIC ACID

Cœruleoellagic acid is prepared by heating ellagic or flavellagic acid (1 part) with sulphuric acid (monohydrate 10 parts) to 200° and allowing the temperature to fall to  $185^{\circ}-190^{\circ}$  and remain there for 30 minutes. The product isolated by pouring into water is purified by conversion into its acctyl derivative, and this is subsequently hydrolysed by means of sulphuric acid in the presence of acctic acid. It may also be obtained by the oxidation of ellagic or flavellagic acids (1 part) in sulphuric acid solution (10 parts) with arsenic acid (1 part) at  $100^{\circ}-130^{\circ}$  (Perkin, Chem. Soc. Trans. 1916, 109, 529)

Cæruleocllague acud, C<sub>14</sub>H<sub>6</sub>O<sub>10</sub>, separates from hot pyridine in small pale yellow prismatic needles which melt above 360° and are very sparingly soluble in the usual solvents. Concentrated solutions of the alkali hydroxides dissolve it with a greenish-yellow colour, which on dilution become green and finally of a blue colour, and these changes appear to arise from oxidation. Sodium and potassium carbonate solutions also give blue liquids. On distillation with zinc-dust fluorene is produced.

Acetylcoruleoellagic acid,  $C_{14}O_{10}(C_2H_3O)_6$ , colourless needles, mp 330°-332°, and benzoylcoruleoellagic acid  $C_{14}H_{10}(C_7H_5O)_6$ , mp 343°-345°, have been prepared. The latter is more sparingly soluble in benzoic anhydride than the corresponding derivative of flavellagic acid, and this property provides a means for the separation of the two substances.

By digestion with 50 p.c. potassium hydroxide solution diluted with its own volume of alcohol, coeruleoellagic acid gives a compound  $\rm C_{12}H_{10}O_8$ , evidently octohydroxydiphenyl. This consists of an almost colourless crystalline powder, soluble in dilute potassium hydroxide solution, with a reddish-violet colouration which becomes brown on exposure to air. The acetyl derivative  $\rm C_{12}H_2O_8(\rm C_2H_3O)_8$  forms colourless needles melting at  $\rm 177^\circ{-}178^\circ$ 

The constitution assigned to corruleoellagic acid is as follows —

a formula which represents it as either a dihydroxy-cllagic or hydroxy flavellagic acid

Coruleoellagic acid possesses well-marked dyeing properties of a similar character, though more strongly developed than those of ellagic and flavellagic acids, and may have practical utility. Owing to its sparing solubility it gives the best results in the paste form. The following shades are obtained by the employment of mordanted woollen cloth —

Chromium Aluminium Tin Iron.
Deep olive- Greenish- Dull Greenishyellow yellow black

In the case of the aluminium mordant the

employment of chalk in the dye-bath exerts a detrimental effect

## CATELLAGIC ACID.

Schiff (Ber. 12, 2590) on heating protocatechuic acid with arsenic acid, obtained a substance which he named catellagic acid, and to this he assigned the formula  $C_{14}H_{10}O_7$  or  $C_{14}H_8O_7$  Perkin and Nierenstein (Chem. Soc. Tians 1905, 87, 1417) obtained a similar substance by the oxidation of protocatechuic acid, and also parahydroxybenzoic acid with potassium persulphate and sulphuric acid to the latter authors, catellagic acid C14H6O6 crystallises from pyridine in colourless needles, which melt above 360°, and sublime with but moderate carbonisation at higher temperatures Solutions of the alkali hydroxides dissolve it with a pale yellow colour, and with nitric acid it gives a magenta coloured liquid Dracetylcatellagic acid, colourless prismatic needles, melts at 322°-324°

Catellagic acid, by distillation with zincdust, gives fluorene, and is closely related to ellagic acid. Its constitution (Perkin and Nierenstein) may be expressed as follows—

From the oxidation products of parahydroxybenzoic acid, Perkin and Nicrenstein isolated, in addition to catellagic acid, a second compound  $\rm C_{14}H_8O_6$ , colourless needles, mp above  $\rm 360^\circ$  This, which gives the diacetyl derivative  $\rm C_{14}H_6O_6(\rm C_2H_3O)_2$ , colourless needles, mp  $\rm 267^\circ - 268^\circ$ , and by distillation with zinc-dust fluorene, possesses the formula

and evidently originates from the interaction of one molecule of protocatechuic acid and one of parahydroxybenzoic acid

## METELLAGIC ACID

Metellagic acid (Peikin and Nierenstein, Chom Soc Trans 1905, 87, 1425) is obtained in small amount together with other substances by oxidising metahydroxybenzoic acid in sulphuric acid solution with potassium persulphate at about 30°. The product is fractionally crystallised from acetic acid, the second crop acetylated, the acetyl derivative thus obtained purified by repeated crystallisation from acetic anhydride and hydrolysed with sulphuric acid in the usual manner.

Metallagic acid  $\mathrm{C_{14}H_6O_5}$  crystallises from acetic acid in colourless needles which readily sublime at high temperatures. With caustic alkaline solutions it behaves similarly to catellagic acid giving a yellow colour which is discharged on heating. Distilled with zine-dust a small quantity of a crystalline hydrocarbon is produced which appears to be identical with fluorene. Acetylmetelluque acid  $\mathrm{C_{14}H_6O_5(C_3H_3O)}$  crystallises in colourless leaflets, in p. 269°-271°

The reactions of metellagic acid are in (Burm.) (nat ord. Myrsinaceæ) harmony with those required by a member of the ellagic acid series, and the following formula assigned to it is probably correct .-

In the mother liquors obtained during the purification of acetyl metellagic acid, a second acetyl compound, in p 237°-243°, was isolated This on hydrolysis gave a substance crystallising in glistening yellow needles, the nature of which has not been ascertained

By the oxidation of suitable hydroxybenzoic acids, a series of hydroxydiphenyldimethyloid derivatives have thus been prepared, viz

Metellagic acid  $C_{15}H_5O_4(OH)$ Catellagic acid  $C_{15}H_4O_4(OH)_2$ Resoflavine  $C_{14}H_3O_4(OH)_3$ Ellagic acid  $C_{14}H_2O_4(OH)_4$ Flavellagic acid  $C_{14}HO_4(OH)_4$ Coruleoellagic acid C14O4(OH)a

AGP

ELLAGITANNIC ACID. A tanning principle present in divi-divi (Lowe, Frdl 14, 35), in algarobilla (Zolffel, Arch Pharm 229, 123), in myrobalans (Lowe, lc 44, Zolffel, lc), and probably to some extent in all plant products which contain a gallotannin (v ELLAGIC ACID)

According to Lowe, the molecule of ellagitannic acid contains 5 hydroxyl groups replaced by acetyl It gives precipitates with gelatin, albumen, alkaloids, tartar emetic, and a nearly black precipitate with feiric acetate Its alcoholic solution gives, with lead acetate, a vellow precipitate

Zolffel (lc) considered it a sugar-free tannic acid of the formula

## $C_{6}H_{2}(OH)_{2}COO_{6}H_{2}(OH)_{2}COOH_{2}$

whereas Perkin and Nierenstein (lc) suggested it to be a glucoside or a condensation product of two molecules of gallotannin

Nierenstein (Ber 1910, 43, 1267) has obtained it in a pure state by repeated treatment of the crude substance from myrobalans with alkalı and ethyl chloroformate, and then decomposing with pyridine according to Fischer's method; and gives its formula as

$$C_{26}H_{28}O_{19},3H_2O$$

It crystallises from a mixture of pyridine and acetic acid in pale-yellow plates, which, after sintering at 300°-306°, melt at 329°-336°  $[a]_{p}^{17} + 1802^{\circ}$  So obtained, it readily yields ellagic acid with dilute sulphuric acid, but is not decomposed by 10 pc sodium carbonate solu-As it is hydrolysed by emulsin to luteoic acid. Nierenstein considers it to be a glucoside of this compound (v Tannins) A G P ELUTRIATION. The separation of the

EMBARIN. Trade name for sodium mercurisalicylsulphonate

EMBELIC ACID. The active constituent of the fruit of the Indian plant Embelia riles

Employed as an anthelmintic

EMBOLITE. Native silver chlorobromide containing chlorine and bromine in indefinite proportions It is the commonest of the hornsilvers or cerargyrites  $(q \ v)$ , occurring as compact horn-like masses or as small, indistinct cubic crystals of a greenish-grey colour Frequently a small amount of rodine is also present, and the formula is Ag(Cl,Br,I); the colour of this iodembolite variety is usually greenish-yellow to orange-yellow Large quantities have been mined with other ores of silver in Chile, Mexico, and Broken Hill in New South Wales Prior and Spencer, Min Mag 1902, 13, 174)

EMERALD v BERYL, and GLUCINUM EMERALD GREEN. Hydrated chromium sesquioxide (v Chromium), also applied to Schweinfurth green (v art Arsenic, also Pia-MENTS)

EMERALD-NICKEL v ZARATITE EMERALD, ORIENTAL, v CORUNDUM

EMERY. (Émeri, Fi , Smirgel, Schmirgel, Ger) An impure variety of coundum. It is, however, more of the nature of a rock, rather than a simple mineral, consisting e-sentially of a fine-grained aggregate of corundum (50-60 pc) and magnetite (30-40 pc) Several other minerals are also present in smaller and variable amounts Hamatite and limonite are present as alteration products of the magnetite, and others, such as diaspore, margarite (emerylite), muscovite, kyanite, have probably been derived from the corundum In addition, there may also be tourmaline, chloritoid, biotite, staurolite, rutile, idociase, pyrites, iron spinel (hercynite), &c The material is dull black, dark grey, or bluish-black, and has much the appearance of a fine-grained iron-ore; sp gr 3 75-4 31. It is massive and opaque, breaking with a more or less regular fracture, and is magnetic abrading power (measured by the amount of glass abraded by a given weight of emery in a certain time) ranges from 65 to 32, as compaied with sapphire at 100. These values are only roughly proportional to the amount of alumina (corundum) present in the mixture, depending also to some degree on the texture of the material.

The analyses on next page are of material from Naxos, J-IV (I and II, the extremes as regards the amount of alumina of seven analyses by Oser, quoted by S. A. Papavasihou, 1913; III and IV, by E. Ludwig, quoted by G. Tschermak, 1894), Asia Minor, V, by R. Kramer, 1907, VI, Peekskill, New York, by G. H. Williams, 1887. Several older analyses have been published by J. L. Smith (Amer J. Sci. 1850, 1851, 1866), and by R. Jagnaux (Bull Soc. Min. France, 1884)

Analysis III corresponds with the mineral composition corundum 52 4, magnetite 32 1, tourmaline 115, muscovite 2, margarite 2 p.c.; and IV with corundum 50, magnetite 33, tourmaline 9, chloritoid 4, muscovite 3, calcité lpc.

The only sources of supply are Greece, Asiatic Turkey, and the United States deposits in the island of Naxos in the Grecian archipelago have been known since remote Here, on the north-east side of the times

island, the emery occurs as irregular beds and lenticular masses in crystalline limestone (marble), associated with crystalline schists and intiuded by granito. Large isolated blocks also occur weathered out on the surface. The methods of mining are very primitive, and resort is made to the old method of fire-setting, the surface of the rock being heated by fires and suddenly cocled by water to develop cracks. The production is the monopoly of the Greek government, and amounts to about 10,000 tons per annum. Emery also occurs on the neighbouring islands of Irakhia, Sikinos, Paros, and Amurgos, but these deposits are not worked (On the Naxos deposits, v. W. H. Cottrell, Foreign Office Rep., Miscell. Ser. No. 368, London, 1895. G. Tscheimak, Min. Petr. Mitt. 1894, anv. 311. S. A. Papavasiliou, Zeits Deutsch Geol. Gesell. 1913, lxv. 1–123.)

The important deposits in western Asia Minor, around Smyrns, were discovered by J Lawrence Smith in 1847 Here also the emery occurs as lenticular bodies in bluish crystalline limestone, associated with mica-schist, gneiss, and granite; and as loose blocks weathered out in the reddish surface soil The principal mines are situated on the Gume Dagh or Messogis Mountain in the Aidin district (E of Ephesus and S E of Smyrna) Others are near Manisa (the ancient Magnesia), near Kula and Adula (N. of Ala-Shehr=Philadelphia), and on the neighbouring islands of Samos and Nikaria The output of 20,000 to 30,000 tons per annum is shipped from Smyrna. (On the Asia Minor deposits, v J L Smith, Amer J Sci 1850, 1851, and Original Researches in Mineralogy and Chemistry, 1884, R. Kramer, Klemasiatische Schmirgelvorkommnisse Inaug -Diss Leipzig, Beilin, 1907)

In the United States, deposits have been worked at Peekskill in Westchester Co, New York, occurring here as segregations in gabbro, and in amphibolite-schist at thester in Hampden Co, Massachusetts The annual output amounts to only about 1000 tons, and that from Chester has now fallen off. (On the United States occurrence, n. G. P. Merrill, The Non-Metallic Minerals, 2nd edit New York, 1910)

An abrasive material mined at Wildenreuth and other places in Bavaria under the name of emery (Schmirgel, Ger) is really a mixture of garnet and quartz. In the trade the name emery has also been applied to the refuse from cutting gems and from gem-washings.

' Also Cr<sub>2</sub>O<sub>5</sub> trace <sup>2</sup> Also P<sub>2</sub>O<sub>5</sub> trace, S 0 01

In the preparation of the material for the market, after being carefully hand-picked at the mine, it is crushed under stamps and sorted into various grades of fineness through wire sieves. The finest 'flour of emery' is prepared by washing and elutriation Emery powder is used by lapidaries and stone workers, for polishing plate glass and grinding lenses In the form of emery paper, emery cloth, and emery sticks, the powder is fixed by means of glue For emery wheels the powder is mixed with a cementing material, such as shellac, sodium silicate, or vulcanite, or it is baked with loam or kaolin and thus embedded in terra-cotta or porcelain Such wheels are much used by lapidaries and dentists, and for grinding and polishing metals, &c Attempts have been made to use pieces of emery, in place of diamond, in the crowns of rock-drills (On the technical uses of emery, v A Haenig, Der Schmirgel und seine Industrie, Wien, 1910) L J S.

EMETAMINE v IPECACUANHA

EMETINE v IPECACUANHA. EMIN RED v PRIMULINE

EMODIN v GLUCOSIDES, RHUBARB; SYN THETIC DRUGS

EMPRESSITE. A silver-tellurum mineral AgTe, discovered in the Empress-Josephine mine, Kerber Creek, Colorado, associated with galena and native tellurum. Lustre, metallic, streak, greyish-black, fracture, conchoidal, hardness, 3–3 5, sp gr. 7 51 (Bradley, Amer J. Sci. 1914, 38, 163)

EMPYROFORM v SYNTHETIC DRUGS.

EMULSIN. The term 'emulsin' applied originally to the enzyme or mixture of enzymes, present in bitter and sweet almonds, which hydrolyses amygdalm to glucose, benzaldehyde, and hydrogen cyanide. The same enzyme was shown subsequently to hydrolyse many natural glucosides as well as the synthetically prepared  $\beta$ -glucosides, though it was entirely without action on the stereoisomeric  $\alpha$ -alkylglucosides (Fischer, Zeitsch physiol Chem 1898, 26, 60) The name is now used to comprise all enzymes which hydrotyse  $\beta$ glucosides Such enzymes are widely distubuted in plants besides the kernels of fruits, they also occur in the leaves and young twigs of the higher plants, in most mould fungi, especially in Polypoius species parasitic on trees, and in bacteria Henry and Auld (Proc Roy Soc 1905, B, 76, 568) have identified emulsin as present in yeast.

β-Glucosides are also hydrolysed by certain animal extracts, e.q intestinal mucous membrane, a fact which is taken to indicate the presence of emulsin

There are, however, well-marked differences in the number of substances which these various emulsin preparations are able to hydrolyse, and the investigations of Armstrong and others (Chem Soc Proc 1910, 334) indicate, that whilst the leaf enzyme (emulsin) is, as a rule, a specific for the glucoside normally occurring in the particular plant, the seed enzyme, especially that of the almond, is able to attack a number of glucosides. For this reason almond emulsin is considered to be a mixture of several closely related enzymes. According to H. E and E F. Armstrong and Horton (Proc Roy So. 1908, 80, 321), it contains a \$\textit{\textit{Boundary of Soc. 1908}} \text{ 1908}.

632 EMULSIN

proper, which attacks  $\beta$ -glucosides; a cyanase, which eliminates hydrogen cyanide from amygdalin, an amygdalase, splitting off glucose from amygdalin; and a luclase, acting on milk sugar (cf. Rosenthaler, Arch. Pharm 1910, 240, 105)

Almond emulsin hydrolyses  $\beta$ -glucosides and also the disaccharides, lactose, gentiobiose, cellose, and melibiose It further hydrolyses the synthetical  $\beta$ -methylgalactoside The emulsin of Aspergillus niger, on the contrary, has no netion on lactose or on  $\beta$ -galactosides In referring to emulsin, it is therefore advisable

to specify the source of the enzyme

Preparation —Ground sweet almonds from which the fat has been expressed are macerated with water and a little toluene or chloroform at the ordinary temperature for 12-24 hours The liquid is expressed through a cloth, protein precipitated with a few drops of acetic acid, and the clear filtrate precipitated with alcohol added 50 c c. at a time till no further precipitate The liquid is decanted and the precipitate rapidly washed with absolute alcohol and ether to dehydrate it, and dried in a vacuum Alternatively the original precipitate may be collected on a filter paper, dued roughly on bibulous paper, and dissolved in water in a closed bottle, to which a little toluene is added The clear solution so obtained is very active, and retains almost constant activity for many It is essential to carry out this preparation as rapidly as possible

The dried enzyme is a soft, white powder, giving most of the reactions of proteins, but losing these on purification. Its chemical nature has not been the subject of any detailed investigation. Active preparations are to be

obtained in commerce

Emulsin exhibits maximum activity in neutral solution Alkali stops the action, small quantities of acids usually increase the activity, owing to their effect in neutralising

alkaline impurity

Experiments with emulsin are usually carried out at about 37°; the optimum temperature is 45°. Emulsin is less resistant to destruction by heat in presence of alcohol below 50 p.c. but above this point the reverse is the case, owing to the fact that in stronger alcohols the enzyme is precipitated, and in this condition is more resistant to heat. In sterilising plants containing enzymes it is best to use alcohol of such strength as to produce a liquid containing about 60 p.c. of alcohol (Bourquelot and Bridel, J. Pharm ('him 1913, 7, 65)

Emulsin is detected qualitatively by its action on amygdalin, liberating hydrogen eyanide. The activity is tested quantitatively either against amygdalin or saliein, by measuring the amount of sugar formed in a given time.

Emulsin is also able to bring about synthetic change (Armstrong, Proc. Roy. Soc. 1905, B, 76, 592), van't Hoff, Sitzungsber K. Akad. Wiss Berlin, 1910, 48, 963). Emulsin exhibits hydrolytic activity in alcoholic solutions. Although unable to hydrolyse salicin in presence of 95 p.c. alcohol, it becomes active in 90 p.c. alcohol, hydrolysis continuing slowly until 37 p.c. of the glucoside has been decomposed. As the strength of the alcohol is diminished equilibrium is more rapidly attained, and a greater proportion of the salicin undergoes hydrolysis (Bour-

quelot and Bridel, Compt rend 1912, 154, 944). Similarly, emulsin is inactive when suspended in solutions of glucosides in acetone or ethyl acetate, but becomes able to effect hydrolysis when 10 pc of water is added to the acetone or the wet ester is used When emulsin acts on a solution of glucose in 85 p c alcohol, the corresponding  $\beta$ -methyl or  $\beta$ -ethyl glucosides are formed, the same equilibrium point being reached in solutions containing originally glucose or alkyl The more dilute the alcohol the greater is the hydrolysis and the less the synthesis (Bourquelot and Bridel, Compt rend 1912, 155, 319) The position of the equilibrium is independent of the quantity of emulsin added and of the temperature, but it varies with the strength of the alcohol and with the amount of glucose present. The property of emulsin to facilitate synthesis has been utilised by Bourquelot to prepare a large number of glucosides of the alcohols, including such substances as geraniol and glycol, and also the corresponding galactosides

The emulsin contained in a number of plant preparations is able to hydrolyse dl-benzaldehyde cyanohydrin, and also to synthesise this compound from benzaldehyde and lydrocyanic acid In some cases the synthesis is asymmetric, and an optically active cyanohydrin is formed (cf. Rosenthaler, Arch. Pharm. 1913,

251, 56)

(For a list of the glucosides attacked by emulsin, v Giucosides) E F A

ENAMEL BLUE. Cobalt blue (v PIGMENTS) **ENAMELS** are vitreous compositions capable of adhering by fusion to the surface of metal or of pottery The base of the enamel is generally a colourless glass, in which are suspended particles of an opaque metallic oxide or salt, generally stannic oxide Up to about 900°, tin dioxide exists finely suspended in the enamel, but at a higher temperature combination or solution may occur and opacity is diminished Titanic oxide has been used in place of stannic oxide, and antimony compounds have been employed. Opacity may also be obtained by the use of arsenious oxide, calcium phosphate, cryolite, or fluorspar. A preparation known as 'artificial cryolite' sometimes replaces the mineral When bone ash is used, a little nitie may be added to remove the grey colour; the nitre also prevents reduc-tion of the lead The vitreous base of most The vitreous base of most enamels is a glass containing much lead, but when the presence of lead is objectionable, as in enamelled vessels for culmary purposes, soda-and potash-glasses should be used. If great fusibility be required, it may be secured by the association of borates with the silicates Borate enamels are very hard, but are deficient in elasticity, and may be affected by moisture. Colour is imparted to the enamels by the introduction of various compounds, generally metallic oxides, the use of which, in many cases, has been known from remote ages Percy's analyses of the enamelled bricks of Babylonia (circa 700 B c) showed that a dense white was obtained by the use of stannic oxide, a nich yellow by means of antimony, apparently in the form of lead anti-moniate ('Naples yellow'); and a deep blue by copper, probably introduced as oxide, but existing in the enamel as a copper sodium silicate. The ancient Egyptian blue enamel, or glaze, ENAMELS 633

contains a definite copper calcium silicate, forming crystals remarkable for their intense pleochroism, to which Fouqué gave the name of vestorien (Bull Soc Fr Min [12] 1889, 36) (v. EGYPTIAN BLUE). The ancient Egyptians seem to have been ignorant of the art of enamelling on metal.

The enamelling of pottery is a simple operation, since it consists in the mere fusion of an opaque glaze on to the surface of the ware. But the application of a vitreous body to a metallic surface is less easy, and it is to this process that the term 'enamelling' is sometimes restricted, while the works of art produced by enamelling on metal are themselves known as 'enamels'

The most ancient enamels found in North-Western Europe are referable to the prehistoric Iron Age, sometimes distinguished as Late Celtic In these ancient enamels, brilliantly coloured opaque glass is embedded in cells of shallow cavities in bronze. It is probable that the vitreous material was applied as a powder, mixed with a vehicle so as to form a paste, and then heated sufficiently to cause its fusion, and thus secure firm attachment to the metal

A similar method, known as champ levé enamelli g, was extensively employed at a much later date in Germany and at Limoges in France—a town which for centuries was the chief centre of artistic enamelling. In this process the design is traced on a plate of copper or bronze, and all the parts to be enamelled are excavated by the graver, these hollows are then filled with enamel, which is afterwards fused, and the entire surface is finally ground smooth. The design thus appears in permanent colour, each tint being defined by ridges, or separated by areas, of metal which are the clevated parts of the original ground. The exposed metal is sometimes gilt.

Another and probably older method of inlaid enamelling is that known as cloisonné Here the design is outlined by strips of metal fixed to the metallic base, and the spaces between these bands are filled with enamel, which is then fused and the surface ground Each coloured area is, therefore, sharply separated from its neighbour by the edge of the metal fillet Of this character were the early Byzantine enamels, which were generally executed on plates of gold. The Chinese have for many centuries (at least since the 13th) been extremely skilful in this work, and the Japanese have applied a similar method to The Japanese the ornamentation of porcelain attach the cloisons to the base with a gummy cement, and even when the ground is a metal, they generally use no solder In some cloisonné work the surface is not ground down, so that the fillets stand in relief above the general surface of the enamel

The use of transparent enamels for the ornamentation of metalwork was introduced by the Italian goldsmiths of the 13th century, and afterwards became popular in France. The design was generally worked in low relief, or chased on gold or silver, and brilliant translucent enamels were applied in such a way that the varying thickness produced differences of tint. This style is known as basse-taille. In certain rare enamels, probably of the 15th century, the pattern is outlined by strips of metal without any foundation, and the spaces in this grating

are filled in with coloured transparent enamels; such cloisonné work is termed plique-à-jour

Artistic enamelling has been largely used, not only for inlaid and encrusted work, but for the production of paintings on metal. The painted enamels of Limoges, introduced in the 15th century, were usually executed on slightly convex plates of copper, the subjects being generally in white and grey on a deep-violet ground, but the process was extended to the decoration of dishes, ewers, and other objects, and various colours were employed, sometimes heightened with gold In this country, enamel painting was largely practised, by the family of Bone, during the latter part of the 18th and the early years of the following century While their smaller works, or miniatures, were executed on gold, the larger examples were on plates of The copper plate, having been annealed copper and cleaned with dilute sulphuric acid, was coated on both sides with white enamel powder it was then fired, and the enamelled face ground This white enamel, which was rendered so opaque by means of stannic oxide as to conceal the metal ground, was imported from Venice in the form of round cakes. The surface Venice in the form of round cakes to be painted was further prepared by the application of a second coat of cnamel, more fusible and transparent than the first, this material, known to the enameller as 'flux,' was used in the form of rods and beads of white Venetian Upon the fluxed surface, carefully ground smooth, the painting was executed in enamel colours, or powdered glasses mixed with an appropriate vehicle, and as it was necessary to vitrify each colour separately, a complicated subject would require several successive firings in a muffle, each liable to injure or spoil the work

Recent years have witnessed a great revival in artistic enamelling, with the introduction of various improvements in technical details

In addition to art enamels, there is a growing demand for coarse work in enamelled sheet-iron for street plates, railway notices, and other advertisements, which are generally executed in blue and white In applying enamel to metal it is necessary to use a material which will adhere firmly to the base, at the same time, it must fuse at a temperature lower than that which softens the metal, or melts the solder if any be present, and the enamel should have a coefficient of expansion by heat as nearly as possible that of the metal ground It is obviously important that, when enamel is used as a lining for saucepans, stew-pans, and other vessels for culinary purposes, it should be free from all ingredients which are poisonous, or may become so by contact with food An important industry has been developed in recent years, especially in Germany, Austria-Hungary, and France, in the manufacture of vessels for domestic use, in cast or sheet metal, soft sheet steel is commonly used for hollow ware

The object to be enamelled, having been carefully cleaned by picking in an acid bath, is coated with a thin layer of ground enamel. This primary coating need not be opaque, and generally contains a little cobalt or nickel oxide. A suitable material is obtained, according to P. Randau, by fusing a mixture of finit or quartz 30 parts, borax 25, and felspar 30 This product is then ground with kaolin 10 75 parts, felspar 6,

634 ENAMELS.

and magnesia, 1.25; the clay tends to lessen the fusibility. The finely powdered ground enamel 18 mixed with water to a creamy consistency and applied to the ware, slightly heated, after the coating has dried, the object is fired in a muffle furnace at a temperature rather under 1000°. After this stage of enamelling, the ware is scrubbed to remove scale, and a second coating is applied, this time opaque white enamel may be made, according to the same authority, from a mixture of flint 375 parts, borax 275, tin dioxide 30, soda 15, nitie 10, ammonium carbonate 75, and magnesia 7, this mixture is fritted and then ground with flint 6 12 parts, tin dioxide 3 66, soda 0 7, and magnesia 0 7. The cover enamel is suspended in water and spread over the ground enamel, and the ware is then carefully fired in a muffle at a lower temperature than that of the first firing In some cases a third coat of enamel is applied, while in other cases the ground layer is dispensed with, and only a single white coating Finally the surface may be decorated by painting or transfer printing in enamel colours, or by photographs In some enamels, like granite ware. the colour is applied by spraying

(On enamels, v Sir H H Cunynghame, On the Theory and Practice of Art Enamelling upon Metals, 3rd ed London, 1906, Lewis F Day, Enamelling, London, 1907, Alexander Fisher, The Art of Enamelling upon Metal, London, 1906; Philip Eyer, Die Eisenemaillierung, Leipsig, 1907, Paul Randau, Die Fabrikation des Emails und das Emailheren, Vienna, 4th ed 1909, Enamels and Enamelling, English translation of P Randau by Charles Salter, London, 1900; Julius Grunwald, translated by Herbert H Hodgson, The Theory and Practice of Enamelling  $\mathbf{F} \mathbf{W} \mathbf{R}$ on fron and Steel, London, 1909)

ENARGITE. Copper sulphaisenate Cu<sub>3</sub>AsS<sub>4</sub> or 3Cu<sub>2</sub>S As<sub>2</sub>S<sub>5</sub>, occurring as orthorhombic crystals with perfect prismatic cleavages and usually a prismatic habit The colour is ironblack with a metallic lustre, sp gr 4 44 It is not a common mineral, but in a few coppermining districts, for example, at Butte in Montana, Morococha in Peru, and in the Sieria de Famatina in Argentina, it is of some importance as an ore of copper

ENDIVE. Cichorum endima (Linn), the blanched leaves are used as a salad or garnish

According to Konig, their average composition is-

ENSILAGE is a process of preserving green fodder for cattle The term silo is applied to the pit or other depository in which the fodder (silage) is contained, and appears to be of Basque derivation, and originally meant a pit for storing This method of preserving grass and other succulent forage crops has been in use for many years in Germany, whence the practice was carried to France, and afterwards to America. Although the German system had been fully described by Johnston, in 1843, in the Transaction of the Highland Agricultural Society (new series, 9), no general notice of it was taken in these islands until 1882, when a report of the British Legation at Washington on ensilage, as practised on Mr Havemever's estate in New Jersey, was published as a blue-book, since which time many silos, of varying forms and construction, have been made in this country The object of all these is to exclude the air from the mass of fodder, allowing only a greater or less fermentation according to the practice of different authorities, and to this end silos have been formed (1) wholly or partly underground, (2) in the form of enclosed buildings. Silage has also been largely made by building up the green fodder in the form of an ordinary stack, of which only the top is covered Whether it be silo or stack, the principal factor is the superposition of a sufficient pressure, either by dead weight or by some mechanical system of screws, levers, or similar appliances The changes which forage undergoes in the silo are due to fermentation, and, as may be supposed, this action varies considerably with the materials stored and with the condition of storage, as, for example, green maize undergoes puncipally lactic fermentation, whilst in English fodder fermentation produces alcohol which is almost immediately converted into aldehyde If the air has not been properly expelled from the silo, or if the fodder has been pitted in a very damp condition, the aldehyde becomes quicky converted into acetic acid

Silage is of two kinds-viz. 'sweet' and 'sour.' Sweet silage is the result of allowing the grass to remain without pressure, and so permitting air to mingle with it until such time as a temperature of 125° to 150° F. is reached by the fermentation process, sour silage, on the other hand, results when pressure is at once applied, whereupon an acetic or lactic fermentation takes place It appears that a temperature of about 125° is sufficient to kill the bacteria which produce acid fermentation; 'if the bacteria are killed and the silo is covered and weighted, the enclosed mass of green fodder will remain sweet, and be practically preserved under the same conditions as fruits, vegetables, or meats are preserved when canned be the case, it will be at once intelligible that by less packing of the fodder when put into the silo, and extending the time of filling until the temperature rises to a point fatal to the bacteria, the resulting silage will be sweet and free from

acidity; whilst sour silage is produced by at once consolidating, covering up, and weighting the grass fodder so as to prevent the temperature rising to the point fatal to the bacteria (A Voelcker, J Roy Agric Soc 20).

Two samples of sweet silage showed only a trace of acid, not exceeding in quantity that contained in ordinary fresh meadow grass —

The subject of changes during ensilage has been very carefully investigated both at Rotham sted by Lawes and Gilbert, and at Woburn by Voelcker The results obtained present a striking similarity, and it will suffice if one set of tables (those of Dr Voelcker) is referred to here, although the Experiments on Ensilage conducted at Rothamsted (Lawes and Gilbert) should also The sile to which these figures relate was one made at Woburn in 1886, and was of the character generally termed 'sour' It was weighted with stones in strong clm boxes to 112 lbs per square foot, and was unprovided with any drain The silo was closed on July 3 and opened on December 16, the contents being very fair,' although 'not really fine,' meadow grass The numbers, in a condensed form, are given in the following table

QUALITY AND COMPOSITION OF THE GRASS PUT INTO SILO, AND OF THE SILAGE PRODUCED

	Total weight	Water	Volatile acids	Non-volatile acids	Soluble albuminoids	Insoluble	Digestible fibre	Woody fibre	Soluble carbo- hy drates, &c	Soluble mineral matter	In-oluble mmeral matter	Total nıtrogen	Albuminoid	Non-albuminoid nitrogen
Grass put in silo Silage removed Loss Loss per 100 lbs of fresh grass	Ibq 32,780 30, *89 2,391 7 29	lbs 23,108 22,035 1,073 3 27	109 +109 +0 33		lbs 47 197 +150 +0 46	lbs 733 252 481 1 47	lbs 3278 2326 952 2 90	lbs 2670 2409 261 0 79	lbs 2265 2254 11 0 03	1b4 430 471 + 11 +0 12	lbs 249 230 19 0 06	lbs 151 155 +4 +0 01	lbs 123 73 50 0 15	lbs 28 82 + 54 +0 16

The main features shown in the table are as follows. The total loss due to formentation, evaporation, &c, in making the silage was 7.29 pc on the fresh grass. Of this, 3\{\} pc consisted of water, so that the loss in dry matter was only about 4 p.c. The loss of total introgen when, as here, no drainage was allowed to flow away, is very slight; but the introgenous bodies have undergone considerable change from the albu-

minoid to the non-albuminoid condition, the fibre has been diminished, insoluble albuminoids have been lessened, and soluble albuminoids increased (Voelcker, J. Roy. Agric. Soc 23, 410)

Since the nutritive value of food depends to a considerable extent on the albuminoid compounds contained in it, it becomes of importance from the economic point of view, to determine the quantity of such compounds in fresh green 636 ENSILAGE

food and in silage Kinch found that 55 p c of the total nitrogen present in the silage of grass was of a non-albuminoid nature, whilst in the original grass only 9 p c was of this form. In the case of mangold leaves, Kellner found that of the total nitrogen present, 27 8 p c. in the original leaves, 45 5 p c in the silage, and as much as 59 7 p c in silage preserved in stoppered jars, was non-albuminoid. Chifford Richardson, examining maize silage, found

Original stalks
Silage No 1
, No 2
Dried fodder
. Per cent total introgen as non-albuminoid
. 21 2
. 44 6
. 44 6
. 15 6

Silage from young maize . 53 3 , , , older , . 47 1

These results with grass, mangolds, and maize show that in ensilage a large portion of the albuminoids is converted into non-albuminoid introgenous substances, whilst in the ordinary drying of fodder no such change seems to take place. This is made clear by a reference to Dr. Voelcker's table given above under the heading 'Quality and composition,' &c, where the woody fibre, as indeed the whole of the fibre, has been diminished, insoluble albuminoids are lessened, and the soluble albuminoids increased

Ensilage is largely practised in Canada and in America for the sake of having a supply of green' fodder during the winter months, especially in Canada where the winter is long In England, since the interest attaching to novelty has waned, it has gradually died out of practice, except as a resource for adoption in unusually wet seasons, when haymaking is impossible or is so long delayed as to threaten loss of the crops In such circumstances those who possess the simple tackle necessary for putting up silage stacks in the open field have a material advantage over their neighbours Otherwise, in a country in which roots are easily grown and preserved for winter use, and where the actual period of the year in which vegetation is suspended is comparatively short, it would seem pieferable, having regard to the deterioration which occurs in ensilage, especially as regards albuminoids, to adhere to the more ordinary practice of hay-making

.The application of silage as fodder and its practical effects with stock have been carefully investigated both at Rothamsted and Woburn

(See Report on the Practice of Ensilage at Home and Abroad, Jenkins in J. Roy. Agric. Soc., new series, 20., On the Chemistry of Ensilage, Voelcker, ibid., Experiments on Ensilage conducted at Crawley Mill Farm, Woburn, 1884-5 and 1885-6, Voelcker, ibid. 22., Experiments on Ensilage conducted at Crawley Mill Farm, Woburn, 1886-7, Voelcker, ibid. 23., articles in the Agricultural Gazette, April. 27, 1855 et. seq., by Sir. J. B. Lawes and Sir. Henry. Gilbert, reprinted in pamphlet form under the title of Experiments on Ensilage conducted at Rothamsted.)

ENSTATITE. Metasilicate of magnesium, usually with some ferrous oxide isomorphously replacing magnesia, (Mg, Fe)SiO<sub>3</sub>, and with increasing iron passing into bronzite and hypersthene lt belongs to the orthorhombic

series of the pyroxene group, and is of importance as a rock-forming mineral and as a constituent of meteoric stones. Rarely it is clear and transparent and of a rich green colour, when it is used as a gem-stone, such material is found in the 'blue ground' of the South African diamond mines.

EPHEDRINE, C<sub>10</sub>H<sub>15</sub>ON, crystals, m p 39°, b.p 225°, occurs in Ephedra vulgaris. It is a secondary base, furnishes crystalline salts, and on 'exhaustive methylation' yields eventually trimethylamine and a-phenylallyl alcohol  $({}^{\circ}_{9}H_{10}O)$ . On distillation the hydrochloride furnishes methylamine and propiophenone When heated with hydrochloric acid, ephedrine undergoes with hydrochloric acid, ephedrine undergoes isomerisation to  $\psi$ -ephedrine (isoephedrine), crystals, in p 117°, which also occurs with it in E vulgaris. Both bases are poisonous and ephedrine hydrochloride has been used as a mydratic (Ngai, Chem Zentr 1894, 1 470, Merck's Bericht, 1893, 13; Ladenburg and Oelschlagel, Ber 1889, 22, 1823; Miller, Arch Pharm 1902, 240, 481; Flaecher, ibid 1904, 242, 380, Schmidt and collaborators, ibid 1905, 243, 73, 1906, 244, 239, 241, 269; 1908, 246, 210, 1909, 247, 141, 1911, 249, 305. 246, 210, 1909, 247, 141, 1911, 249, 305, 1913, 251, 320, Apoth Zeit 1911, No 37; Fourneau, J. Pharm. Chim. 1904, [v1.] 20, 481, Emde, Arch Pharm 1907, 245, 662, Gadamer, ibid 1908, 246, 566; Calliess, Apoth Zeit 1910, 25, 677) According to Rabe (Ber 1911, 44, 824) the ammonium base of ephedrine decomposes into water, trimethylamine and  $\alpha$ -phenylpropylene-  $\alpha\beta$ -oxide, and he regards ephedrine and  $\psi$ -ephedrine as optically isomeric β-methylamino-a-OH CHPh CHMe NHMo phenyl-propane-a-ols (cf Emde, lc.) This view is shared by Schmidt (Arch Pharm 1914, 252, 89, 1915, 253, 52), (cf Emde,  $\bar{l}$  c.) who considers the isomerism due to the difference in the spatial arrangement of the —CHOH group Uf also Eberhard (Arch Pharm 1915, 253, 62). a-Ephedrine has been synthesised by Nagai (Eng Pat 120936) and shown to differ from Fourneau's products and to be the racemic form of the natural variety (see Chem Soc Abst 1919,

The name ephedrine has also been applied by Spehr to a crystalline alkaloid C<sub>13</sub>H<sub>19</sub>ON, m p 112°, obtained from Ephedra monostachya, a drug used as a remedy for syphilis and gout in Bessarabia and Wallachia Ordinary ephedrine is known commercially as 'ephedrine (Merck)' and the second species as 'ephedrine (Spehr)'

EPSOM SALTS. Magnesium sulphate (v. MAGNESIUM

EPSOMITE or Epsom Salts, MgSO<sub>4</sub>.7H<sub>2</sub>O<sub>5</sub> as a mineral usually occurs as silky white fibres forming efflorescences in limestone caves, mine galleries, &c ('rystals are orthorhombic with spheroidal hemihedrism and a prismatic habit, the prism angle being nearly a right angle (89° 26') Although good crystals are readily obtained by artificial means, in nature they are of rare occurrence They have, however, been found in the salt deposits at Stassfurt in Prussia; where also a massive variety ('reichardtite') forms thin layers in carnallite. This epsomite forms thin layers in carnallite is no doubt derived by the hydration of the more abundant kieserite, MgSO<sub>4</sub>,H<sub>2</sub>O Albany Co, Wyoming, and on the border of British Columbia and Washington, there are several small lakes containing fich deposits of compact white epsomite—At Epsom in Surrey, from which place the name is derived, the salt occurs only in solution in mineral waters

LJS

ERBIUM or Neo-Erbium Sym Er At wt 167 7 A dark-grey powder, sp gr 4 77 at 15° (S Meyer, Monatsh 1899, 20, 793)

Sources - Ytterbite (gadolinite), yttrotant-

alite, euxenite, venotime

The oxide of this metal belongs to the group of yttrium earths, forming with dysprosium and thulium the erbium sub-group, the salts of which are distinguished by their colour and by their characteristic absorption spectra in solution

Separation and purification of the yttrum earths. The following methods have been employed in separating the closely related

members of the yttrium earths

1 Fractional decomposition of nitrates (Bahr and Bunsen, Annalen, 1866, 137, 1) nitrates, heated until nitrous fumes are evolved, leave a vitieous residue of basic mitrates, the solutions of which, in hot water, slowly deposit, on cooling, small pink needles containing the greater proportion of the coloured erbium earths. The crystals are extracted with 3 p.c. intric acid, the solution evaporated, the residue again heated, and the whole series of operations repeated many times. The erbium earths accumulate in the less soluble basic salts, whilst the remaining yttiium earths, and any cerum earths which may be present, accumulate in the final mother liquors, and are not readily freed completely from the erbium earths Further separation is effected by heating these , nitrates from the final mother liquors so strongly that the residue consists of oxides mixed with insoluble basic nitrates. On extraction with water, the erbium compounds remain undissolved, and the operation is repeated till the more soluble yttrium salts no longer show absorption bands

According to Wichers, Hopkins and Balke (J Amer. Chem Soc 1918, 40, 1615) the nitrate fusion method is very efficient for separating erbium and yttrium and is much better than any of the later methods, although the cobalticyamde and the nitiite precipitation methods (v supra) are both good, the latter being the more practicable and efficient

2 Differences in the solubility of the oxides. -The oxides are mixed with water and treated

with an amount of nitric acid insufficient to convert the oxides into normal nitrates The mixture becomes hot, and, after cooling, concentrated nitric acid is added until the product assumes a reddish tint. The precipitate is then digested with alcohol, which dissolves the normal nitrate, to the exclusion of the basic nitrates The latter consists chiefly of erbium salts mixed with some ytterbium and scandium compounds, the more basic yttiium and cerite metals passing into solution The final separation of erbium from ytterbium and scandium is effected by fractionally precipitating the basic nitrates by adding oxides to the solution of normal nitrates In this operation ytterbium and scandium are precipitated as basic nitrates, while cibium remains dissolved (v. Drossbach, Ber. 1902, 35,

3 Fractional precipitation by alkalis or aniline—The addition of ammonia to hot solutions of the salts of the yttnum group occasions the precipitation of basic salts which

are easily filtered

The neutral chloride dissolved in 50 p.c. alcohol is decomposed at 90° with alcoholic aniline, or the hydroxide is treated with aniline hydrochloride in aqueous solution (Prossbach, Ber 1896, 29, 2452, Mullmann and Baur, *ibid* 1900, 33, 1748; 1902, 35, 2382, Urbam, Comptrend 1901, 132, 136, Kruss, Annalen, 1891, 265, 1; Zertsch anorg ('hem 1893, 3, 108, 353, 407).

4 Fractionation with ammonium carbonate and acetic acid —The hydroxides of the yttrium group are moderately soluble in concentrated aqueous ammonium carbonate, and from this solution the earths may be fractionally precipitated by acetic acid (Dennis and Dales, J Amer Chem Soc 1902, 24, 400)

5 Fractionation of oxalates, acetales, acetylacctonates, ethylsulphates (Urbain, Ann Chim. Phys 1900, [7] 19, 184, Maic, Ber 1902, 35, 2370), formates (K A Hofmann, ibid 1908, 41, 308), ferrocyanides (Bohm, Die Darstellung der seltenen Eiden), bromates (James, J Amei Chem Soc 1908, 30, 182), chromates (Kruss and Zoose, Zeitsch anoig Chem 1893,

Various methods of separation of erbium from yttrium have been examined by Willand and James (J. Amer. Chem. Soc. 1916, 38, 1198), who find that fractional precipitation with (1) sodium nitrite, (2) with potassium cobalticyanide from a hydrochloric acid solution, (3) with sodium phosphate from a dilute nitric acid solution of the oxides on the whole yield the best results. In all three methods the last fraction was obtained by the addition of oxalic acid to the final liquois

Erbia (erbium ouide) Er<sub>2</sub>O<sub>3</sub> A pink powder obtained by heating the oxalate at 575°-845°; sp gr. 864, sp ht 0065 So prepared is apt to retain carbon dioxide

The salts of erbium have a pink or reddish colour, a sweet, astringent taste, and their solutions exhibit characteristic absorption bands in the red, green, and blue regions of the spectrum The wave lengths corresponding with the two most prominent bands are as follows: λ 522 5-523 5 and 647 5-651 5

Unless ionic dissociation is repressed, dilute solutions of the various orbium salts exhibit

dentical absorption spectra (Zeitsch. physikal. hem 1906, 56, 624; v Purvis, Proc Camb.
Phil Soc. 1903, 12, 202, 206) The absorption ands undergo displacement when the solutions re placed in a magnetic field (J Becquerel, lompt rend. 1907, 145, 1412)

(For accounts of the flame, spark, and arc mission spectra, v Thalen, ibid 1880, 91, 326, Exner and Haschek, Wien Akad Ber 1899, 108, Ia, 1071, 1123, Eder, Chem Zentr 1916, 1 242; ibid ii 455) According to Eder erbium is

robably complex.

Erbium salts exhibit signs of radio-activity

Strong, Amer Chem J. 1909, 42, 147). **Erbium sulphate** E<sub>12</sub>(SO<sub>4</sub>)<sub>3</sub>,8H<sub>2</sub>O nonoclinic crystals, separating from aqueous olution at  $20^{\circ}-25^{\circ}$ , isomorphous with the orresponding yttrium, praseodymium, and leodymium salts (Kraus, Zeitsch Cryst 1901, 4, 307)

The double sulphates Er<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>, K<sub>2</sub>SO<sub>4</sub>, 4H<sub>2</sub>O and  $\text{Er}_{2}(SO_{4})_{3}(NH_{4})_{3}SO_{4}H_{2}O_{4}$  are readily

oluble in cold water

 $\text{Et}(\text{NO}_3)_3,5\text{H}_2\text{O}$ Erbium nitrate Large eddish crystals stable in air. When heated on platinum wire, the nitrate imparts an intense reenish colour to the flame, which, when viewed hrough the spectroscope, shows bright lines in he yellow-green and orange-blue regions of the pectrum. These bright lines correspond in position with the dark bands of the absorption pectrum.

Erbium formate E<sub>1</sub>(CHO<sub>2</sub>)<sub>3</sub>,2H<sub>2</sub>O Crystal-

ises from cold aqueous solution

Erbium oxalate Er<sub>2</sub>(C<sub>2</sub>O<sub>4</sub>)<sub>3</sub>,10H<sub>2</sub>O (K A fofmann, Ber 1910, 43, 2631) is a reddish, paringly soluble microcrystalline powder

Erbium platinocyanide E12[Pt(CN)4]3,21H2O, ike the corresponding yttiium salt, crystallises n red prisms with a green metallic reflex other salts, see Morgan and James, J Amer them Soc 1914, 36, 10, Katz and James, ibid G T M 913, 35, 872

ERECTHIDIS OIL consists of a terpene 110 II 16, which boils at 175°, and at 185° has a p gr of 0 838 This body absorbs a molecule of ydrochloric acid without the separation of a rystalline compound. The portion of the oil thich boils above 200° also consists of a terpene Beilstein and Wiegand, Beil 15, 2854)

EREPSIN v Enzymes, art FERMENTATION

ERGAMINE, ERGOSTEROL, ERGATHI-NEINE, ERGOTIN, ERGOTININE, ERGO-'OXINE v ERGOT

ERGOT OF RYE. Spurred 14e, Ergota, 3 P , USP Secale cornutum (Ergot de seigle, er; Mutterkorn, Ger) Ergot of 1ye consists f the dried sclerotium (resting stage) of the ungus Claviceps purpurca (Tulasne) developed rom the ovary of the ryo (Secale cereale) The rains are dark violet-black, 1-4 centimetres ong, slightly curved and tapering at both ends The same or a closely related fungus occurs on number of other grasses, wild and cultivated, ind on some Cyperaceae The first definite nention of ergot which the writer has been able o trace, is in the 1582 edition of Adam Lonicer's Kreuterbuch, cap ccclxx. p 285, where its ise by midwives is also referred to From an ccount by the medical faculty of Marburg, sublished in 1597, down to the middle of the

19th century, there is a voluminous literature in German and in French, on ergotism, there seems little doubt, however, that the epidemic ignis sacer of the Middle Ages was also due to the presence of ergot in flour (cf Ehlers, L'ergotisme, Paris, 1896) Only one outbreak of ergotism in England (due to wheat) has been described (Phil Trans Roy Soc 1762, 52, 530) The use of eigot by midwives was forbidden in several countries about 1770-1780, but in the second decade of the last century it was definitely introduced into scientific medicine by the American physicians Prescott and Stearns, and now ergot is only important as a drug, being chiefly employed as a stimulant of uterine muscle In the United States ergot growing on wild grasses (especially on species of Elipmus, cf. also Amberg, Schweiz Woch Chem Pharm 1911, 49, 489), has occasionally given rise to extensive poisoning of horses and cattle Further botanical and historical details are given by Fluckiger and Hanbury, p. 740. Cooke, Brit Fungi, 772, Pharm J [m ] 1, 702, Paisons, Rep US Commissioner Agriculture, 1880, 136, Holmes, Pharm J 1886, [m ] 16, 684; Kobert, Historische Studien, Halle, 1889, Carruthers, Rep. Roy. Ague. Soc. 1874, [n.] 10, 443 (with illustrations of eigot on other grasses)

The chief commercial varieties of ergot of rye come from Russia and from Spain eigot with large grains, is probably of no special value, because several writers agree that the larger grams have a smaller percentage of alkaloid than the smaller ones Although they are not official, other eigots, growing on wild grasses, deserve attention as a source of alkaloid Ey that on Mondia cardea has been found to contain as much as 0.81 p.c. Festuca ergot contains 0.34 p.c. (Pharm J. 1913, 130). Perhaps 'Diss' ergot on Ampelodesmos tenar (Link), occurring along the coast of Algeria, might thus be utilised (if Germaix et Chassang, Rev. méd et phaim de l'Afrique du Nord, Alger, 1898, 1, 45, 78, 113, 146, 184, also Holmes, Pharm J 1886, [m ] 16, 684) Diss ergot has better keeping properties than eigot of rye, about which the Brussels Conference agreed that it should not be more than one year old and should be preserved entire. The rapid deterioration of eigot seems to be due to oxidation, which is favoured by the presence of the oil. Hence removal of the latter by light petroleum has been recommended Aymonier (J Pharm Chim 1897, [vi] 6, 359) suggests coating the ergot with a dilute ethereal solution of tolu balsam

The literature on the chemistry of ergot is as voluminous as that on ergotism first investigation is recorded by J G Model in his Chymische Nebenstunden (Wittenberg, 1771), seven years after von Munchhausen had first recognised the drug as a fungus Among older writers we need, however, only mention here Tanret (Compt rend 1875, 81, 896), who first obtained the crystalline alkaloid ergotinine, and Buchheim (Aich. exp. Path Pharm 1874, 3, 1) who, albeit without experimental evidence, expressed the view that the activity of ergot is due to decomposition products of protein. The active principles of ergot have only been obtained pure in recent years. They are a complex alkaloid and some simpler bases

Ergotoxine  $\mathrm{C}_{35}\mathrm{H}_{41}\mathrm{O}_6\mathrm{N}_8$ , mp 162°-164°, an amorphous alkaloid yielding crystalline salts, of which the phosphate  $\mathrm{C}_{35}\mathrm{H}_{41}\mathrm{O}_6\mathrm{N}_5$ ,  $\mathrm{H}_3\mathrm{PO}_4\mathrm{H}_2\mathrm{O}$ , m.p. 187°-188°, is the most readily obtainable (Barger and Carr, Chem. News, 1906, 94, 89, Trans Chem. Soc. 1907, 91, 337, Barger and Ewins, ibid 1910, 97, 284; 1918, 113, 235). This alkaloid had been obtained in an impure form as 'amorphous ergotimne' by Tanret, and was termed hydroergotimne by Kraft (Arch. Pharm 1906, 244, 336, 1907, 245, 644), who, without analyses, first recognised it as a hydrate of Tanret's ergotimne

The alkaloids of ergot are best obtained on a small scale by extracting the powdered drug with ether and shaking the ethereal solution with a weak acid (citie, tartaric) Excess of strongly ionised mineral acids precipitates the salts of the ergot alkaloids, which, on account of their high molecular weight, are semi-colloids. This property led many of the earlier investigators into error, but may be put to account when working on the large scale. The residue left on evaporation of an alcoholic tincture of ergot is extracted with light petroleum, to remove the fat. It is then dissolved in ethyl acetate and shaken with citric acid, sodium bromide solution then precipitates the mixed hydrobromides almost quantitatively. The latter are dissolved in dilute caustic soda, from which ether removes only ergotinine The caustic soda solution is then neutralised, made alkaline with sodium carbonate and extracted again with ether The crude ergotoxine left on evaporation, together with that from the mother liquois of the crystallisation of ergotinine (see below), is dissolved in 80 p.c. alcohol and a slight excess of syrupy phosphoric acid in alcohol is added On standing for a few days the ergotoxine phosphate crystallises in thin needles, which on recrystallisation from 50 parts of 90 pc alcohol may be transformed into broad plates They are soluble in 313 parts of cold and 14 parts of boiling 90 p c alcohol By shaking with cold distilled water a 1 pc solution is obtainable, which is strongly opalescent and sets to a thick jelly on the addition of electrolytes. For physiological experiments ergotoxine is best dissolved in dilute sodium hydroxide

Ergotinine, although not physiologically active, may be considered here. The alkaloid left on evaporation of its ethereal solution (above) readily crystallises from absolute alcohol in needles, mp  $229^{\circ}$  (corr.), and having the composition  $C_{3b}H_{39}O_5N_5$ . It is extremely soluble in cold chloroform, and dissolves in 292 parts of absolute alcohol at  $18^{\circ}$ , in alcohol  $[\alpha]_D = +338^{\circ}$ ; the solutions are strongly fluorescent. Prolonged boiling with alcohol lowers the rotation and produces an amorphous decomposition product. Heating in alcoholic solution with slightly more than one equivalent of (phosphoric) acid transforms ergotinine into ergotoxine phosphate which may be crystallised. The same change takes place slowly in cold dilute acetic acid. Conversely ergotoxine is dehydrated to ergotinine by boiling with methyl alcohol or by warming with acetic anhydride.

Both alkaloids give the following colour

reaction (Tanret). A solution of 1 mg. of the alkaloid in ether or in ethyl acetate is allowed to evaporate on the surface of concentrated sulphuric acid (containing oxides of nitrogen). A transitory orange colour is developed changing to violet-blue Keller (Schweiz Woch Chem. Pharm. 1894, 32, 121) has improved this by dissolving 2-3 mg of the solid alkaloid in sulphuric acid on a watch glass and stirring in a trace of anhydrous ferric chloride, when an orange colour is produced, changing to deep red and then becoming blue or green at the edges Alternatively the solution of the alkaloid in glacial acetic acid may be poured on sulphuric acid, without mixing The test yields a positive result with the crude alkaloid from I gram of ergot

Both alkaloids are sensitive to general alkaloidal precipitants, potassium mercuric iodide giving a faint opalescence with 1 part of alkaloid in 1-2 millions of water. On dry distillation both alkaloids yield a crystalline sublimate in isobutyryl formamide CH(CH<sub>3</sub>)<sub>2</sub>CO CO NH<sub>2</sub> (Barger and Ewins, Ic) Ergotoxine probably contains a carboxyl group and ergotinine is the corresponding lactone. Both contain one N-methyl group, but no O-methyl group (Barger and Ewins, Chem. Soc. Trans. 1918, 113, 235). Ergotimine does not yield any crystalline salts.

The total alkaloids of ergot (i.e. ergotoxino +ergotinine) may be estimated by exhausting the finely powdered drug with light petroleum, mixing it with magnesia, extracting with ether and shaking the ether with dilute acid. After making alkaline with ammonia the alkaloids are again shaken into other, and estimated gravimetrically (Keller, l.e.). For details and results of analysis, sie Allen's Comm. Organic Analysis, 1913, vol. vi. p. 21. The alkaloidal content varies roughly from 0.1 to 0.4 p.c., and in Russian and Spanish ergot is generally between 0.2 and 0.3 p.c. Konig (Apot Zeitsch 1912, 27, 879) found 10 samples of German ergot to contain 0.032-0.14 p.c. An approximate idea of the ergotoxine content may be obtained by physiological means (Barger and Dale, Bio-Chem. J. 1907, 2, 240)

In addition to a specific alkaloid, the active principles of ergot comprise a number of simpler bases, derived from the amino-acids of protein by loss of carbon dioxide. Of these \$\beta\$-iminazo-lylethylamine (from histidine) and \$p\$-hydroxy-phenylethylamine (from tyrosine) are therapeutically the most important. They can be prepared synthetically and are also formed by putrefaction. Their physiological action has been much studied of late and they have been applied practically.

Histamine (β-iminazolylethylamine 'β-1,' 4-β-aminoethylglyoxaline, ergamine)

$$\begin{array}{c} \text{CH=N} \\ | \\ \text{NH\cdotCH} \end{array} \hspace{-0.5cm} \text{CCH}_2 \hspace{0.5cm} \text{CH}_2 \hspace{0.5cm} \text{NH}_2$$

was obtained first synthetically by Windaus and Vogt (Ber 1907, 70, 3691) and then by Ackermann (Zeitsch. physiol. Chem. 1910, 65, 504) by the putrefaction of histidine Its intense physiological activity was not recognised until it was isolated from a commercial dialysed ergot preparation (Barger and Daie, Chem. Soc. Trans.

1910, 97, 2592). Kutscher (Zentralb Physiol 1910, 24, 163) isolated it simultaneously from ergot, but did not correctly identify it substance is certainly present in eigot as such, but its amount may be increased by such processes as prolonged extraction and dialysis. The base can be obtained directly from histidine by putrefaction (D R. PP 2528724, 256116, Hoffmann, La Roche & Co, D. R P 250110, F. Bayer & Co; the yield is inconstant but may reach 60 pc or more) It may also be made from histidine by heating with acids (Ewins and Pyman, Trans Chem Soc 1911, 99, 339, yield 25 p.c ) It is best obtained by reduction of the nitrile of iminazolylpropionic acid (Pyman, Trans Chem Soc. 1911, 99, 668), which nitrile in its turn is obtained most conveniently from histidine by the action of chloramine-T (Dakin, Biochem J 1916, 10, 322), although it may also be synthesised, according to Pyman (lc; cf also Koessler and Hanke, J Amer ('hem Soc 1918, 40, 1706) The most important salts are the *phosphate* C<sub>5</sub>H<sub>9</sub>N<sub>3</sub> 2H<sub>3</sub>PO<sub>4</sub> forming large crystals, and the dipicrate

### $C_5H_9N_3(C_6H_3O_7N_3)_9$

yellow rhombic leaflets, mp  $238^{\circ}-242^{\circ}$  (corr) The free base is readily soluble in water, its solutions give Pauly's histoline reaction with sodium p-diazobenzene sulphonate; a very distinct rose-pink colouration is still obtainable at  $1\ 10,000$ 

**Tyramine** (p-Hydroxyphenylethylamine) OH C<sub>8</sub>H<sub>4</sub> ('H<sub>2</sub> ('H<sub>2</sub>NH<sub>2</sub> is similarly derived from tyrosine by loss of carbon dioxide. On a small scale it can be obtained by heating tyrosine to 260°-270° under reduced pressure (Schmitt and Nasse, Annalen, 1865, 133, 211, Ehrlich and Pistschimuka, Ber 1912, 45, 1006, thus obtained a 50 pc yield) On a larger scale it is best got by reduction of p-hydroxybenzylcyanide according to Barger (Trans Chem Soc 1909, 95, 1123), who first isolated It also occurs as a product of it from ergot putrefaction (Barger and Walpole, J. Physiol 1909, 38, 343). The free base melts at 161° and boils at 175°-180° and 8 mm. It dissolves in 95 parts of water at 15° and can be extracted from aqueous solutions by shaking many times with ether, more readily by amyl alcohol gives Millon's reaction, the most characteristic derivative is the dibenzoyl compound C<sub>22</sub>H<sub>19</sub>O<sub>3</sub>N, m p 170°

### Acetylcholine

#### OH(CH<sub>3</sub>)<sub>3</sub>N CH<sub>2</sub> CH<sub>2</sub>O OC CH<sub>3</sub>

occurs in ergot and ergot extracts in varying small amounts. It was isolated by Ewins (Biochem J 1914, 8, 44) from a BP liquid extract. It is hydrolysed almost at once by rendering its solution alkaline with caustic soda.

Physiological action of the active principles— Ergotinine is inert, but ergotoxine causes, on intravenous or intramuscular injection, a prolonged rise of blood pressure and contraction of the pregnant uterus. Repeated administration leads to dry gangrene, eg of the cock's comb, which is coloured purplish black by small doses, a reaction used at one time for the testing of ergot preparations (for criticism v. Cronyn and Henderson, J Pharm exp. Therap 1909 1, 231). Ergotoxine is the poisonous principle Vol. II.—T.

responsible for epidemic ergotism (Kobert attributed the two types of this disease to the alkaloid cornutine and the resin sphacelinic acid, but both these substances seem to have been ergotoxine in an impure or modified form: cf Barger and Dale, Blochem. J., 1907, 2, 240). \$\beta\$-Immazolylethylamine is one of the most potent of drugs, causing marked contraction of the isolated guinea-pig's uterus in a bath containing 1 25,000,000 p-Hydroxyphenylethylamine resembles adrenaline in action, as in structure, but is much less potent; it causes a rather transitory rise of blood pressure Acetylcholine is not a therapeutically desirable constituent It has a muscarine-like action, inhibiting the heart, and stimulates intestinal muscle (Hunt and Taveau, Hygienic Bulletin, Washington, No 73, 1911) In most ergot pieparations the amount is negligible For a detailed account of the last three and most of the following bases, see Barger, the Simpler Natural Bases, Long. mans, 1914

In addition to  $\beta$ -immazolylethylamine, phydroxyphenylethylamine and acetylcholine, there have been found in ergot quite a number of other sulstances of bio-chemical interest, which are not peculiar to the drug. They are which are not peculiar to the drug mert, or have only a slight physiological action Putrescine and Cadaverine (Rielander, Sitzber. Ges Naturw Marburg, No 7, 1908), isoamyl-Physiol Soc amine (Barger and Dale, Proc May 15, 1909), and agmatine (Engeland and Kutscher, Zentralbl. Physiol 1910, 24, 479) are all amines, derived respectively from ornithine, lysine, leucine and arginine, by decarboxylation Agmatine has an action on the uterus like that of B-immazolylethylamine, but very much feebler It is guanidylbutylamine

# NH, C(NH) NH CH, CH, CH, CH, NH,

and was first discovered in herring roe by Kossel (Zeitsch physiol Chem 1910, 66, 257). A few amino-acids have also been found as such leucine (Buchheim, lc), asparite acid (Bargei and Dale, Biochem J 1907, 2, 240), leucine, isoleucine, valine (van Slyke, J Pharmac exp Therap 1909, 1, 265). A mixture of these was described as an active principle, 'clavin' by Vahlen (Acrh exp Pharm Path 1906, 55, 131). There are further present choline which gives rise to the odour of trimethylamine, when ergot is treated with sodium hydroxide (Brieger, Zeitsch physiol Chem 1887, 11, 184), (for acetylcholine, see above), betaine and uracid (Rielander, lc), vernine C<sub>16</sub>H<sub>20</sub>O<sub>8</sub>N<sub>8</sub>,3H<sub>2</sub>O, which also occurs in leguminous seedlings (Schulze and Bosshard, Zeitsch physiol Chem 1887, 10, 80), lactic acid, mannitol, trehalose, phytosterols and fats (see below)

Inert constituents which so far have not been found elsewhere are secale ammonulphonic acid  $C_{16}H_{24}O_{16}(NH_2)SO_3H$  (Kraft, lc), prisms, mp 200°, soluble in water giving an acid solution; ergothnoneine  $C_9H_{16}O_2N_3S_2H_2O$ , isolated by Tanret (J Pharm Chim. 1909, [vi] 30, 145) in an amount of 0 l pc and shown by Barger and Ewins (Trans Chem Soc 1911, 99, 2336) to be the trimethylbetaine of thiolistidine; secalonic acid  $C_{14}H_{14}O_6$ , a crystalline yellow colouring matter, mp. 244°, present to the extent of about 2 pc (Kraft, lc) This substance is probably the lactone of an hydroxy

acid, and possibly identical with sclerocrystallin Path. Pharm 1877, 6, 174). Another crystalline yellow colouring matter  $C_{15}H_{14}O_{7},H_{1}O_{7},m_{1}O_{1}$ . 350°, after regeneration of a crystalline acetyl derivative, has been described by Freeborn (Pharm. J. 1912, [iv.] 34, 568) The most important colouring matter of ergot, sclererythrin, is not known in a pure condition 18 the cause of the deep purplish red colour of the outer cells of the grain and is valuable for the recognition of ergot in flour, &c. substance is acidic, and apparently present as a salt, for it is not extracted by other until the ergot has been moistened with water containing It is soluble in aqueous alkalis tartaric acid with a red colour. Clavicepsin C18H34O16, m p 198° when anhydrous,  $[\alpha]_D^{20} = +142 27^\circ$ , was extracted from ergot by Marino-Zuco and Pasquero (Gazz chim ital 1910, 41, 368) It is hydrolysed by acids to two molecules of glucose and one of mannitol The oil is quantitatively the most important constituent (mostly 30-33 p.c.) and has been examined by Rathje (Arch Pharm 1908, 246, 692), who found D. = 0.9250,  $n_D = 1.4685$ saponification number 179 3, acid number 11 38, 10dine number 740, Hehner number 96 25, Reichert-Meissl number 0 63 and true acetyl number 27 44 The percentage composition is oleic acid 68, hydroxyoleic acid 22, palmitic acid 5, unsaponifiable matter 0 35, morganic matter 0 2, alkaloid 0 6, and glycerol 7 5

Ergosterol C<sub>27</sub>H<sub>42</sub>O,H<sub>2</sub>O, m p 165°, and fungsterol C<sub>28</sub>H<sub>40</sub>O,H<sub>2</sub>O, m p 144°, have been separated by Tanret (Compt rend 1908, 147, 75). The second at least seems to exist in other

fungi.

The detection of ergot in flour is based on the presence of alkaloids and of sclererythrin, and on the fact that the ergot particles float when the flour is shaken with an alcoholchloroform mixture of density 1 435 After pouring off, alcohol is added, when the ergot sinks and can be examined microscopically For further details, see Allen's Commercial Organic Analysis, vol vii, 1913, p. 23, and Marino-Zuco and Duccini (Gazz. chim. ital. 1914, 44, 437)

For a critical discussion of the ergot preparations of the British Pharmacopæia, see Carr and Dale (Pharm J 1913, [iv.] 37, 130) It should be noted that 'ergotin' is not a pure substance, but a purified soft extract The varying activity of different extracts should be controlled by physiological test

ERGÖTINE v. ERGOT OF RYE. ERGOTININE v ERGOT OF RYE.

ERICA B v PRIMULINE

ERICIN. Trade name for salicylic methoxy-

methyl ester C<sub>6</sub>H<sub>4</sub><0H OCH<sub>2</sub> OCH<sub>3</sub>

ERICOL. Guaracol acetate. ERICOLIN is found in several plants belonging to the order Ericacea, especially in the herb of the marsh wild rosemary, Ledum palustre (Linn) (Rochleder and Schwarz, Annalen, 84, 368), less abundantly in the common heath or ling, Calluna vulgaris (Salisb) (Rochleder, ibid 354), in Rhododendron ferrugineum (Linn ) (Schwarz, ibid. 361), and in the red bearberry, Arctostaphylos Uva-ursi (Spreng) (Kawalier, Sitz. W. 9, 29).

To prepare it from L palustre, the chopped (Dragendorff and Podwyssotzki, Arch. exp. leaves are thrown into boiling water and boiled for several hours. The filtrate obtained after adding basic lead acetate to the liquid is evaporated in a retort to one-third of its bulk Thal's modification of this process (Ber. 16, 1502), the liquid is concentrated in vacuo, the separated lead salt filtered off, and the liquid freed from lead by hydrogen sulphide. The filtrate is then evaporated to a syrup, and the ericolin dissolved out by anhydrous ether alcohol. The substance left on evaporating this solvent is repeatedly dissolved in a mixture of ether and alcohol till it no longer leaves any residue (Rochleder and Schwarz).

On heating the mother liquor obtained in the preparation of arbutin from the leaves of red bearberry with dilute hydrochloric or sulphuric acid, ericolin is deposited as a resinous precipitate, which may be purified by solution in alcohol and precipitation by water (Kawalier)

Rochleder and Schwarz, after deducting 10 6 p.c ash, found erreolin to contain 51.71 p c carbon and 7 19 hydrogen, whence they deduced its formula to be  $C_{34}H_{56}O_{31}$  (51 00 C and 7 00 H).

Thal (lc), after separating an admixed substance (containing 57.5 pc carbor and 7.29 hydrogen), which was insoluble in ether alcohol, from ericolin, assigned to the latter body the formula C<sub>28</sub>H<sub>24</sub>O<sub>3</sub>, but subsequently altered it to C<sub>26</sub>H<sub>30</sub>O<sub>3</sub> to explain the decomposition equations of the substance. Ericolin, as prepared by Thal, is a brown-yellow, odouiless, hygroscopic, bitter substance decomposing even below 100°. It is decomposed by water. By extracting successively with benzene, chloroform, and a mixture of ether and alcohol, different substances go into solution; it appears that the cricolin is thus broken up into a sugar and ericinol With dilute sulphuric acid warmed to 100°, a sugar and a resinous brown yellow viscid mass, hydroericinol, are produced. An analysis of the latter body gave numbers corresponding with the formula  $x(C_6H_{12}O_2)$ , subsequently modified to  $x(C_5H_{10}O_2)$ .

The equations representing these decompositions are as follows :-

$$\begin{array}{c} {\rm C_{28}H_{30}O_3 + 4H_2O = C_8H_{12}O_8 + C_{20}H_{28}O} \\ {\rm Ericolm} & {\rm Ericinol.} \\ {\rm C_{20}H_{26}O + 7H_2O = 2(C_{10}H_{20}O_4)} \\ {\rm Hydroericinol.} \end{array}$$

Power and Tutin, however, could not isolate ericolin by Thal's process, and they found that ericinol was identical with furfural (Chem. Zentr 1907, 1 916)

Thal also isolated ericolin from Calluna vulgaris (Salisb), and recognised it by the smell of ericinol in many Ericacea and Vacciniea.

Kanger extracted ericolin from the leaves of the cowberry (Vaccinium vitis idea) by means of ether alcohol. It was then purified by precipi-tating foreign substances with lead acetate, and removing excess of the latter with sulphuretted hydrogen The substance so obtained was of a resinous nature, completely soluble in ether alcohol, and corresponded with the composition  $C_{16}H_{25}O_{10}$  (Chem. Zeit. 1903, 27, 794). Ericolin is probably not a chemical individual, but consists of a mixture of glucoside-like substances.

Ericolin is poisonous towards many microorganisms, particularly hose belonging to the colon group, but has no action on acid-fast bacilli. Twort (Proc. Roy. Soc. 1909, B. 81, 248) has used it as a medium for the isolation and culture of human tuberculous bacilli from sputum.

ERIGERON CANADENSE is an oil consisting of a terpene boiling at 176°, which, when pure, has sp.gr. 0 850-0 870, and an optical rotation +52°. It is soluble in an equal volume of alcohol, and rapidly resimfies The commercial oil has sp.gr. 0 8549-0 8963, optical rotation, +28° 48′ to 84 20°; and b.p. 172°-178° (Kepler and Pancoast, Amer. J. Pharm. 75, 216).

According to Rabak (Pharm Review, 1905, 23, 81; 1906, 326), the oil obtained from the fresh herb (0 66 p.c.) is of a bright-yellow colour with a peculiar odour like that of caraway. On exposure to air, it deposits crystals, and a brownish resinous mass is formed. The oil from the dried herb (0 26 p.c.) was darker in colour, had a powerful aromatic odour, and gave no crystals when exposed to air. It also differed from the fresh herb oil in sp. gr., optical rotation and other characteristics. In all probability, the terpeneol found in erigeron oil is a decomposition product. The oil absorbs two molecules of h, drochloric acid to form a solid dihydrochloride C<sub>10</sub>H<sub>16</sub>.2HCl, melting at 47°-48° (Beilstein and Wiegand, Ber. 15, 2854, Wallach, Annalen, 227, 292)

ERINOID. See GALALITH

ERIOCOCCUS CORIACEUS. This is a scale insect consisting of a small pinkish white sac occurring in clusters, and which encase the stems of young shoots of the Eucalypti, more especially those on old or burnt stumps. These insects contain a colouring matter which dyes wool mordanted with chromium, aluminium, tin, and iron, brown, light amber, pale orange-brown and sage-green shades respectively. The colours thus obtained are not specially brilliant, and are not fast to alkalis (Gurney, Report of the Australasian Association for the Advancement of Science, 1898).

A. G. P.

ERIOGLAUCINE. The trade name of the dyestuff obtained by condensing benzaldehydeosulphonic acid with ethylbenzylanihnesulphonic acid (J Soc Chem Ind of Basle, Eng Pat 25128; Gnehm and Schule, Annalen, 299, 347)

ERODIAMINE C<sub>10</sub>H<sub>17</sub>ON<sub>3</sub>, light yellow plates, m p 287°, and rutaecarpine C<sub>18</sub>H<sub>17</sub>ON<sub>3</sub>, light yellow needles, m p 258°, occur in the fruit of Erodia rutaecarpa (Asahina and Kashiwati J. Pharm. Soc Japan, 1915, No 405, 1293; Asahina and Mayeda, ibid. 1916, No 416, 871; Amer Chem Soc. Abstr. 1916, 607, 1917, 332).

The annexed constitutional formulæ have been assigned. Perhaps they are not fully established, but they are of considerable interest as showing that the alkaloids are derivatives of

indole; they also show a relationship to harmaline and harmine. On boiling with alcoholic hydrogen chloride erodiamine (I) is converted into isoerodiamine  $C_{19}H_{17}ON_3,H_2O$ , in p 155°–156°, and this is decomposed by alcoholic potash into carbon dioxide, N-methylanthianilic acid and a base  $C_{10}H_{12}N_2$ , in p 120°, which has been identified as  $2-\beta$ -aminoethyl indole. Isoerodiamine is regarded as

$$\begin{array}{c|c} \operatorname{HN} \operatorname{C}_6\operatorname{H}_4\operatorname{CH} : \operatorname{C} \operatorname{CH}_2\operatorname{CH}_2 \operatorname{N} \operatorname{CO} \operatorname{C}_6\operatorname{H}_4\operatorname{N(Me)} \operatorname{CHOH} \\ & & \\ \end{array}$$

Rutaecarpine (II) is similar to erodiamine, but more soluble in alcohol, hot potassium hydroxide in ammonium hydroxide yields anthramlic acid, and an unidentified product, which on fusion with potassium hydroxide, like the base  $C_{10}H_{12}N_2$  from erodiamine, yields 2-indole carboxylic acid G. B.

ERUBESCITE v. BORNITE

ERUCIC ACID C22H42O2 A homologue of acrylic acid obtained, together with oleic acid, by the saponification of the fixed oil of white mustard. It was found together with beheme acid by Goldschmiedt (Sitz W 70, 451) in the oil expressed from black mustard, and by Fitz (Ber 1871, 442) in the fat oil of grape seeds — It is best obtained by saponifying rape oil (from Brassica campestris, Linn ) with alcoholic potash distilling off the alcohol and dissolving the acid liberated on the addition of sulphuric acid in three times its volume of 95 pc alcohol, on cooling to 0°, crystals of erucic acid separate out in an almost pure condition (Reimer and Will, Ber 1886, 3320). It may be obtained by saponifying colza oil, freeing the erucic acid from arachidic acid by treatment with glacial acetic acid, in which the latter is insoluble (Ponzio, Gazz. chim ital 1904, ii 50) It is also present in cod liver oil (Bull Ber 1906, 3570)

Erucic acid crystallises in colourless needles, mp 34°; bp 281° at 30 mm Heated with phosphorus oxychloride, it forms an anhydride  $\rm C_{44}H_{82}O_3$ , an oil which may be crystallised in a freezing mixture By treatment with nitrous acid, or better, by warming erucic acid with dilute nitric acid to the melting-point and then adding sodium nitrite, brassidic acid (brassic acid) is produced. This acid stands to crucic acid in the same relation as elaidic to oleic acid Cf Mascarelli, Atti R Accad Inneel, 1917, [v] 26, 1 71 Fused with potash, erucic acid yields aradic (arachidic) and acetic acids Concentrated nitric acid converts erucic acid into brassilic acid (C<sub>13</sub>H<sub>24</sub>O<sub>4</sub>), pelargonic acid, arachidic acid, and a small quantity of dinitiononane (Fileti and Ponzio, J. pr. Chem [2] 48, 323), and concentrated sulphuric acid into behenolactone (Shukow and Schestakow, Chem. Zentr 1908, With hydriodic acid and amorphous phosphorus, it is converted into behenic acid (Goldschmiedt, J. 1876, 579) On treatment with phosphorus triodide, iodobehenic acid is obtained, which on treatment with alcoholic potash, yields iso-erucic acid, m p 54° (Ponzio, lc) Erucic acid is converted into behenic acid by heating with iodine in a sealed tube for 4 hours at 270° (Reychler, Bull Soc chim [3] 1, 296). When bromine is added to erucic acid under water, a dibromide C22H42Br2O2 is produced. It crystallises from alcohol in small white nodular crystals, mp 42°-43°, and is reduced to erucic acid by sodium amalgam in alcoholic solution. Its barium and lead salts (C<sub>22</sub>H<sub>41</sub>Br<sub>2</sub>O<sub>2</sub>)<sub>2</sub>Ba and (C<sub>22</sub>H<sub>41</sub>Br<sub>2</sub>O<sub>2</sub>)<sub>2</sub>Pb are white, viscid, easily decomposable precipitates (Otto, Annalen, 127, 182, 135, 226). Erucic acid dibromide heated in scaled tubes to about 145° for 7–8 hours, with 4 or 5 mols potassium hydroxide in alcoholic solution, yields the potassium salts of behenolic acid

$$C_{22}H_{40}O_2(=C_{22}H_{42}Br_2O_2-2HBr)$$

(Holt, Ber 1892, 961). Behenolic acid, on treatment with zinc-dust and acetic acid, yields brassidic acid and not crucic acid. At ordinary temperatures, only 1 mol of hydrobromic acid is abstracted by potash in alcoholic solution, monobromerucic acid  $\rm C_{22}H_{41}BrO_2$  is formed, with rise of temperature and separation of potassium bromide. On diluting the solution with water and adding hydrochloric acid, the acid separates as an oil which soon solidifies. It melts at 33°-34° and remains liquid for a long time. It is heavier than water, and insoluble therein, but dissolves readily in alcohol and ether. It unites with bromine, forming a dibromide  $\rm C_{22}H_{41}BrO_2^{\circ}Br_2$ , which melts at 31°-32°, and forms amorphous viscid salts

When erucic acid dibromide is triturated with water and an excess of silver oxide, and heated untilit turns brown and evolves hydrogen bromide, the mass, on boiling with water, yields a yellow oil which is a mixture of liquid hydroxyerucic acid  $C_{22}H_{42}O_3$  and dihydroxybehenic acid  $C_{22}H_{44}O_4$ The latter partially crystallises out on long standing For complete separation, the washed oil is saponified with baryta water; the precipitate is exhausted with ether and the dissolved barium hydroxyerucate is decomposed by hydrochloric acid. The hydroxyerucic acid, which separates as a colourless oil, is purified from alcohol It is viscid, lighter than water, insoluble therein, but miscible in all proportions with alcohol and other. Its salts  $C_{22}H_{41}O_{4}M$ are amorphous All excepting those of the alkalı metals and barıum are insoluble in water. Hydroxyerucic acid may also be formed from monobromerucic acid by the action of silver oxide Boiled with potash lye, it is converted into dihydroxybeheme and (Haussknecht, Annalen, 163, 40) Dihydroxybeheme and, mp 1322-133°, is also obtained by the oxidation of crucic acid with potassium permanganate (Hazura and Grussner, Monatsh 9, 947) Sodium erucate C<sub>22</sub>H<sub>41</sub>NaO<sub>2</sub> is soluble in alcohol, and gives precipitates of lead and barium erucates on the addition of an alcoholic solution of the acetates of these metals The silver salt is a curdy precipitate, which becomes coloured

nexposure to light.

Ethyl erucate  $C_{12}H_{41}(C_{2}H_{5})O_{2}$  is a colourless oil boiling above 360° without decomposition. The amide  $C_{22}H_{41}O(NH_{2})$ , mp 84° (Reimer and Will, Ic), mp. 78°-79° (Krafft and Tritschier, Ber. 1900, 3580), and the annide, mp. 55°, are crystalline bodies readily soluble in ether or

benzene, sparingly soluble in alcohol.

ERUCIN. A crystalline body said to exist in white mustard seed. It is insoluble in water, sparingly soluble in alcohol, easily in ether or in oils (Simon, Pogg. Ann. 64, 593)

n ols (Simon, Pogg Ann 64, 593)

Dierucin C<sub>3</sub>H<sub>5</sub>OH(C<sub>22</sub>H<sub>41</sub>O<sub>2)2</sub> When rape oll is allowed to stand for a long time, a yellowish

tallow-like deposit is found frequently in the casks. This, by repeated solution in ether and subsequent addition of alcohol, may be obtained in silky needles. Dierucin melts at 47° and is readily soluble in ether and light petroleum, insoluble in cold but soluble in hot alcohol. A trierucin could not be separated from rape oil, but was obtained by heating dierucin and erucic acid at 300°, mp. 31° (Reimer and Will, lc) (v. Oils and Fats)

ERVASIN. Trade name for acetyl p-creso-

ERYTHRENE. See BUTINENE.

**ERYTHRIN**, Erythric acid, Erythrinic acid, Erythrolecanoric acid  $C_{20}H_{22}O_{10}, H_2O$ , is a constituent of most lichens from which archil is prepared 1t was discovered by Heeren (Schweigger's Jour f Chem. 59, 513) in Rocella tinctoria (D C), from which lichen and several others of the same genus it may be extracted by boiling water, or better with milk of lime (cf. also Kane, Stenhouse, and Hesse (l c); Schunck, Annalen, 61, 69; De Luynes, Annales de Chim [4] 2, 385; Menschutkin, Bull Soc chim. [2] 2, 424)

The method adopted by Stenhouse to prepare this substance from the Rocella fucifirms is as follows (Annalen, 68, 72, and 149, 290). Three pounds of the lichen are mace lated for 20 minutes in a milk of lime made by shaking ½ lb of lime in 3 gallons of water, and the product filtered by means of a bag filter. The clear liquid, as it passes through, is immediately precipitated with hydrochloric acid, as prolonged contact with the lime decomposes part of the crythrin. The crude crythrin collected on bag filters is freed from acid and calcium chloride by stirring it up once or twice with a considerable quantity of water and again collecting

Erythrm forms small colourless needles, melting at 148° (Hesse, Ber. 1904, 37, 4693), and not at 164°, as stated by Ronceray (Chem. Zentr 1904, n 1504), and is sparingly soluble in water, easily soluble in alcohol, ether, and alkalis Alcoholic ferric chloride gives a purple-violet colouration, which passes to brownish-red on addition of excess of the reagent

When boiled with water, crythrin gives (a) orsellinic acid and (b) picro-erythrin (Schunck,

Annalen, 61, 65)

 $\mathrm{C_{20}H_{22}O_{10}+H_2O}=(a)~\mathrm{C_8H_8O_4}+(b)~\mathrm{C_{12}H_{16}O_7}$  whereas by boiling with alcohol, picroerythrin and orsellinic acid ethyl ester (c) are produced (Heeren, l~c; Kane, Annalen, 39, 25)

 $C_{20}H_{22}O_{10} + C_2H_5OH = (c) C_8H_7(C_2H_5)O_4 + C_{12}H_{16}O_7$ 

With amyl alcohol, a similar reaction occurs with formation of (d) amylorsellinate and picroerythrin (Hesse, Annalen, 139, 22)

 $C_{20}H_{22}O_{10}+C_5H_{12}O=(d)$   $C_8H_7O_4$   $C_5H_{11}+C_{12}H_{16}O_7$ On the other hand, excess of lime water (Lamparter, Annalen, 134, 255) gives orcin,  $CO_2$ , and erythrite

$$C_{20}H_{22}O_{10} + 2H_2O = 2C_7H_8O_2 + CO_2 + C_4H_{10}O_4$$

Tribromerythrin  $2\mathrm{C}_{20}\mathrm{H}_{19}\mathrm{Br}_3\mathrm{O}_{10},3\mathrm{H}_2\mathrm{O}$  (Hesse, Annalen, 117, 310; and *ibid* 139, 32) consists of white crystalline spherules which cake together a little above  $100^\circ$  and melt at  $139^\circ$ . Boiled with alcohol, it is resolved into *ethyldibromorsellinate* and *brompicrocrythrin*.

Picroerythrin or erythro-orsellinic acid C<sub>19</sub>H<sub>14</sub>O<sub>7,3</sub>H<sub>9</sub>O

forms colourless prisms, melts at 158°, is readily soluble in hot water, and gives with ferric chloride a purple-violet colouration. It appears to be most readily obtained pure by Hesse's method of boiling erythrin with amyl alcohol (*l c*)

Digestion with hot baryta water converts pieroerythrin into CO<sub>2</sub>, orcin, and erythrite

$$C_{12}H_{16}O_7 + H_2O = CO_2 + C_7H_8O_2 + C_4H_{10}O_1$$

The experiments of de Luynes, Menschutkin, and Hesse have confirmed the view first put forward by Berthelot, that erythrin is the monolecanoric ester (1), and picroerythrin the monoorsellinic ester of erythrite (2).

According to Hesse (Ber. 1904, 37, 4693), erythrin contains a free carboxyl group, and must therefore be represented as follows—

$$\begin{smallmatrix} \mathrm{C_4H_6(OH)_3 \ O \ C_6H_2(OH)CO \ O \ C_6H_2(OH)COOH} \\ \mathrm{CH} \end{smallmatrix}$$

whereas picroerythrin has the formula

On the other hand, Zerner (Monatsch , 1914, 35, 1021) considers that the structure of erythem is best represented thus

 $\beta$ -Erythrin  $\mathrm{C}_{21}\mathrm{H}_{24}\mathrm{O}_{10}$  is prepared by the action of lime water on some varieties of the R fuciformis (Menschutkin,  $l\,c$ ). It is a white crystalline powder; in p. 115°–116° (Lamparter,  $l\,c$ ), nearly insoluble in water, soluble in alcohol and ether with violent evolution of  $\mathrm{CO}_2$ . Boiled with water, orsellinic acid, and  $\beta$ -picrocrythrin are produced, with alcohol, the latter body together with othylorsellinate

β-Picroerythrin  $C_{13}H_{16}O_{10}$  crystallises in needles, very soluble in water and alcohol Boiled with baryta water, it is resolved into  $CO_2$ , erythrite, and β-orcinol (Menschutkin)

According to Hesse (lc), it is probable that  $\beta$ -erythrin is not a chemical individual, but consists mainly of erythin, the properties of which are modified by the accompanying impurities.

A G. P

ERYTHRITE or Cobalt-bloom. A mineral consisting of hydrated cobalt arsenate,  $Co_3(AsO_4)$ ,  $SH_2O$ , crystallising in the monoclinic system and isomorphous with the iron salt vivianite Sometimes, as at Schneeberg in Saxony, it occurs as beautiful radially-arranged groups of blade-shaped crystals with a bright crimson colour and brilliant lustre. More usually, however, it forms an earthy, peach-blossom red encrustation on other cobalt minerals, of which it is an alteration product—It has been found in the Dolcoath mine in Cornwall, Thuringia, Allemont in France, Cobalt in Ontario, Chile, &c. The name was given by F. S. Beuda.t,

in 1832, from  $\epsilon\rho\nu\theta\rho\delta s$ , red — The same name was also used by T Thomson in 1843 for a flesh-red variety of orthoclase-felspar

L. J S.

**ERYTHRITOL.** Erythrol, Erythromannite, Erythrite (v. Carbohydrates).

ERYTHRODEXTRIN v DEXTRIN

ERYTHROL NITRATE v. SYNTHETIC DRUGS. ERYTHROPHLEINE C<sub>28</sub>H<sub>43</sub>O<sub>7</sub>N (?) is an amorphous alkaloid from Sassy bark of Erythrophlœum guineense, G. Don, a large leguminous tree from the West Coast of Africa The bark is used as an arrow poison and in ordeals, and is also known as Casca, Red water, or Mancona bark. The alkaloid yields only amorphous salts, and is the only known one having a digitalis-like action on the heat Heated with concentrated hydrochloric acid it is hydrolysed to methylamine and an amorphous acid Erythrophleine hydrochloride is used to a limited extent in medicine (Gallois and Hardy, Bull Soe chim 1876, 26, 39, Harnack, Chem Zentr 1897, 1 301, Power and Salway, Amer J. Pharm 1912, 84, 337)

# ERYTHROSIN (Tetravodofluorescein)

C20H8O5I4

is prepared by electrolysing a mixture of fluorescein (1 part) and finely powdered iodine (1.5 parts) in soda solution. The vessel is provided with a diaphragm, and the fluorescein mixture occupies the anode space, whilst a dilute solution of soda or sodium hydroxide forms the kathode liquid (D. R. P. 108838, 1899), Chem. Zentr. 1900, i. 1176, cf. also Frdl. 1877–87, 2151.

The commercial product is a red-brick powder dissolving in dilute alkalis without any marked fluorescence It can be purified by dissolving in aqueous ether, filtering and shaking with dilute sodium hydroxide. The sodium salt 14 precipitated by the addition of strong alkali, and, after filtering, washing, and recrystallisation from alcohol, it is dissolved in water, and the free erythiosin is liberated by treatment with hydrochlone acid (Mylius and Foerster, Ber When pure, it is of a lighter 1891, 24, 1482) colour than the impure product, almost insoluble in absolute ether, benzene, or chloroform, but more readily so in acetone, alcohol, and aqueous ether The colour of erythrosin fades under the influence of light and of hydrogen peroxide, particularly in the presence of potassium hydroxide (Zeitsch Farbenindustr 7, 299). Light also causes it to act hamolytically in photodynamic reactions (Sacharow and Sachs, Chem Zentr 1905, 1 1420)

Erythrosin considerably enhances the action of light in its influence on bacteria (Mettler, Chem. Zentr 1905, ii 1037, Huber, ibid 1906, ii 148, Sachaiow and Sachs, lc) Erythrosin is employed in the cotton and paper industries, and Thouert (Compt rend. 1909, 148, 36) has attempted to apply it to colour photography, but with little success so far (cf also Stark, Physikal Zeitsch 1907, 8, 248), it has also been used as a sensitiser in photo-electric experiments (Schlenderberg, J. Phys. Chem. 1908, 12, 574) as an indicator in analysis (Mylius and Foerster, lc.; J. Amer. Chem. Soc. 1899, 21, 359).

Erythrosin is often mixed with rose Bengal (tetralodochlorofluorescein) to suppress its fluorescence, and with common salt to increase its solubility. The former mixture is often used in France to colour foodstuffs, but the presence of rose Bengal in erythrosin is forbidden in America. Jean (J. Soc Chem. Ind. 1908, 70) gives a method for testing and estimating rose Bengal in erythrosin.

Silver erythrosin, which is of an intense blue colour, is prepared by dissolving 1 gram of erythrosin in 400 c c water, adding 7 1 c c. of a 10 p c solution of potassium bromide, and then 12 c c. of a 10 p c silver intrate solution. It forms a colloidal solution which becomes 'ripened' on waiming or standing for a few days, depositing a very fine sediment which has a pure blue colour in transmitted light (Luppo-Cramer, Zeitsch Chem Ind Kolloide, 1907, 1 227; 1908, 2, 325)

The sodium or potassium salt is sometimes known as Erythrosin B, Pyrosin B, Iodeosin

Dianthine B, Eosin J, &c

ERYTHROXYANTHRAQUINONE  $C_{14}H_sO_3$  is produced, along with an isometic hydroxyanthraquinone, by the action of phthalic anhydride on phenol, in presence of sulphuric acid,  $C_8H_4O_3+C_6H_6O=H_2O+C_{14}H_8O_3$  Salicylic acid, anisole, and even anisic acid behave in the same way as phenol. The two hydroxyanthraquinones are separated by boiling with water and barium carbonate, crythroxyanthraquinone is unaltered by this treatment, whereas in the case of the isomeride a soluble barium compound is formed

Érythioxyanthraquinone may also be prepared from aminoanthraquinone, dissolved in acetic acid to which a little sulphuric acid has been added, by adding potassium intrite till the colution becomes yellow. After a short time, on adding water and boiling, yellow flakes of crythroxyanthraquinone separate, and increase as the acetic acid evaporates (D. R. P. 97688, Rower, Ber. 1882, 15, 1793, Perger, J. pr. Chem.

[2] 18, 147).

It is also formed by oxidising the amino-salt with fuming sulphuric acid (D R P 67063, Frdl. in 203), or by heating crythroxyanthraquinone acid (C<sub>15</sub>H<sub>8</sub>O<sub>5</sub> at 270° (Birnkow, Ber 1887, 20, 2438), and by heating anthraquinone-a-monosulphonic acid with a mixture of alkali hydroxide and a salt of an alkaline carth metal under pressure (Fr. Pat 336867, J. Soc. Chem.

Ind 1904, 438, ibid 1905, 841).

Erythroxyanthraquinone crystallises from alcohol in groups of pomegranate-yellow needles, more soluble in hot than in cold alcohol melts at  $173^{\circ}$ – $180^{\circ}$  (Baeyer and Caro), at  $190^{\circ}$ (Liebermann), at 191° (Romer) It begins to sublime at 150°, and condenses to form fine needles, reddish-yellow in colour, like alizarin It is almost insoluble in dilute ammonia, and only slightly soluble in strong ammonia With lime or baryta water it gives a dark-red, almost insoluble lake, decomposable by carbon dioxide The absorption spectrum of a sulphuric acid solution of erythroxyanthraquinone differs from that of its isomeride, hydroxyanthraquinone; the latter body is also more easily converted into alizarin by fusion with caustic otash than the former (Baeyer and Caro, Ber. 7, 986).

Nitric acid oxidises ethythroxyanthraquinone to phthalic acid.

When sodium erythroxyanthraquinone sulphonate is heated with bromine and water at 120°-123°, 2.4-dibromo-1-hydroxyanthraquinone is formed, crystallising in reddish-yellow needles, m.p. 233°. When heated with p-toluidine at 80°-100°, this bromine derivative loses the bromine atom in the -4- position, and is converted into bromoquinizarin blue

which crystallises in blue needles, giving a green colouration with sulphuric acid (D. R. P. 127532, 1902).

Erythroxyanthraquinone forms an acetate  $C_{16}H_{10}O_4$ , yellow needles, m >  $176^\circ$ - $179^\circ$  (Liebermann and Hagen, Ber 1882, 5, 1804)

The constitution of erythroxyanthraquinone has been established by Liebermann (Ber 10, 611, 11, 1611), who synthesised it from a reduction product of quinizarin, hydroxyhydro- $C_6H_4$   $C_{CH(OH)}$   $C_6H_3(OH)$ , anthranol which the hydroxyl-group in the benzene nucleus occupies the ortho-position Frand (Ber 12, 237) was also able to show that in methylhydroxyanthraquinone, a derivative of ordinary hydroxyanthraquinone, the hydroxyl-group was in the para-position, and hence, in the isomeric erythroxyanthraquinone, the hydroxyl- group must be in the ortho-position with regard to the ketone group. Erythroxyanthraquinone is therefore o-hydroxyanthraquinone (v Alizarin AND ALLIED COLOURING MATTERS)

ESCALIN. Trade name for a paste of

aluminium powder and glycerol

ESERAMINE, ESERIDINE, ESEROLINE v ORDEAL BEAN

#### ESERINE or PHYSOSTIGMINE

# NHMe CO·NHC<sub>13</sub>H<sub>15</sub>N OH

(Herzig and Meyer, Monatsh 1897, 18, 389, Heubner, Chem Zentr 1905, n 1111, Straus, Ann 1913, 401, 350; 1914, 406, 332, the most recent work is by Polonovski and callaborators, e q part viii Bull Soc. chim 1918, 23, 356) is the most important of the alkaloids occurring in Calabar bean, in the seed of which it was first found by Jobst and Hesse, in 1864 (Annalen, 1864, 129, 115, Hesse, ibid 1867, 141, 82).

It is present in variable amount (0 04–0 27 pc Carr and Reynolds, Pharm J 1908, 542), and may be extracted by shaking the powdered seed with warm alcohol containing about 1 gram of tartaric acid per litre. The alcohol of the extract is distilled off and the residue is taken up with water, filtered to remove resinous matter and repeatedly shaken with ether until the latter ceases to be coloured. The aqueous extract is then made alkaline with sodium bicarbonate and finally repeatedly shaken out with ether. On evaporation, the alkaloid separates in scaly crystals which may be purified by recrystallisation from ether.

Eserine forms thin rhomboidal, colourless lamellæ, m p 105°-106°, which gradually assume a rose tint and even a yellow colour when exposed to air. It is sparingly soluble in water,

but readily so in alcohol, ether, chloroform, benzene, and carbon disulphide. Eserine is lævo-rotatory, its specific rotation varying between  $-82^{\circ}$  and  $-120^{\circ}$ , depending on the solvent employed (Petit and Polonovski, Bull. Soc. chim. 1893, 9, 1008, cf Orloff, Chem. Zentr. 1897, 1. 1214). Polonovski and Nitzberg, Bull Soc chim 1915, 17, 235 et seq , idem 1916,

When eserine is isolated in the form of its salicylate, the base liberated with sodium carbonate, extracted with ether, and finally allowed to crystallise from a mixture of benzene and petroleum, it separates in stout prisms, mp.  $86^{\circ}-87^{\circ}$ ,  $[\alpha]_{D}$  -75  $8^{\circ}$  By recrystallising in the presence of a crystal of Petit and Polonovski's modification, mp 105°-106°, it is completely converted into the latter, and has  $[\alpha]_D$ -75 8°; the alkaloid is therefore dimorphous (Salway, Chem. Soc. Trans 1911, 2151)

When eserine or its salts are distilled with caustic potash in a current of hydrogen, methylamine and carbon dioxide are amongst the products of decomposition, whilst the residual liquid contains eseroline, a colourless crystalline body, which turns red by the action of moisture Eseroline is also formed, together with methyl carbamide, when eserine is heated in a scaled tube with alcoholic ammonia at 150°. When heated with aqueous potash in presence of air, yields rubreserine C13H16N2O2, red needles, these, in alkaline solution, are gradually converted into eserine blue, which, according to Ehrenberg (Chem Zentr 1894, n 439), is a true dye, colouring wool and silk without mordants. The constitution of cserine blue is not known, of Salway, Chem Soc Trans 1912, 986 not poisonous, but it has a paralysing effect on the heart and central nervous system of the frog (Heubner,  $l \epsilon$ ).

Salts of eserine. Eserine salicylate

$$C_6H_4(OH)CO_2H,C_{15}H_{21}O_2N_3$$

forms slightly bitter, colourless, stout prisms, m p.  $180^\circ-181^\circ$  (Salway), soluble in 150 parts of cold and 30 parts of boiling water, in which it forms an acid solution, it is more readily soluble in alcohol and in chloroform

Eserine metacresotate (metahydroxytoluate)

$$\mathrm{C_{15}H_{21}O_2N_3~C_6H_3(OH)MeCO_2H}$$

m.p. 156°-167°, is prepared by mixing ethereal solutions of metacresotic acid and of eserine Escrine benzoate, m p. 115°-116°, soluble in four parts of cold water, and eserine hydrogen citrate, are prepared similarly The two former are not deliquescent, and yield neutral aqueous solutions, whereas the latter, and also normal eserune tartrate, prepared by dissolving eserine in tartaric acid and crystallising over sulphuric acid, are very deliquescent (Petit and Polonowsky, ic). The methodide forms deliquescent yellow prisms, m p 100° (decomp), and the sparingly soluble picrate crystallises in feathery yellow needles, mp. 114°. Eserme yields no definite aurichloride or platinichloride

Eserine sulphate  $(C_{15}H_{21}O_2N_1)_2H_2SO_4$  is prepared by adding a 10 p c. sulphuric acid, drop by drop, to an ethereal solution of eserine until the newly formed salt no longer separates. After filtration, it is carefully dried at about 40° It

is a white or yellowish-white micro-crystalline powder, odourless, and having a bitter taste It is readily soluble in water, alcohol, and in chloroform. Gold chloride solution, when added to the aqueous solution of the salt, gives a beautiful purple colour, whilst platinic chloride precipitates a yellowish white salt When evaporated with ammonia, the sulphate, like the salicylate, yields a blush residue. If a little eserine sul-phate is placed on a glass slip and moistened with water, and then a drop of sulphuric acid added, characteristic crystals of a spaningly soluble sulphate separate This characteristic appearance is maintained for some time, but eventually the crystals become only and then resinous (Reichard, Pharm Zeit 1909, 50, 375) Eserine and its salts turn red on treatment with alkali or on standing in solution, but the sulphite C<sub>15</sub>H<sub>21</sub>O<sub>2</sub>N<sub>3</sub>,H<sub>2</sub>SO<sub>3</sub>, the aqueous solution of which does not turn red, but remains colourless, has been prepared by Merck by treating a solution of eserine with sulphurous acid, and evaporating the mixture (D R P 166310; J Soc Chem Ind 1906, 443) It is a white powder, readily soluble in water

A derivative, the intensity of the fluorescence of which exceeds that of all known substances. is obtained by allowing an aqueous solution of physostigmine to stand for a few months until it has become deep blue, then adding phthalic and. The substance forms dark-blue crystals with a blood-red fluorescence, and colours cotton, silk, alcohol, ether, &c , dark blue with no fluorescence The aqueous solution, on the other hand, is colourless by transmitted light, but shows a beautiful red fluorescence by reflected light (Goubert, Compt. rend. 1909, 149, 852).

Escrine and its salts should be kept in amber-

coloured, well-stoppered phials

Test for eserine or its salts -A small fragment (the size of a grain of sand) is placed in a porcelain capsule and dissolved in a drop or two of fuming mitric acid The dark-yellow solution formed on warming is evaporated with stirring, the residue, which is of a pure green colour, dissolves in water, strong alcohol, and in sulphuric acid to a clear green solution. 0 005 gram of the alka-loid can thus be detected. The green colouring matter has been termed chloreserine (Ferreira da Silva, Compt rend 1893, 117, 330, Formanck, Chem Zentr 1895, 1.1148, Reichard, *lc*) When exposed to nitric acid fumes, the blue residue becomes violet-blue, and when dissolved in a drop of nitric acid it forms a beautiful reddishviolet solution, which soon changes to blood-red, and on standing or on dilution becomes greenishyellow Escrine reduces molybdic acid very slowly in the cold, but rapidly gives a blue colouration on warming (Reichard, lc) ammonium selenite in concentrated sulphuric acid, eserine gives a lemon-yellow colouration, which becomes orange, and then paler after standing for 3 hours (da Silva, Compt rend 1891, 112, 1266) Eserine can also be detected by means of the polarisation microscope (Kley, Rec trav chim 1903, 22, 367) (For the estimation of eserine or physostigmine, see Heikel, Chem Zentr 1909, 1 949)

Eserine and its salts are of considerable therapeutic value, being employed chiefly as a myotic to contract the pupil of the eye and to decrease intraocular pressure in glaucoma.

According to Pal (Chem. Zentr 1900, in. 1031), esemine forms an antidote to the poisonous effect of curare.

Bilateral antagonism exists between eserine and curare in their effect on muscle. Those muscles which, like the diaphragm, are last paralysed by curare are first set free again by the injection of eserine. The latter also stimulates the respiratory centre (Rothberger, Pfluger's Archiv. 1901, 87, 117)

(For other investigations on the physiological effect and use of eserine or physostigmine, see Matthews and Brown, Amer. J. Physiol. 1904, 12, 173, Edmund and Roth, ibid. 1908, 23, 28, 46, Joseph, ibid. 1909, 23, 215, Anderson, J. Physiol. 1905, 33, 414; Magnus, Pfluger's Archiv. 1908, 123, 99, Kress, ibid. 1905, 109, 608; Modrakowski, ibid. 1907, 118, 52, Unger, ibid. 1907, 119, 373; Harnack, Chem. Zentr. 1908, ii. 338, Winterberg, ibid. i. 750, Loewi and Mansfeld, ibid. 1910, i. 941; Powsner, Biochem. Zeitsch. 1907, 2, 339, Fuhner, Arch. expt. Path. Pharm., 1917, 82, 205.) (V. Ordeal Bean.)

ESPARTO, Stipa maicrochloa (tenacissima) (Linn.) This grass is a native of Spain, Portugal, Greece, and North Africa It is largely used as a raw material for paper making, having been introduced into this country by Routledge. For this purpose it possesses many advantages, as it grows abundantly without cultivation, is easily harvested, yields a large percentage of cellulose of high quality with comparatively simple treatment.

Of the various kinds known to commerce, such as Spanish, Tripoli, Arzen, Oran, Sfaz, Gabes, &c, the first-named is preferred by paper makers, as it yields more and better fibre. It

therefore commands a higher price

To give some idea of the importance of esparto as a paper-making material, it may be mentioned that the annual imports into the United Kingdom are between 200,000 and 300,000 tons

It is also used for the purpose of making coarse mats and topes (v Spon's Enc of the

Industrial Arts)

Esparto arrives in this country firmly pressed The first operation which it underinto bales goes in the paper mill is that of 'dry-picking,' in contradistinction to a subsequent process known as 'wet picking'. The grass is spread out on tables covered with coarse wire cloth, and any root ends, weeds, &c, which may have found their way into the bales through im-Any sand or perfect gathering are picked out The redirt escapes through the wire cloth moval of dut can be more completely effected by machinery. For this purpose the grass is fed into a mechanical duster or willow, where it receives a violent shaking, the dirt being loosened and removed The cleaned esparto is then fed into 'vomiting' boilers, where it is treated with caustic soda solution at pressures varying from 10 to 40 lbs per sq inch for from 3 to 5 hours The amount of soda required is about 17 lbs of 60 pc caustic soda per cwt, but it varies with the quality of the grass, the form of boiler, the pressure at which it is boiled, and the time allowed. When the boiling is completed, the liquor is run away, evaporated to dryness, and ignited, and the alkali recovered in the form of

carbonate This is dissolved in water, converted into caustic by means of lime, and is again available for use.

The boiled grass is washed once or twice in the boiler, and then subjected to the 'wetpicking' process, whereby any unboiled portions are removed. The process is being gradually abandoned in favour of what is known as the 'presse-pâte' system, which consists in purifying the pulp by passing it when bleached through a series of strainers and knotters. It is then made into a coarse web of pulp on the 'presse-pâte,' which may be described as a paper machine without the drying cylinders.

The subsequent treatment of esparto does not differ essentially from that of other fibres, and

need not be particularly described

The haulms (really leaves) of esparto vary in length from 0.3 to 0.5 in, the mean thickness being about 1.5 mm, the individual fibres are 100-400 mm. long, and 0.009-0.5 mm thick

The fibres possess, owing to their fineness and their tendency to curl, considerable 'felting' properties. Paper made from esparto is soft to the touch, 'bulks' well, and at the same time is

strong.

Esparto fibre can be recognised in a paper by the fact that when boiled with a solution of aniline sulphate a rose-pink colour is developed. A similar colour is produced with straw cellulose, but of a paler shade. With rodine and sulphuric acid the wall of the actual bast-fibre assumes a rusty colour, showing that it is not composed of cellulose, with aniline sulphate (cold) it is stained yellow, and with phloroglucinol and hydrochloric acid a crimson colour is assumed, thus demonstrating the presence of bodies characteristic of lignified walls. They can be distinguished by the size and shape of the peculiar serrated epidermal cells, which are to be seen when the commercial fibre is examined under the microscope.

Moreover, espaito pulp always has a number of the short conical, often hooked, hairs which line the inner (upper) surface of the 'iolled' leaf, and which serve to distinguish it from straw, the outer (lower) surface of the leaf is

glabrous

The chemical characteristics of espaito are those of the ligno-celluloses and the pecto-celluloses, the latter predominating

Its composition is shown by the following analyses (Hugo Muller).—

				Spanish.	African.

The names 'esparto,' 'sparto,' and 'alfa' ('halfa'), are also given to the leaves of another grass, Lygeum spartum (Loefl.), which likewise grows in Spain and North Africa. These leaves are used as an inefficient substitute for those of Stipa. Microscopically they differ, in that the hars have a considerable lumen, and are

usually blunt-ended; the epidermis has peculiar little rounded silica cells; and the ribs of bast fibres are isolated (not linked together to form a continuous band, as in Stipa)

ESTERIFICATION. The reaction between an acid and a monohydric alcohol appears, at first sight, to be exactly analogous to the neutralisation of an acid by a monoacid base: the equations are:

 $CH_3 CO OH + C_2H_5 OH = CH_3 CO OC_2H_5 + H_2O$ 

The product formed in the second reaction is a metallic salt, and that in the first reaction is termed an alkyl salt or more commonly an ester The esters can be regarded as metallic salts in which the metallic radicals have become replaced by alkyl- groups Corresponding with mono-, di-, and trivalent-metallic radicals are the monodi-, and trivalent hydrocarbon radicals, methyl CH<sub>3</sub>—, ethyl C<sub>2</sub>H<sub>5</sub>—, propyl C<sub>3</sub>H<sub>7</sub>—, &c, methylene CH<sub>2</sub>=, ethylidene C<sub>2</sub>H<sub>4</sub>=, &c, glyceryl C<sub>3</sub>H $\equiv_5$ , &c The process of the corversion of an acid into its alkyl-salts is usually termed esterification, and is the common method by means of which esters are prepared Although this reaction appears to be similar to the process of neutralising an acid by means of an alkali, there are two important points of difference

1. The reaction between an acid and an alkalı in aqueous solution is instantaneous, whereas the reaction between an acid and an alcohol is usually slow, and lends itself readily to study as a time reaction

2. In the process of neutralisation between strong acids and strong alkalis, the reaction proceeds to completion when equivalent quantities of acid and alkali are used, but when equivalent amounts of acid and alcohol are brought together, complete conversion into ester and water never takes place The reaction begins slowly and proceeds until a state of equilibrium is established. The rate at which the reaction proceeds, and the final equilibrium depend upon the specific acid and alcohol employed and upon the temperature process of esterification is a typical balanced or reversible reaction ·

$$R CO_2H + R' OH R CO_2R' + H_2O$$

as the water formed in the process of esterification can hydrolyse the ester to a certain extent This reaction is one of the best to study in order to illustrate the effects of mass action

The reaction between acetic acid and ethyl alcohol was studied by Berthelot and Pean de St. Gilles, in 1862, they showed that working with equivalent quantities of alcohol and acid, equilibrium is reached when 66 pc. of the reacting compounds have been transformed into ester and water. They were able to show that, by working with an excess of alcohol, a higher percentage of the acid can be transformed, as illustrated by the following numbers.

Equivalents of alcoholfor lequiva- 0.205 1015204012 50 lent of acid

p.c. of acid trans-formed into ester 19 42 66.5 78 83 88 93 10^

According to Guldberg and Waage's law of mass action formulated in 1867, the rate of chemical reaction is proportional to the concentrations (molecular) of the reacting substances. and to a constant which is characteristic of the reaction and retains the same value provided the temperature is constant. In the balanced reaction

$$CH_3 CO_2H + EtOH \ge CH_3 CO_2Et + H_2O$$

the direct reaction proceeds at a rate which can be denoted by K a b, where K is the specific constant for this reaction, and a and b are the concentrations of the and and alcohol at the time of measuring the rate Similarly, the reverse reaction proceeds at a rate K' c d, where c and d are the concentrations of the ester and water at the particular time. When the state of equilibrium is reached, we have:

$$K a b = K' c d$$

Using one equivalent of acid and one equivalent of alcohol, Berthelot and St Gilles showed that equilibrium is reached when 0.66 mol of acid and of alcohol have been transformed, leaving 0 33 mol in the free state, we thus have

$$K \times 0.33 \times 0.33 = K' \times 0.66 \times 0.66$$
  
or  $K = \begin{bmatrix} 0.66 \\ 0.33 \end{bmatrix}^2 = 4$ 

The ratio K/K' is denoted by K, and is usually termed the equilibrium constant ratio of the constants for the direct and reverse reactions, and is independent of concentration, but may vary with temperature

This equilibrium constant enables us to calculate the amount of acid transformed when any known quantities of the given acid and alcohol are mixed at the given temperature and kept until equilibrium is attained

With a mixture of a, b, c, d equivalents of acid, alcohol, ester, and water at the given temperature, a-x and b-x equivalents of acid and alcohol will be present when equilibrium is attained, and c+x and d+x equivalents of ester and water will also be present, as each equivalent of acid reacts with an equivalent of alcohol and produces one equivalent of both ester and water

$$K_{K'} = \frac{(c+x)(d+x)}{(a-x)(b-x)}, \text{ but } K_{K'} = 4$$

$$\cdot \cdot \cdot \frac{(c+x)(d+x)}{(a-x)(b-x)} = 4$$

and x can be calculated when a, b, c, d are

It is necessary to distinguish between esterification by means of the acid and alcohol alone, and esterification of an acid by an alcohol in the presence of a catalytic agent The former process is generally termed 'direct esterification,' or sometimes 'autocatalytic esterification,' as it has been suggested that the organic acid itself can act as a catalyst to a certain extent second process is termed the catalytic method of est rification, and is the method most commonly used in the laboratory for the prep ration of esters.

Catalytic esterification. The modern laboratory method is due to E Fischer and Speier (Ber. 1895, 28, 3252). It consists in heating the acid with excess of alcohol, usually about five times the theoretical amount, in the presence of a catalyst. The most efficient catalysts are strong acids, and hydrogen chloride (about 3 p c. of the alcohol) or concentrated sulphuric acid (about 10 p.c. of the alcohol) is generally When hydrogen chloride is used it is advisable to prepare a 3 p c solution of this in the alcohol before adding the organic acid The 3 pc solution is best prepared by weighing the alcohol and passing in the dry gas by means of a delivery tube which just touches the surface of the liquid, and weighing from time to time until the requisite increase in weight is attained The organic acid is then added, and the whole boiled in a reflux apparatus for 3 hours. The greater part of the alcohol is distilled off, the residue poured into about 5 times its volume of cold water, and the solution neutralised with sodium carbonate It is then extracted with ether, the ethereal solution dued and distilled, when a 90 p c yield of the ester can usually be obtained Esters which are readily hydrolysed by water, or esters which are extremely soluble in water, can sometimes be isolated by subjecting the reaction mixture to distillation under reduced pressure J. and M Phelps (Amer J. Sci 1907, [iv | 24, 194) advise heating the acid. eg succinic or benzoic, with about its own weight of 1 p c alcoholic hydrogen chloride, and a small amount of solid zinc chloride at 100°-110°, and afterwards passing in a current of alcohol (compare abid 1908, 26, 281) For constants and properties of common esters, see Mathews and Faville (J. Physical Chem. 1918, 22, 1)

The function of the catalyst is to accelerate the rate of esterification; many acids which react very slowly with alcohol alone,  $e\,g.$  acctic acid at the ordinary temperature, can be transformed rapidly into esters in the presence of a small amount of catalyst Hydrogen chloride is a more efficient agent than sulphuric acid, the ratio being three to one (Kailan, Monatsh 1909, 30, 21), but sulphuric acid is frequently used, as it is more convenient to work with Phelps (Amer J. Sci 1908, [iv ] 260, 290, 296) has examined theaction of various acid sulphates, eg NaHSO<sub>4</sub>, KHSO<sub>4</sub>, piperidine and aniline hydrogen sulphates, but finds that they are not so efficient as sulphuric acid, and similarly he has studied the action of metallic chlorides on the catalytic action of hydrogen chloride Charcoal (Freundlich, Zeitsch physikal Chem 1906, 57, 412) and finely divided platinum (Sudborough and Turner) also act as feeble catalysts. It is usually stated that the presence of the catalyst does not affect the equilibrium, and that provided the ratio of alcohol is kept the same, the percentage of ester formed when equilibrium has been obtained, is the same in both catalytic and direct processes; but Phelps does not agree with this statement Ultra violet does not agree with this statement light brings about esterification of solutions of benzoic and other cyclic acids, especially in the presence of a trace of hydrochloric acid (Stoermer and Ladewig, Ber 1914, 47, 1803).

The amount of ester formed by the catalytic process depends upon the specific acid and alcohol used, and tends to become less when the

ester is readily hydrolysable. In the case of esters extremely soluble in water, or very readily hydrolysed, it is not advisable to pour into water, but to distil immediately under reduced pressure. Phelps and Eddy (Am. J. Sci. 1908, 26, 253) recommend adding solid potassium carbonate to the reaction mixture and distilling under reduced pressure. Certain finely divided metallic oxides have a catalytic action on the formation of esters.

A method of catalytic esterification consists in passing a mixture of the vapours of the acid and alcohol through a tube containing finely divided titanium dioxide at 290°-300° (Sabatiei and Maihle, Compt iend 1911, 152, 494; A. Maihle, Chem Zeit 1913, 37, 777 and 806)

According to Hauser and Klotz (Chem Zeit 1913, 37, 146), glueinum oxide is more efficient than titanium oxide, and even tertiary alcohols yield esters when this oxide is used

Senderens and Aboulenc (Compt rend 1911, 152, 1671, 1855, 1912, 155, 168, 1012) state that by the addition of 5 p c of aluminum sulphate or of potassium hydrogen sulphate to a mixture of equivalent amounts of acetic acid and ethyl alcohol an 82 p c yield of ester is obtained, and that 1 p c of sulphuric acid by voluine gives an 86 5 p c yield. The actual catalyst is stated to be ethyl hydrogen sulphate.

Various esters derived from cyclic alcohols, e.g., cyclohexanol, have been prepared by the method. The temperature, however, must not be too high and the method does not work with aromatic acids containing a carboxylic group directly attached to the benzene nucleus.

For use of (a) anhydrous calcium chloride, see Chem Soc Abstr 1911, 1 601, (b) nickel sulphate Kurtenacker and Habermann, J Pr Chem 1911, (u) 83, 541, and (c) dilute sulphuric acid Bodioux, Compt rend 1913, 156, 1079, 157, 938, 1428 A convenient method for certain esters appears to be a saturated aqueous solution of sodium chloride as solvent and a little sulphuric acid as catalyst

Relationship between constitution and esterification using the catalytic method. V Meyer and Sudborough (Ber 1894, 27, 510, 1580, 3146) were the first to point out any clear relationship between the constitution of an acid and its conversion into an ester by the catalytic method. Their original method was to saturate the alcoholic solution of the acid with hydrogen chloride, to leave at the ordinary temperature for several hours, and then to isolate and weigh the ester formed. Subsequently the Fischer-Speier method was used. They were able to show that practically any substituted benzoic acid, in which the two ortho- positions with respect to the carboxylic group are substituted, does not yield appreciable amounts of ester when its alcoholic solution is saturated with hydrogen chloride and kept for several hours at the ordinary temperature, or when the acid is boiled with a 4 p c. solution of hydrogen chloride m alcohol. All substituents react in much the same manner, eg CH<sub>3</sub>, Cl, Br, F, I, CO<sub>2</sub>H, NO<sub>2</sub>, &c, but the substituents F, OH, CH<sub>3</sub> have not so marked an effect as nitro-, carboxylic, and

halide radicals; eg. acids of the type  $C_gH_2Me_3CO_2H(CO_2H . Me_3=1:2:4:6)$  are esterified to an appreciable extent when hydrogen chloride is passed through their

boiling alcoholic solutions for several hours (Meyer and Sudborough, Ber 1894, 27, 1580, Meyer, *ibid.* 1895, 28, 182, 1254; compare also Kahn, *ibid.* 1902, 35, 3857).

The presence of a second benzene nucleus, as in naphthalene- and anthracene-carboxylic acids, has much the same effect as nitro- or halogen substituents; thus 2-chloro-1-naphthoic acid, anthracene-7-carboxylic acid and 1-chloroanthracene-9-carboxylic acid do not yield esters by the catalytic method, whereas the isomeric 3-chloro-2-naphthoic acid, anthracene-1-carboxylic acid, and 3-chloroanthracene-2-carboxylic acid yield 90 p.c. of ester under the same conditions.

It has been shown by V. Meyer (Ber. 1895, 28, 3197, and Rupp, *ibid* 1896, 29, 1625) that the dibasic acids—tetrachloro, tetrabromo, and tetraiodo-terephthalic acids, tetrachloro, tetrabromo, and tetraiodo-isophthalic acids, i.e. acids in which both carboxylic groups are diortho- substituted, do not yield esters when heated with a 3 p c solution of hydrogen chloride in alcohol An acid in which one of An acid in which one of the carboxylic groups is dioitho-substituted and the other is not, yields an acid ester under similar conditions, e g 2 6-dimethylterephthalic

acid, 
$$C_6H_2Me_2(CO_2H)_2$$
 gives  $CO_2Me \underbrace{\hspace{1cm}}_{Me} CO_2H$ 

(Jannash and Weiler, Ber 1895, 28, 531) Similarly, hemipinic acid, 3.4-dimethoxyphthalic

(Wegscheider, Monatsh 1895, 16, 135) further examples, see Wegscheider, ibid. 1900, 21, 621, 638, 1902, 23, 405, McKenzie, Chem Soc Trans 1901, 79, 1135) An appaient exception is met with in the case of 3 6-dichlorophthalic acid, which, according to Graebe (Ber. 1900, 33, 2026), yields the acid ester

$$Cl$$
 $CO_2Et$ 
 $Cl$ 
 $CO_2H$ 

when its alcoholic solution is saturated with hydrogen chloride and kept at the ordinary Tetrachloro-, tetrabromo-, and temperature tetraiodo-phthalic acids also yield acid esters (Rupp, *ibid* 1896, 29, 1625), o-nitrophthalic acid and papaverine acid (Miller, Annalen, 1881, 208, 243, Wegscheider and Lipschitz, Monatsh. 1900, 21, 790, Wegscheider, *ibid* 1002, 22, 260), belanger 1902, 23, 369) behave in a similar manner, yielding neutral esters, and it is probable that the esters are formed by the conversion of the acids into their anhydrides under the influence of the hydrogen chloride or sulphuric acid, and the subsequent addition of alcohol to the anhydrides. 3 6-Dichlorobenzoylbenzoic acid and tetrachlorobenzoylbenzoic acid are also readily esterified, and it is possible that these react with alcohol as the tautomeric hydroxyphthalides; eg.:

$$\begin{array}{l} C_6 \text{Cl}_4 \swarrow \begin{array}{c} \text{CPh(OH)} \\ \text{CO} \\ \text{\longrightarrow} \text{CO}_2 \text{Et} \cdot C_6 \text{Cl}_4 \cdot \text{CPh(OH)}_2 \\ \text{\longrightarrow} \text{CO}_2 \text{Et} \cdot C_6 \text{Cl}_4 \cdot \text{CPh} \\ \end{array}$$

The results obtained with tri- or even (Graebe). hexa-carboxylic acids show the same inhibiting effect of ortho-substituents. Thus trimesic acid benzene 1 3:5-tricarboxylic acid, yields a neutral ester, hemimellitic acid, the 1 2 3-tricarboxylic acid, yields a dimethyl ester , pyromellitic acid, benzene-1 2 4 · 5 · tetracarboxylic acid, yields a normal ester, prehnitic acid, 1 · 2 : 3 · 4 · tetracarboxylic acid, gives a dimethyl ester in the cold, and the neutral ester on heating, the formation of the latter is probably due to the fact that an anhydride is first formed, and this, with methyl alcohol, gives the dimethyl ester

which is further esterified to the normal ester Dinitro-pyromellitic acid, mellitic acid, and hexahydromellitic acid do not yield esters (Meyer, Ber 1894, 27, 1590, 28, 182, 1896, 29, 840) Isohydromellitic acid, on the other hand, yields a monomethyl ester (Van Loon, ibid 1895, 28, 1272)

Substituted benzoic acids in which the substituents are not in ortho-positions, give good yields of esters by the Fischer-Speici method, and this difference in behaviour has been used for the following purposes 1 Separation of an ortho-disubstituted benzoic acid from isomerides (compare Martz, Ber. 27, 3147, for separation of dinitro-benzoic acids; Jannasch and Weiler, ibid. 3445, for separation of isomeric trimethyl-benzoic acids) Rosanoff and Prager (J Amer Chem Soc 1908, 30, 1912) show that a mixture of benzoic acid with an ortho-substituted benzoic acid can be separated by partial esterification in the cold with a 3 p c solution of hydrogen chloride in ethyl alcohol 2 Determination of the constitution of particular substituted benzoic acids. (Compare V. Meyer, Ber 1895, 28, 187, for 2-methyl - 5 - bromobenzoic acid, Zincke and Francke, Annalen, 1896, 293, 123, for 4-acetyl-5-bromo-iso-phthalic acid, and Matthews, Chem. Soc Pioc 1900, 16, 187, for 2 3 5-trichlorobenzoic acid. See also Blaise, Compt rend. 1898, 126, 733, for substituted succinic acids)

When the carboxylic group is not directly attached to the benzene nucleus, but is united to a side chain, the presence of ortho-substituents does not prevent the formation of esters, eg. 2 4 6-tribromo-3-aminophenylpropionic acid and 2 4 6-tribromophenylpropionic acid, mesitylacetic and mesitylglyoxylic acid all gave good yields of esters when the alcoholic solutions are saturated with hydrogen chloride. Kellas (Zeitsch-physikal. Chem 1897, 24, 221) and Goldschmidt (Zeitsch. lect ('hem 1909, 15, 4) have shown that the introduction of one ortho-substituent into the benzoic acid molecule retards esterification to an appreciable extent, the nitro- group having a greater inhibiting effect than Me, Cl. Br. or I Kailan also shows that o-aminobenzoic acid hydrochloride is esterified more slowly than its isomerides (Monatsh 1906, 27, 1038), but he finds that o-nitrocinnamic acid is esterified more readily than the p- and m-nitro acids (ibid 1907, 28, 1163). Goldschmidt was able to show that using a dilute alcoholic solution of the acid with hydrogen chloride as catalyst, the velocity of the reaction can be determined by means of the equation for a unimolecular reaction, K=

 $1/t(\log a/a - x)$ ; since under these conditions the mass of the alcohol can be regarded as constant, and the reaction is practically non-reversible in the presence of the large excess of alcohol. The concentration of the acid at any given moment can be determined by direct titration with standard barium hydroxide solution, using phenolphthalein as indicator. When, however, the ester formed is readily hydrolysed, as in the case of ethyl formate, ethyl trichloracetate, and ethyl pyruvate, it is necessary to titrate with ammonium hydroxide solution, using litmus as indicator, as the end point is not definite when baryta is used, owing to the instantaneous hydrolysis of the ester by the baryta. The constant K is directly proportional to the concentration of the hydrogen chloride in the absence of water, and falls somewhat as t (time) increases, owing to the fact that the water produced during the esterification has a retard-The influence of small amounts of ing effect. water has been studied by Kallan (Monatsh 1906, 27, 543, 997, 1907, 28, 115, 571, 673, 705, 965, 1069, 1137, 1187, 1908, 29, 799; 1909, 30, 1), who has shown that the relationship between the rate of esterification and the amount of water can be represented by means of an equation of the type, eg in the case of cinnamic acid

$${\begin{aligned} &\overset{1}{K} &= 0.665 + \frac{4876}{c} - \frac{1.678}{c_2} + \left(2.911 - \frac{3.212}{c} + \frac{4.358}{c_2}\right) & \\ & + \left(-27.54 + \frac{31.78}{c} - \frac{2.284}{c_2}\right) & \\ & \end{aligned}} w^2$$

for concentrations of water w=0 3 to 1 3, and for concentrations of hydrogen chloude c=0 15 to 0 66 (Compare also Fitzgerald and Lapworth, Chem. Soc Trans 1908, 93, 2168.)

The inhibiting action of water on a mixture of acid and alcohol is readily shown by comparing the rates of esterification of the same mixture of acid and alcohol. (a) in presence of water; (b) in presence of a corresponding quantity of benzene (Kailan, Zeitsch physikal Chem 1915, 89, 676) When 25 or 50 volume p.c. of alcohol is used the relative effects of benzene and water are as 1.100 or 150 The effect of water on the esterification of dibasic acids has also been examined (Kailan, ibid. 1913, 85, 706; 1914, 87, 619)

Sirks (Rec. trav. chim. 1908, 27, 237) has

Sirks (Rec. trav. chim. 1908, 27, 237) has obtained the following values for the esterification constants of the isomeric dintrobenzoic acids at 25°, using ethyl alcohol containing a little water with hydrogen chloride as catalyst . 3:4-dintro-acid, 0 0086, 3.5-acid, 0 0050, 2:3-acid, 0 0005, 2.5-acid, 0 0003, 2.4-acid, 0 0002, and 2.6-acid, nil. The values for  $\mathbf{E}_{\mathrm{ktoh}}^{25\circ}$  obtained for benzoic, m-, and o-nitrobenzoic acids were 0 0132, 0 0071, 0 001.

These numbers indicate the retarding effect of one or two nitro-groups in the ortho-position; even one m-group retaids, but the introduction of a second intro-group into the meta-position of the m-nitro acid molecule, increases the rate.

From a comparison of the rates of esterification of these acids with their dissociation constants, Sirks comes to the conclusion that acids with small dissociation constants are esterified more readily by the catalytic method than acids with high dissociation constants; but an examination of certain alkyl-derivatives of aliphatic acids shows that the statement does not hold good generally.

Sudborough and Lloyd, by using Goldschmidt's method of determining esterification constants, have shown that the introduction of one substituent into the acetic acid molecule has a retarding effect, whatever the nature of the substituent The introduction of two substituents usually has a more marked effect than one, and three a greater influence than two, when the two or three substituents are alike. A comparison of the esterification constants for the normal fatty acids gave the following values for  $E_{MeOH}^{15^{\circ}}$ . formic 1124, acetic 104, propionic 92, and from butyric to stearic values between 50 and 54 The introduction of a carbonyl-group in place of the α-methylene group of a normal fatty acid produces a retarda on (Kailan, Monatsh 1907, 28, 1187, Sudborough, Chem Soc Trans 1912, 101, 1227) The introduction of methyl- groups into the molecule of methyl hydrogen succinate also produces a lowering of the esterification constant (Bone, Sudborough, and Sprankling, Chem Soc Trans. 1904, 85, 534)

In the case of unsaturated acids, the following generalisations have been drawn (compare Sudborough and Lloyd, Chem. Soc. Trans 1898, 73, 81, Sudborough and Roberts, ibid 1905, 87,1840, Sudborough and Thomas, ibid. 1907, 91, 1033, Sudborough and Gittins, ibid. 1909, 95, 315, Sudborough and Davies, ibid. 975). 1 An abunsaturated acid is esterified much less readily than its saturated analogue, in many cases the ratio is 1 40. 2 An ab-unsaturated acid is esterified far less readily than the isomeric acids, in which the double linking is further removed from the carboxyl-group As a rule, βγ- unsaturated acids are esterified more readily than their saturated analogues,  $e g \beta \gamma$ -phenylcrotonic acid has  $E_{MeOH}^{15^{\circ}}$  86 6, and the saturated  $\gamma$ -phenyl-n-butyric acid  $E_{NeOH}^{15^{\circ}}$  56 25 γδ-Acids and other unsaturated acids, in which the double linking is further removed from the carboxyl- group, are esterified at much the same rate as the corresponding saturated acids, e gE for oleic acid is 543, and for palmitic acid 497 3 In most cases the introduction of a substituent into the a- position in the acrylic acid molecule has a greater inhibiting effect than when introduced into the \$\beta\$- position 4 The effect of a substituent in the cis- position is more marked than in the trans-, thus an acid of the

The difference in the rates of esterification of an  $\alpha\beta$ - unsaturated acid and the saturated analogue, a difference which has been confirmed by Kailan (Monatsh. 1907, 28, 1137) in the case

<sup>&#</sup>x27;The letter E is used to denote the ester'fication constant of an acid, using normal hydrogen chloride as catalyst, and the temperature and specific alcohol are also given, as the constant varies with these.

of cinnamic and hydrocinnamic acids, affords a very convenient method for separating mixtures of the two. This is well shown in the preparation of hydrocinnamic acid. The acid is obtained by the reduction of cinnamic acid, and is liable to contain small amounts of the latter, which are difficult to remove by crystallisation, but a complete separation can be effected by the action of a dilute solution of hydrogen chloride in ethyl alcohol. The saturated acid is completely transformed into ester, and, under suitable conditions, the unsaturated acid iemains A similar method can also be unesterified. used with advantage for the separation of a mixture of an  $\alpha\beta$ - unsaturated acid and the isomeric  $\beta\gamma$ -acid, this method is preferable to the older method used by Fittig, in which the  $\theta\gamma$ -acid was transformed into the  $\gamma$ -lactone (Sudborough and Thomas, Chem Soc Trans. 1911, 99, 2307)

Gyr (Ber 1908, 41, 4308) has determined the esterification constants of a number of mono-, di-, and tri- substituted acetic acids, and confirms the results obtained by Sudborough and Lloyd The values, for example, for acetic, phenyl acetic, dipnenyl acetic, and triphenyl acetic, at 25° are respectively 7.76, 3.57, 0.20, and 0.001 worked with absolute methyl alcohol, and recommends boiling some three or four times with small amounts of metallic calcium in order

to remove the last traces of water

Kistiakowsky (Zeitsch physikal Chem 1898, 27, 250) has determined the velocity of reaction of an acid and alcohol in mixtures of the alcohol and water containing hydrogen chloride this case the esterification and hydrolysis proceed side by side, and the velocity constants for the two are denoted by K and K'. Then:

$$K = \frac{1}{t} \frac{\xi}{a} \log_e \frac{\xi}{\xi - x} \text{ and } K' = \frac{1}{t} \frac{a - \xi}{a} \log_e \frac{\xi}{\xi - x}$$
$$K + K' = \frac{1}{t} \log_e \frac{\xi}{\xi - x}$$

when the amounts of water and alcohol are large compared with the amount of acid present Edenotes the gram-molecules of acid transformed into ester at equilibrium, and x the number of gram-molecules transformed at end of time t K can also be calculated from K+K' by

means of equation ·

$$K = (K + K')^{\xi}_{\alpha}$$

The values of K and K' and also the value  $\frac{\xi}{z}$ are independent of the original concentration of

the organic acid

The same values for K and K' are obtained when a mixture of acid, alcohol, water, and catalyst, or ester, alcohol, water, and catalyst are used, provided the proportion of water and alcohol and the concentration of the catalyst are kept the same

The temperature coefficient between  $t = 25^{\circ}$ and  $t = 30^{\circ}$  is about 10 pc per degree, using mixtures of alcohol and water containing

13-70 p.c. alcohol

The values of both K and K' fall on passing from formic to acetic, and again from acetic to monochloracetic

The effect of the proportion of alcohol and water present is marked The value of K in the

case of formic acid rises from 0 to 300 as the percentage of alcohol increases from 0 to 914. whereas the value for K' falls from 198 to 60. as the percentage of alcohol is increased from 0 to 914 In the absence of a catalyst, the velocity of esterification falls as the organic acid is used up, whereas the velocity of hydrolysis is first small, and gradually increases as fresh acid is formed, and both K and K' diminish with an increase in the amount of alcohol present

Direct method of esterislication. The reaction between alcohol and a mineral acid is frequently used as a method for the preparation of ethyl esters of inorganic acids, e y ethyl chloride bromide, nitrite, sulphate (for ethyl bromide, cf Weston, Chem Soc Trans 1915, 107, 1489,

Holt, ibid. 1916, 109, 1) Norris, Watt, and Thomas (J. Amer Chem Soc 1916, 38, 1071) have studied the reaction between different alcohols and dilute solutions of hydrochloric and hydrobromic acids Thev find that the rate of formation of esters in the case of primary alcohols tends to decrease as the molecular weight of the alcohol in-Of the three groups of alcohols, the tertiary are the most, and the primary least, reactive

Menschutkin, working with the fatty acids (J pr Chem 1881, [n] 24, 49; *ibid* 1882, [n] 25, 193, Ber 1897, 30, 2783), was one of the first to draw attention to the relationship between the rate of esterification and the constitution of the acid and of the alcohol, and found that the amount of acid converted into ester in a given time diminished with the complexity of the acid molecule, and also with the complexity of the alcohol molecule. By heating a given amount of acetic acid with equivalent amounts of different alcohols for one hour at 135°, Menschutkin was able to show that, on the whole, a primary alcohol is esterified more rapidly than a secondary, and a secondary than a tertiary. Some of the results obtained by Menschutkin for primary alcohols are not true measures of velocity, as equilibrium had already been obtained within the hour It is also pointed out that the introduction of side chains or of negative substituents into a primary alcohol also tends to lower the rate of esterification, and the greater the number of such groups introduced the more pronounced is the effect. The introduction of an olefine linking into the molecule of the alcohol in the  $\alpha\beta$ - position also diminishes the rate of esterification. Subsequent experiments made by heating the alcohol with given weights of acetic anhydride gave similar results Still later work with hydroxy-polymethylenes (Chem. Soc. Trans. 1906, 89, 1533), using the acetic anhydride method, indicates that these compounds are esterified more readily than analogous open-chain compounds, eg the value for methyl-propyl-carbinol and cyclopentanol are respectively 98 and 189, and that cyclic tertiary alcohols are esterified least readily and primary most readily. The results also indicate that methyl- groups in the o- position with respect to the hydroxyl- group also produce retardation, but not to the same extent as whon attached to the carbon atom to which the OH is attached Michael and Wohlgast (Ber. 1909, 42, 3157) have determined the rates

of esterification of trichloracetic acid with following numbers, using the equation for a various alcohols at 25° and 50°, and give the bimolecular reaction:—

Primary alcohols	$K \times 10^s$	Secondary	K × 10° 25°	Tertiary	K×10' 25°
Methyl Ethyl	3690 24,000 650 4,210 725 1200 740	Dimethyl-carbinol Methyl-ethyl ,, Methyl-propyl ,, Methyl-hexyl ,,	. 98 . 90 . 76 . 109	Ter-butyl Ter-amyl	. 118
Heptyl Octyl Cetyl	1160 1860 2500 16,300				

According to Michael, factors which are of importance are. 1 Degree of association of the alcohol; as this is greater in the case of the simpler alcohols, the rate of exterification would be reduced to a greater extent 2 Readiness with which the alcohol decomposes into H and RO in order to react with the carbonyl- group 3 The influence of alkylgroups on the affinity of the RO and H for the unsaturated atoms of the carbonyl- group Michael claims that his results do not afford the slightest evidence for the view that atoms or groups can produce effects by mere filling of Space

As regards the influence of the constitution of the acid on the velocity of esterification, Menschutkin drew the following conclusions as the result of experiments made by heating the respective acids for one hour with isobutyl The introduction of an alkyl- group alcohol into the formic acid molecule invariably produces a retardation in the esterification. The introduction of alkyl- groups into the acetic acid molecule also produces a retardation, and this is greatest when three alkyl- groups replace the three hydrogen, eg trimethylacetic acid, and is least when only one alkyl- group is introduced Unsaturated acids of the type of crotonic and cinnamic are esterified less readily than their saturated analogues

Lichty (Amer Chem J 1895, 17, 27; 1896, 18, 590) found, however, that in the case of the chlorinated acetic acids the introduction of a chlorine atom into the acetic acid molecule tends to facilitate the formation of ester when the direct method is used. The presence of an  $\alpha\beta$ - ethylene linking has not the same marked effect in direct esterification as in catalytic esterification (Thomas and Sudborough, Chem Soc Trans 1912, 101, 317) It is obvious that the results obtained by the direct and catalytic methods of esterification are not comparable, and Sudborough and Feilmann (Chem. Soc Proc. 1897, 13, 241) have suggested that at least two factors are concerned in the process of esterification when using the same alcohol, viz (1) strength of the acid esterified, (2) the presence of substituting groups in close proximity to the carboxyl- group When the direct method of esterification is used, the former appears to be the determining factor, whereas with the catalytic method the latter is of primary importance; but in either case both factors are involved Compare also Flurscheim, Chem Soc. Trans. 1909, 95, 718

Rosanoff and Prager (J. Amer. Chem. Soc. 1908, 30, 1895) have also shown that durthosubstituted benzoic acids can be esterified by the direct method, provided they are heated with

excess of the alcohol at a comparatively high temperature (183°) for about 100 hours. The reaction proceeds even at the boiling-point of alcohol, but requires prolonged heating. Rosanoff and Prager determined both the velocity constant K and the reciprocal of the equilibrium constant, viz  $\mathbf{K}'=\mathbf{K}'/K$ . They used different weights of alcohol and acid in each experiment, and by taking the volume of the solution into account, they calculated K by means of the equation

$$K = \frac{2\ 3026v}{t\sqrt{(a-b)^2 + 4ab}\mathbf{K'}} \times \frac{2ab - x(a+b-\sqrt{(a-b)^2 + 4ab}\mathbf{K'})}{\log_{10}\ \frac{2ab - x(a+b+\sqrt{(a-b)^2 + 4ab}\mathbf{K'})}{2ab - x(a+b+\sqrt{(a-b)^2 + 4ab}\mathbf{K'})}}$$

where a and b are the molar concentrations of the acid and alcohol, v is the volume of the mixture in litres, x the number of gram-molecules of the ester formed after time t-(in days). The values of K obtained for a few acids are.

and it is pointed out that in many of these cases an increase in velocity of esterification runs parallel with an increase in the electrolytic dissociation constants of the acids, although the two sets of constants are not proportional

the two sets of constants are not proportional Michael and Oechslin (Ber 1909, 42, 317) have determined the amounts of ester formed when various mono- substituted benzoic acids are heated with methyl alcohol in sealed tubes at 135° without a catalyst, but they did not determine the actual constants. They found that many m- and p- substituted benzoic acids containing negative substituents are esterified somewhat more readily than benzoic acid, but that an ortho- substituent, with the exception of Cl, tends to retard esterification, and that the effect is the greatest in the case of the methylgroup.

The following are some of the values obtained after 7 hours. benzoic 11·1, o-chlorobenzoic 11·9, o-bromobenzoic 10·4, o-iodobenzoic 9·7, o-nitrobenzoic 10·0, salicylic 7·7, and o-toluc 6·2

The results obtained by Rosanoff and Prager and by Michael and Oesc'.elin are compatible

with the view that at least two factors are concerned in esterification either by the catalytic or the direct method; that in the former case the chief factor is the presence of substituents in close proximity to the carboxyl- group (steric hindrance) whereas the strength of the acid, as measured by its dissociation constant, is of but secondary importance; in the direct method the relative values of the two factors are frequently (Note The dissociation the exact opposite constant for s-trichlorobenzoic acid is not known) The results do not justify the conclusion drawn by both Rosanoff and Michael, that substituents do not retard esterification by mere space filling

For direct esterification of dibasic acids, see Kailan (Zeitsch physikal Chem 1915, 89, 676)

The reaction between a mercaptan and an acid is analogous to that between an alcohol and an acid, and the product is the ester of a thio-acid. The reaction has been studied in detail by L. S. Pratt and E. E. Reed (J. Amer. Chem. Soc. 1915, 37, 1934) at a temperature of 243°, and using different mercaptans. The limiting values are much less than when the corresponding alcohols are used, and tend to dimmish as the molecular weight of the alcohols increases.

Other methods for preparing esters. which cannot be obtained by direct esterification, eg. the esters of diortho-substituted benzoic acids, can be prepared by the following methods 1 Action of the alcohol on the acid chloride or acid anhydride. The latter action is accelerated by the presence of small amounts of a strong acid (Reychler, Bull Soc chim Belg. 1907, 21, 428) 2 Action of the alkyl iodide on the dry silver salt, or, in the case of aromatic acids, by the action of alkyl chlorides on dry potassium salts in the presence of a trace of a base such as triethylamine Benzyl benzoate is readily prepared by heating together at 95°-100° potassium benzoate (100), benzyl chloride (120), and triethylamine (1) 3 Action chloride (120), and triethylamine (1) of methyl sulphate on an aqueous solution of the sodium salt of the acid (Werner and Seybold, Ber 1904, 37, 3658) 4 Action of an ethereal solution of diazomethane on the acid

Sulphonic acids. Sulphonic acids do not give good yields of esters when warmed with alcohol alone or with alcohol and a mineral acid. This is probably due to the fact that the ester formed immediately reacts with the alcohol, giving the free acid and an ether:

$$C_6H_5SO_2\cdot OMe + MeOH = C_6H_5SO_2OH + Me_2O$$

(comp Krafft and Roos, Ber 1893, 26, 2823, Wegscheider and Furcht, Monatsh 1902, 23, 1094) The esters are not formed when the sodium salt of the acid is warmed with alkyl iodide and alcohol (Wegscheider and Furcht); but can be obtained by the action of methyl sulphate on the acid or by the action of the alcohol on the acid chloride at low temperatures (Krafft, Ber. 1892, 25, 2256)

Esters of dibasic acids. A dibasic acid can give rise to both an acid and a normal ester, e.g. CO<sub>2</sub>H CH<sub>2</sub> CO<sub>2</sub>H—>CO<sub>2</sub>H CH<sub>2</sub> CO<sub>2</sub>Me and CO<sub>2</sub>Me CH<sub>2</sub> CO<sub>2</sub>Me. With the exception of diortho-substituted aromatic dibasic acids, the normal esters can be obtained by the Fischer-Speier method of esterification. For the preparation of the acid es'ers, the following methods

are resorted to: 1. Addition of alcohol or of sodium alkyl oxide to the acid anhydride. 2. Partial hydrolysis of the normal ester 3. Partial esterification of the acid. 4 The action of alkyl iodides on the acid silver salts, if these can be prepared, or on the acid potassium salts. In the case of a symmetrical dibasic acid, the same acid ester is formed by all these methods, although, in most cases, except those coming under the first heading, the yields are not very good, as free acid and normal esters are also formed, and the separation is not always easy

With an unsymmetrical dibasic acid, two isomeric acid esters (the a and the b)  $^1$  can exist. and which of these is formed depends largely on which method of preparation is used Wegscheider has carried out numerous experiments (comp. Monatch. 1895, 16, 75, 1897, 18, 418, 629, 1899, 20, 685, 1900, 21, 621, 638, 787, 1902, 23, 317, 357, 369, 393, 405, 1903, 24, 413, 915, 1905, 26, 1039, 1906, 27, 487, 777; 1907, 28, 819, 1908, 29, 525, 531, 535, 541, 557, sulphonated benzoic acids, *ibid* 1902, 23, 1093, tribasic acids, *ibid* 1910, 31, 1253) on the following acids hemipinic (3 4dimethoxyphthalic), nitrohemipinic, camphoric, mitro-, bromo-, amino-, and hydroxy-terephthalic, 3- and 4-nitrophthalic, 4-hydroxyphthalic, phthalonic, homophthalic, aspartic, phenylsuccinic, and papaverinic, and has drawn the following conclusions under the assumption that the two carboxylic groups differ appreciably as regards their relative strength 1 By the addition of alcohol to the anhydride and by the action of alkyl iodides on the acid potassium or acid silver salts, the stronger carboxyl- group is esterified, so that under these conditions a-acid esters are formed. If there is but little difference in the relative strengths of the two carboxylgroups, then a mixture of the two acid esters is obtained, but the a- compound preponderates;  $e q = C_6 H_2(CO_2 H)_2(OMe)_2(1 \cdot 2 \cdot 3 \cdot 4)$  gives, by these methods, the acid ester

Exception phenyl succinic anhydride Diazomethane and the acid give mainly neutral ester, but also small amounts of acid ester derived from the stronger carboxyl- group 2. By the process of catalytic esterification the carboxylic acid group, which is freer from adjacent substituents, is esterified first, thus opianic acid gives the b- ester C<sub>8</sub>H<sub>2</sub>(CO<sub>2</sub>Et)(CO<sub>2</sub>H)(OMe)<sub>2</sub>,

1 2 3 4

but neutral ester and small amounts of the aisomeride may also be formed, especially if the
conditions are such that anhydride formation
can occur. The same rule holds good for
direct esterification if the possibility of anhydride
formation is excluded. 3 The addition of
sodium alkylate in the absence of alcohol and
water to the anhydride yields the b- acid ester,
with appreciable amounts of the isometide
4. The partial hydrolysis of the neutral ester
gives the acid ester, which is difficult to prepare

<sup>&</sup>lt;sup>1</sup> The term b-ester is given to the acid ester with the higher dissociation constant, and the isomeride is termed  $t_{-6}$  a- (Ber 1902, 35, 4329, 1903, 36, 304).

by the method of catalytic esterification; eg dimethylhemipinate gives the a-acid ester. Exceptions the hydrolysis of methyl hydroxyterephthalate, 4-hydroxyphthalate, 4-nitroph-

thalate, aminoterephthalate, phthalonate.
For formation of esters of phthalic acid in presence of hydrochloric acid and hydrolysis of the esters, see Wegscheider and Amann (Monatsh 1915, 36, 549 and 633)

In the case of the majority of symmetrical dibasic acids the two carboxylic groups are esterified at the same rate; in other words, the replacement of OH by OEt does not affect the rate of esterification In the case of both maleic and oxalic acids, however, there is a retardation produced by the conversion of one of the CO<sub>2</sub>H groups into a CO<sub>2</sub>Et This is attributed by Kailan (Zeitsch physikal Chem 1914, 87, 619) to the proximity of the two carboxylic groups to one another, and as the retardation is greater in the case of maleic acid, it is argued that in this acid the two carboxylic groups are closer than in oxalic acid

Theories of esterification.—Direct method The reaction between the acid and alcohol is not a simple ionic reaction, since the acid with the highest dissociation constant is not necessarily esterified most readily, and in the case of a dibasic acid it is not always the stronger CO2H group which is esterified first. The view usually accepted at the present time is that an additive compound of alcohol and acid of the type ∕OEt

R C OEt, ie a dialkyl-derivative of an ortho-OH

carboxylic acid, is first formed by the addition of a molecule of alcohol to the carbonyl- group of the acid (Wegscheider, Monatsh 1895, 16, 137, Henry, Ber 1877, 10, 2041) Michael suggests that before this additive compound is formed an unstable 'Kekulé double molecule' is formed, perhaps by the coming into play of the two latent valencies of the oxygen atoms

$$R < \stackrel{C=O}{<} \stackrel{OH}{<} Et$$

it is well known that many esters can form additive compounds with sodium ethoxide, and, therefore, presumably with ethyl alcohol, although compounds of the latter type have not been isolated Pechmann (Ber 1898, 31, 503) has been able to show that the esters of diorthosubstituted benzoic acids cannot yield additive compounds with sodium ethoxide, probably owing to the space filling (steric hindrance) of the group in the ortho-position; by analogy, the diortho-substituted acids would not yield the orthocarboxylic acid derivative at all readily, and this would account for the fact that diorthosubstituted benzoic acids are not readily esterified

Catalytic esterification According to Michael, the processes of direct and catalytic esterification are essentially different, the former is a reaction between the organic acid and alcohol, and the latter a reaction between the organic acid and an additive compound of the alcohol and catalyst (Ber. 1909, 42, 312). This reaction does not consist of addition to the carbonylgroup of the acid, but in union of the acid with the alcohol-catalyst complex to form a large 'double molecule,' which decomposes immediately into ester, water, and catalyst. The fact

that esterification is facilitated by the presence of the catalyst is accounted for by the assumption that the alcohol-catalyst complex contains a greater store of energy, is therefore more reactive than the alcohol itself, and can more quickly develop the maximum entropy of the alcohol-acid system It is questionable whether these views are in harmony with the facts established by Wegscheider, viz that the same acid ester is obtained from an unsymmetrical dibasic acid, whether the direct or catalytic method of esterification is adopted, provided that anhydride formation is excluded. Goldschmidt also comes to the conclusion that the two processes are essentially different (Zeitsch Elektrochem 1909, 15, 4) He claims to have shown that the presence of sodium trichloracetate does not depress the velocity of esterification of trichloracetic acid by the direct method, and, therefore, the direct esterification cannot be a simple case of hydrion catalysis Later experiments of Sudborough and Turner show that the presence of salts of trichloracetic acid does diminish the rate of esterification of the acid, and hence Goldschmidt's conclusion is not justified. The fact that in direct esterification the strength of the acid is an important factor is compatible with the view that the organic acid itself plays the same part in direct esterification that the catalyst does in catalytic esterification agrees again with the fact that the reaction in certain cases of direct esterification is bimolecular (Goldschmidt, Ber 1896, 29, 2208), provided the reaction is not between the ions of acid and alcohol.

Kaılan (Monatsh 1908, 29, 799) is also of opinion that the processes of direct and catalytic esterification are not analogous, since the addition of a small amount of water increases the rate of esterification of trichloracetic acid by the direct method, but diminishes the activity of trichloracetic acid when it is used as a catalyst.

Various views are held with regard to the function of the catalyst Goldschmidt and Uddy (Zeitsch physikal Chem. 1907, 60, 728; comp also Ber 1906, 39, 711, and Zeitsch. physikal Chem. 1910, 70, 627) conclude that the hydrions of the catalyst are the active agents, since the activity of different acids is in the order of their relative strengths, eg. the relative values of the acids hydrochloric, pieric, trichloracetic, and dichloracetic as catalysts are indicated in the order given, and the addition of salts of the acid used as catalyst diminishes the activity of the catalyst They further conclude that the hydrions unite with the alcohol, and

that the complex ion (C2H6O,H) is the active agent. They suggest the following modified formula for calculating the velocity constant:-

$$K.c = \frac{1}{t}(n+r+a)\log_{\theta}\frac{a}{a-x}-x$$

where c =concentration of catalyst, n =concentration of water, and r =hydrolytic constant of the complex alcohol ion for

$$(C_2H_6^+O,H)$$
  $r=1.5.$ 

The constants obtained by means of this equation agree better, and do not show the tendency to decrease as t increases, a tendency which is marked when the constants calculated

by means of the ordinary equation for a unimolecular reaction are used.

A marked exception to the depressing effects of the addition of salts is met with in the case of hydrogen chloride, where the addition of chlorides such as calcium chloride, tetramethyl-ammonium chloride, and aniline hydrochloride, have no appreciable effect on the catalytic activity of hydrogen chloride (Goldschmidt, Sudborough)

Many chemists are of opinion that in catalytic esterification, as in catalytic hydrolysis of esters by means of mineral acids (see art on Hydro-LYSIS), a complex is formed between the substance transformed (acid in esterification and ester in hydrolysis) and the catalyst This compound is probably an oxonium salt containing quadra-

valent oxygen, e.g. R C The salt. only small amounts of which may be present,

is ionised into (R CO<sub>2</sub>H,H) and Cl, and the esterification proceeds by the reaction of the complex cation with the alcohol (Acree and Jol nson, Amer Chem J. 1907, 38, 334), eg..

$${\scriptstyle (R~CO_2^+H,H)+C_2H_5OH=R~CO_2Et+H_2O+\overset{+}{H}}$$

and not with the ions of the alcohol as suggested This reaction is more rapid than by Lapworth the simple reaction between the acid and alcohol, and in this way the accelerating effect of the catalyst is accounted for

The retarding effects produced by small amounts of water are, according to Lapworth (Chem Soc Trans 1908, 93, 2167, 2196), due to the water competing with the organic acid for the catalyst, and giving use to the com-

plex ion (H2O,H), which is not catalytically active The fact that in alcohol containing water, the velocity of esterification at constant volume decreases more rapidly than the concentration of the catalyst (Goldschmidt and Uddy, Zeitsch physikal Chem 1907, 60, 735, Kailan, Monatsh 1906, 27, 543, 997, Annalen, 1907, 351, 186), is also held to be opposed to the view that a complex hydrion is formed with the alcohol

Work on the catalytic activity of strong acids tends to show that this activity is exerted in two ways · (a) by means of hydrions, (b) by the non-ionised acid, and that the effect due to the non-ionised acid is greater for highly ionised than for slightly ionised catalysts. methyl and ethyl alcohol the retarding influences of water on esterification is of much the same magnitude for different acids, and this is held to support the view that an intermediate compound of alcohol and catalyst plays a most important part in the change (Goldschmidt and Thuesen, Zeitsch. physikal Chem. 1912, 81,

Ethyl antimonite (C<sub>2</sub>H<sub>5</sub>O)<sub>3</sub>Sb, bp 115°-120°, from action of C<sub>2</sub>H<sub>5</sub>OH upon Sb<sub>2</sub>O, in presence of anhydrous CuSO<sub>4</sub>, colourless liquid (McKey, Chem Soc Trans 1909, 95, 604)

Ethyl arsenite (C<sub>1</sub>H<sub>5</sub>O)<sub>3</sub>As. A liquid formed by action of C<sub>2</sub>H<sub>5</sub>OH upon As<sub>4</sub>O<sub>6</sub> in presence of anhydrous CuSO<sub>4</sub>, the yield being 4 5 p c (Lang, McKey, and Gortner, Chem Soc Trans 1908, 1908). 93, 1368) According to Crafts (Bull Soc ching 1870, ii 14, 99), it is obtained in very small yields by

(1) Action of Et<sub>3</sub>S<sub>1</sub>O<sub>3</sub> upon As<sub>4</sub>O<sub>6</sub> at 200°,

(2) Action of Ag<sub>3</sub>AsO<sub>3</sub> upon Etl at 150°,

(3) Action of AsBr, upon NaOEt Auger (Compt rend 1906, 143, 907) obtained a yield of 12 p c by heating EtOH and As4O6 in a sealed tube far above the boiling-point of the alcohol

Ethyl arsenate. A liquid boiling above 200° with partial decomposition. Decomposed by water immediately. Formed by heating together

water immediately. Formed by heating together in sealed tubes at  $100^{\circ}$  Ag<sub>3</sub>AsO<sub>4</sub> and Et1 (Crafts, Bull Soc chim 1870, ii 14, 99)

Ethyl boride (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>B Tricthyl boride, Borethyl, b p 95°, sp gr 0 696 at 23°, V D at  $132^{\circ} = 3598$ ; at  $101.6^{\circ} = 3.76$ , calc = 3.399From action of  $Zn(C_2H_5)$ , upon  $(C_1H_5)_3BO$ ,, or from  $BCl_3$  and  $Zn(C_2H_5)_2$  (Frankland, Trans Roy Soc 1862, 167, Proc Roy Soc 1876, 25, 165)

A spontaneously inflammable, colourless liquid burning with green flame; decomposed by HCl, evolving  $\mathrm{C}_2\mathrm{H}_6$ , and forming  $\mathrm{B}(\mathrm{C}_2\mathrm{H}_6)$ , c'l is slowly decomposed by water, and destroyed by HNO3, with formation of boric acid Absorbs NH3, forming an only liquid NH3B(C2H5)3 of an aromatic odour, which is fairly stable even in contact with O  $B(C_2H_5)_3$  absorbs O and forms  $B(C_2H_5)_3O_2$ , bp 125° This, by the action of water, yields ethylboric acid  $B(C_2H_5)(OH)_2$ , a crystalline solid resembling naphthalene in appearance, can be sublimed at 40°, has a sweet taste, and acid action, but does not combine sweet taste, and action, but does not combine with bases By action of  $Zn(C_2H_5)_2$  upon this body we get  $B(C_2H_5)(CC_2H_5)_2$  and  $B(CC_2H_5)_3$ , bp  $112^\circ$ , V D. (dissoc) 2.78. By further action of  $Zn(C_2H_5)_2$  upon ethylboric acid we get  $B(C_2H_5)_2CC_2H_5$ ; bp.  $102^\circ$ , V D. = 3.914 Water converts this into  $B(C_2H_5)_2CH$ , a spontaneously inflammable liquid, which absorbs c:ygen, yielding B(C<sub>2</sub>H<sub>5</sub>O)C<sub>2</sub>H<sub>5</sub>OH; m.p. 8°.

Ethyl bromide  $C_2H_6Br$  Hydrobromic or Bromhydric ether; mp  $-116~0^\circ$  (Ladenburg and Krugel, Ber 32, 1818),  $-125~5^\circ$  (Schneider, Zeitsch. physikal Chem. 22, 233); bp. 38 22° (corr) (Thoipe and Rodger, Phil Trans. 1894, A, 11, 472), sp gr 1 4189 at 15° (Mendéleeff), l 4733 at 0° (Pierre), l 4685 at 13 5°; crit temp 236° (Pawlewski, Ber. 16, 2633)

Preparation — 1 By action of P and Br upon alcohol (Serullas, Ann Chim Phys [2] 34, 99) 40 parts red P and 160 parts absolute alcohol are slowly mixed with 100 parts Br, kept cool until all action is over, the mixture is then distilled, and the distillate purified by washing with water and rectification (Personne, Compt rend 52, 468) —2 Absolute alcohol is heated with Br and distilled, and the distillate is freed from excess of Br by washing with KOH and redistillation (Lowig, Annalen, 3, 288)—3 4 parts KBr and 5 parts of a mixture of 2 parts H<sub>2</sub>SO<sub>4</sub> and 1 part alcohol of 96 p c are distilled, and distillate purified as above (De Vrij, J. 1857, 441, Tabourg, Bull Soc chim 1911, [iv] 9, 124) Weston (Chem. Soc. Trans. 1915, 108, 1489) has given details of a modification of De Viij's method, using sodium bromide in place of potassium bromide and paying attention to the rate of heating, whereby yields of 80–90 p c of the theoretical amount of pure ethyl bromide can be obtained (cf. Holt, Chem. Soc. Trans. 1916, 109, 1.)—4. ('2H<sub>4</sub> in presence of AlBr<sub>3</sub> at 0° combines with HBr to form ('2H<sub>5</sub>Br. (Gustavson, J Russ Phys Chem Soc 16, 95) To prepare pure  $\rm C_2H_5Br$ , the commercially pure bromide is shaken with  $\rm H_2SO_4$  and allowed to separate It is then shaken with dilute alkali and distilled with 10 p c of sweet almond oil (Adrian, Chem Zentr 1895, 1 20)

Ethyl bromide is a colourless liquid with a sweet taste, and burning after-taste. Its vapour has an esthetic properties (Robin, Compt. 1 end 34, 649.) Webster, Bio. Chem. J. 1906, 1.328., Cole, J. Physiol. 29.) It is slightly soluble in water, and miscible with alcohol and ether. The vapour is decomposed by heat, yielding C<sub>2</sub>H<sub>4</sub> and HBr, or, if the temperature be higher, C. is deposited (Lowig). Burns in air with a green flame, evolving HBr. By introduction of Cl. two isomeric bodies of the composition C<sub>2</sub>H<sub>4</sub>(IBr, b. p. 84.5° and 104°-108°, and 2 isomerides of composition C<sub>2</sub>H<sub>3</sub>Cl<sub>2</sub>Br, b. p. 137°, 151° (Lescœur, Bull. Soc. chim. 1878, 29, 483) are obtained. At 100° Br. reacts, forming CH<sub>2</sub>Br CH<sub>2</sub>Br, whilst at 200° CH<sub>3</sub> (HBr<sub>2</sub>. is the product (Meyer and Muller, Ber. 24, 4247, J. pr. Chem. [2] 46, 161). By action of Br. and P. upon alcohol, we get, further, C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub>, b. p. 160°; C<sub>2</sub>H<sub>3</sub>Br<sub>3</sub>, b. p. 180°; C<sub>2</sub>H<sub>2</sub>Br<sub>4</sub>, b. p. 196°-200° (Bertrand, Finot, Bull. Soc. chim. 34, 28). (v. Ethylene bromide). Heated with AlBr<sub>1</sub>, yields successively C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub>, C<sub>2</sub>H<sub>2</sub>Br<sub>4</sub>, and C<sub>2</sub>Br<sub>6</sub> (Mouneyrat, Compt. rend. 127, 109). With ammonia it yields NH<sub>2</sub>(C<sub>2</sub>H<sub>5</sub>), HBr., and with ethylamine, diethylammonium bromide NH(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>HBr; similarly, with diethylamine, it yields N(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>HBr.

Ethyl chloride C<sub>2</sub>H<sub>5</sub>Cl Chlorhydric or Hydrochloric ether; mp. -142 5° (Schneider, Zeitsch. physikal Chem 22, 233); b.p. 12 5° (Regnault, J. 1863, 67), crit. temp. 187 2; crit. press. 51·7 atm (Berthoud); sp.gr. 0 9214 at 0°; 0 9176 at 8°, 0 920 at 0° (Pierre), 0 £51

at b p. (Ramsay, Chem. Soc. Trans. 35, 470); S.V 75 8 (Kopp). (Robiquet and Colin, Ann Chim. Phys [2] 1, 343; Regnault, *ibid.* 71, 355, Kuhlman, Annalen, 33, 108; Lowig, Pogg Ann 14, 346, Gm 7, 367; Gerh. 11, 308) For a table of its vapour pressure between  $-30^\circ$  and  $+100^\circ$ , see Henning, J. Soc. Chem. Ind. 1920, 1. T.

Known as far back as 1500, and its preparation described by Glauter in 1648. From alcohol by the action of  $S_2Cl_2$  or metallic chlorides (Rouelle [1759]), from alcohol and HCl (Basse [1801]). Composition first ascertained by Robiquet and Colin—Also formed by action of Cl upon  $C_2H_6$  (Darling, Annalen, 150, 216), and of HCl upon ether in scaled tubes (Berthelot)

The action of HCl upon alcohol gives a very poor yield of C<sub>2</sub>H<sub>5</sub>Cl, unless ZnCl<sub>2</sub> is added to the alcohol before passing in HCl (droves, Chem Soc Trans 1874, 636) Kiuger (J pr Chem [2] 14, 193) recommends that a mixture of 1 part of ZnCl<sub>2</sub> in 82 parts of alcohol should be saturated with HCl gas in the cold, and then heated to boiling, HCl being passed in during distillation. A reflux condenser stops the alcohol vapour, and the C<sub>2</sub>H<sub>5</sub>Cl passes on and is collected in a well-cooled receiver.

The formation of  $\mathrm{C_2H_5Cl}$  in this process is partly due to the action of HCl upon alcohol, and partly to the umon of the nascent  $\mathrm{C_2H_4}$  with HCl (Schorlemmer, Chem Soc Trans 1875, 308), this view is sustained by the fact that if amyl alcohol be thus treated, both primary and secondary amyl alcohol are produced, and the latter can only be formed from the radical  $\mathrm{C_5H_{10}}$  Ethyl (bloride is also formed by the action of PCl<sub>5</sub> upon alcohol, and also, to some extent, by the action of Cl upon alcohol. Hence the formation of ethyl chloride in the manufacture of chloral

It is a colourless mobile liquid, has a pungent ethereal smell, and a sweetish taste, is inflammable and burns with a green-edged flame, evolving HCl. It is spaingly soluble in water (1 pirt in 3000), but mixes readily with alcohol and ether. It dissolves phosphorus, sulphui, fats, oils, and many resins. It combines with many metallic chlorides—eg SbCl<sub>5</sub>, Fe<sub>2</sub>Cl<sub>6</sub>—to form crystalline compounds. Mainly used for Ethylation in the manufacture of dye stuffs and drugs, and as a refingerant and solvent

It is used in medicine like ether, but, on account of its volatility, it is mixed with an equal volume of alcohol, and is then known as 'alcoholised muriatic ether, B.P.' It is decomposed at a red heat into  $C_2H_4$  and HCl, at higher temperatures carbon separates, and ('H<sub>4</sub>, H, and HCl are set free Strong HNO<sub>3</sub>, when boiling, liberates HCl and forms  $C_2H_5NO_3$  in small quantity (Thénard, Boullay) SO<sub>3</sub> absorbs it, forming SO<sub>3</sub>  $C_2H_5Cl$ , a fuming liquid, bp. 130°—probably the three isomerides  $C_2H_5O$  SO<sub>2</sub> Cl, CH<sub>2</sub> ClCH<sub>2</sub> SO<sub>2</sub> OH, and CH<sub>2</sub>(OH) CH<sub>2</sub>SO<sub>2</sub> Cl (Purgold, Zeitsch Chem 1868, 669; Ber. 6, 502). When vapour of  $C_2H_5Cl$  is passed through boiling  $H_2SO_4$ , HCl is evolved (Thénard), also  $C_2H_4$  and SO<sub>2</sub> (Boullay). When the vapour is led through a tube containing heated soda-lime, a mixture of CH<sub>4</sub> and H is evolved, and NaC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> and Na<sub>2</sub>CO<sub>3</sub> are formed (L. Meyer, Annalen, 139, 282), while, according to Dumas and Stas,  $C_2H_4$  and Macl are formed. On

AgNO<sub>3</sub>,C<sub>2</sub>H<sub>5</sub>Cl has no action until after prolonged contact, but even after some months only a very small quantity of AgCl is formed (Thénard, Boullay); but AgCl is rapidly thrown down when C2H5Cl is heated with a solution of AgNO, in sealed tubes (G. C. Foster)

Heated with bromine and non wire at 100° C<sub>2</sub>H<sub>5</sub>Rr and ethylene dibromide are formed (V Meyer and Petrenko-Kutschenko, Ber 25, 3307

NH, has only a slight action at ordinary temperatures, but on heating a mixture of NH3 and C2H5Cl, ethylene and a deposit of NH4Cl are formed (Dumas and Stas, Ann Chim Phys 73, When a mixture of ethereal NH, and C2H5Cl is exposed to sunlight, crystals of ethylamine hydrochloride separate (Stas) When heated with alcoholic  ${\rm NH_3}$  to  $100^\circ$  in sealed tubes,  $\overline{NH_2(C_2H_5)}$ ,  $\overline{HCl}$  is also produced, together with traces of  $\overline{NH(C_2H_5)}_2$ ,  $\overline{HCl}$  and  $\overline{N(C_2H_5)}_3$ ,  $\overline{C_2H_5}$  (Groves, Chem Soc Trans. 1861, 13, 331) KOH slowly removes Cl from C<sub>2</sub>H<sub>5</sub>Cl, yielding (in aqueous sol ) alcohol and KCl Alcoholic KOH and C<sub>2</sub>H<sub>5</sub>Cl heated to 100° in sealed tube deposits KCl and forms ( $C_2H_5$ )<sub>2</sub>O (Balard, Ann Chim Phys [3] 12, 302). Passed into heated sol of  $K_2$ °, ethyl sulphide is formed, with alcoholic KHS, mercaptan is formed (Reg-

Chlorine in the sunlight yields di-, tri-, tetra-, penta-, and hexa- chloro- derivatives of ethane (Regnault), of the dichloro- derivatives CH3 CHCl2 is the main product. If, however, ethyl chloride is heated with a halogen carrier, CH2CI CH2CI is the chief product (D Ahns and Kautzsch, J pr Chem [2] 1909, 80, 305, Staedel ibid 303; Ber 6, 1403, Meyer and Muller, J pr Chem [2] 46, 161)

Trichlorethane C<sub>2</sub>H<sub>3</sub>Cl<sub>3</sub> 1 Chlorethylene chloride CH<sub>2</sub>Cl CHCl<sub>2</sub>, b p 115° (Pierre, Annalen, 80, 127), 113 7° at 760 (Stadel, Ber 15, 2563), 113 5°-114° at 753 2 (Schiff, Annalen, 220 97), sp gr 1 4223 at 0° (P), 1 4577 at 9 4°/4°, 1 2945 at 113 5°/4° (Schiff, 1 4406 at 25 6°,  $\mu_{\rm A} = 1$  4719 at 22°  $R_{\infty}=42.26$  (Kanonnikow), from  $C_2H_3Cl$  (Regnault, Ann Chim Phys [2] 69, 151), or CHCl, CH, (Meyer and Muller, J pr Chem [2] 46, 174), and SbCl.

2 Ethenyl trublorude ('H<sub>3</sub> CCl<sub>3</sub>; bp 74 5° (Geuther, J 1870, 435), 74 1° at 760 mm (Stadel, Ber 15, 2563), spgr 1 3465 at 0° (Pierre, Annalon, 80, 127), 1 372 at 16° (Regnault, Annalen, 33, 317), 1 3657 at 0°, 1 3249 at 26°;  $\mu_{\rm A} = 14199$  at 21°,  $R_{\rm C} = 42$ 0 (Kanon-level),  $R_{\rm C} = 42$ 0 (Kanon-le nikow); by the chlorination of ethyl chloride (Regnault, ibid 33, 317) Decomposed by sodium ethoxide, giving C2H2Cl·O C2H5, C2H4O2,

and C<sub>2</sub>H<sub>3</sub>(OEt)<sub>3</sub>.

Tetrachlorethane C<sub>2</sub>H<sub>2</sub>Cl<sub>4</sub>.

 $1~as\text{-}\mathrm{CH_2Cl}~\mathrm{CCl_3}$ , b.p.  $135^\circ$  (Regnault, Ann Chim Phys [2] 69, 162), 138 6° (Pierre, Annalen, 80, 130), 135 1° (corr) (Geuther, Brockhoff, J. 1873, 317); sp gr 1 6116 at 0° (P), 1 576 at 19° (R), 1 5825 at 0°, 1 5424 at 26°,  $\mu_{\rm A}$ ab  $t^{\circ} = 14772 - 0000437t$ ;  $R_{\infty} = 5072$  (Kanonnikow). Formed by chlorination of ethyl chloride (Laurent, Annalen, 22, 292), or action of Cl upon CH<sub>2</sub>Cl CHCl<sub>2</sub> (Regnault), by heating at 110° acetylene tetrachloride and AlCl<sub>3</sub> (Mouneyrat, Bull. Soc. chim. 1898, 19, 499).

Decomposed by sodium ethoxide

Decomposed by somular convaries  $C_2HCl_2 O C_2H_5$  and  $CH_2(OC_2H_5)CO_2Na$ . 2. s-CHCl<sub>2</sub> CHCl<sub>2</sub>; b p 147 2°, sp gr. 4°/4° =1 6208, 17°/17° =1 6013,  $\mu_D$  at 17° = 1 495587 $\pm$ 0 000006 (Veley, Proc Roy. Soc. 1910, B 82, 217), R $\propto \pm$ 50 6 (Kanoninkow). From C2H2 and SbCl5 (Berthelot, Jungfleisch, Annalen, Suppl 7, 254), from dichloraldehyde and PCl<sub>5</sub> (Paterno, Pisati), from ethylene chloride and AlCl<sub>5</sub> at 75° if Cl and C<sub>2</sub>H<sub>5</sub> be led into the mixture (Mouncyrat), by long heating

yields HCl and C<sub>6</sub>Cl<sub>6</sub>

If S<sub>2</sub>Cl<sub>2</sub> and I p c of its weight of reduced iron be saturated with (I, and if the excess (I be removed with CO<sub>2</sub>, and then dry acetylene be passed in at a temperature of 40°, and the cycle repeated until no more C<sub>2</sub>H<sub>2</sub> is absorbed, sym-tetrachloroethane, pentachloroethane, and hexachloroethane are produced, the two latter m small quantity (Michel, Zeitsch angew Chem 1906, 19, 1095) The sym-tetrachlorethane is distilled off from the mixture, either alone or ın steam (D. R. P. 174068), Chem. Soc. Absti 1906, 1 169)

Pentachlorethane CHCl<sub>2</sub> CCl<sub>3</sub>, b p 159 t° (corr), 161 7° at 760 mm (Stadel), mp. 18, sp.gr. 1 7089 at 0°, 1 6926 at 10 15 '/4" (Therpe, Chem Soe Trans 37, 192),  $\mu_{\Lambda}=1.4871$  at 251°,  $R_{\infty}=59.05$  (Kanonnikow) By action of chlorine upon C2H3Cl also from chloral and PCI, (Paternò, Annalen, 151, 117), or AlCI, (Mouneyrat, Bull Soc chim 1898, 19, 260)

Hexachlorethane CCLCCL trichloride, art CARBON)

(For mixed halogen derivatives of ethane, see Mouneyrat, Bull Soc chim 1898, 19, 499, Swartz, Rec trav chim 17, 234 and 235, Bull Acad Roy Belg 36, 519, ibid 1909, 60 and 728, ibid 1899, n 281, Elbs and Newmann, J. pt. Chem 1898, 58, 245, Biltz, Bci 1902, 35, 3524, Lemoult, Compt. 1end. 1903, 136, 1333. Besson, Bull. Soc. chim. [3] 11, 920. Nef, Annalen, 298, 353, 354, 358, and 360, Thiele and Peter, dud 369, 149 Lawrie, Amer Chem J 1906, 36, 487)

Ethyl isocyanate. F theyl  $C_2H_5N$  C O, bp 60°, sp gr 0.8981, heat of formation (Lemoult, Compt rend 1898, 126, 43); absorption spectrum (Hartley, Dobbie and Walker, Chem Soc Trans 1901, 856). By the action of dry KCNO upon  $\mathrm{KC_2H_5SO_4}$  at 180°-250° (Wurtz, Ann Chim Phys 1854 [3] 42, 43), distillate is a mixture of isocyanate and isocyanurate, which can easily be separated by By passing CNBr into absolute distillation alcohol and ether (Ponomarew, Bei 1882, 15, 515, Mulder, Rec trav chim 1, 210, 2, 133) by passing CNBi (Mulder, ibid 3, 306) or CNC1 (Cloez, Compt rend 44, 428, Annalen, 102, 355) into C<sub>2</sub>H<sub>5</sub>ONa in absolute alcohol, by the action of diazomethane on sym-ethylmtrousea (Degner and Pechmann, Ber 1897, 30, 653), by heating the mercuic chloride derivative of ethyl thiolcarbamate (Anschutz, Annalen, 1908, 359, 202)

In 1895 Nef (ibid 287, 310) showed that the compound hitherto known as ethyl cyanate was ethyl isocyanate. Ethyl isocyanate is a mobile It is decomliquid having a suffocating smell posed by water into diethylcarbamide, and by ammonia into ethylcarbamide

Ethyl cyanide. Propionitrile  $C_2H_3C:N$ ,

m.p -103 5° (Schneider, Zertsch. physikal. Chem 22, 233), bp. 98 1° (corr.) (Engler, Annalen, 133, 153), 97 08° (corr.) (Thorpe, Chem Soc. Trans 37, 205), sp. gr. 0 8010 at 0°, 0 7938 at 7 36°/4° (Thorpe), 0 7015 at 97°/4° (Schiff, Ber 19, 567), H. C. 440 7 Cals (Berthelot and Petit. Compt. rend. 108, 1217). Latent lot and Petit, Compt rend 108, 1217), latent heat of vapoursation (Louguinine, Chem Zentr 1900, 1 451), molecular refraction 25 10 (Bruhl, Zeitsch physikal Chem 16, 214; Eykman, Rec trav chim 12, 172, Costa, J. 1891, 336); magnetic rotation (Perkin, Chem Soc. Trans 55, 701), cut temp 2912°, crit. density 0 2401 (Ter-Gazaman, J. Chim. Phys. 1906, 4, 140)

From Ba(C<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>)<sub>3</sub> and KCN (Pelouze, Annalen, 10, 240), from cyanogen chloride and Zn(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> (Gal, Zeitsch Chem 1868, 252), from Zn(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> and (CN)<sub>2</sub> (Frankland and Graham, Chem. Soc. Trans. 37, 740), from proponamide and P<sub>2</sub>O<sub>5</sub> (Dumas, Malaguti and Leblanc, Annalen, 74, 329) By heating ethyl socyanide to 240° (Nef, ibid 280, 296)

Preparation—By heating C<sub>2</sub>H<sub>5</sub>I with pure KCN and alcohol to 180°, C<sub>2</sub>H<sub>5</sub>Cl dissolved in three times its weight of alcohol is heated with KCN to 100° or 150° (Rossi, Annalen, 159, 79) C2H5I is heated with KCN in closed tubes to 180°, and the product distilled, and the distillate is freed from excess of C2H51 by means of a solution of CaCl2, upon which the C2H5CN swims, while the heavier  $C_2H_5I$  sinks to the bottom (Williamson, Phil Mag [4] 2, 205, Gauthier, Ann Chim Phys [4] 17, 180)

It is a mobile colourless liquid with an agreeable odour, soluble in water, from which CaCl, or NaCl causes it to separate, miscibility with water (Rothmund, Zeitsch physikal Chem 26, 453), V D 1 928 It combines with the hydracids, e q HCl, the product  $C_3H_5NHCl$ forms monoclinic prisms soluble in water and melting at 121° (Gauthier) HCl gas passed into a well-cooled solution of the cyanide in acetic acid gives acetyl chloride and C<sub>2</sub>H<sub>5</sub>CONH<sub>2</sub>,HCl (Colson, Bull Soc chim [3] 17, 57) Chlorine combines with C<sub>3</sub>H<sub>5</sub>N to form dichlorpropionitile CH<sub>3</sub> CCl<sub>2</sub> CN, a liquid body, b p 103°-107°, which polymerises on standing to a solid  $(C_3H_3Cl_2N)_3$  Propionitrile also forms compounds with metallic chlorides and with cyanogen chloride C<sub>3</sub>H<sub>5</sub>N CNCl is a liquid decomposed by water, b p 60°-68° (Hencke, Annalen, 106, 280) Compounds with AlCl<sub>3</sub> (v Perrier, Compt rend 1895, 120, 1423) Propionitrile is hydrolysed by acids or alkalis yielding propionic acid, electrolytic reduction yields n-propylamine (Ahiens, Zeitsch Elektrochem 1896, 3, By the action of metallic sodium, polymerisation ensues, the products being sodium cyanide, ethane, and α-iminopropionylethyl cyanide (Meyer, J. pr. Chem. [2] 38, 326, 45, 63)

Ethyl isocyanide, Ethylcarbylamıne C<sub>2</sub>H<sub>5</sub>N C; b p 79°; sp gr. 0 759 at 4°, 0 7150 at 44 5° (Gauthier, Ann Chim Phys. [4] 17, 233); molecular refraction 16.26 (Costa, Gazz. chim. ital 22, i 104) By the interaction of C<sub>2</sub>H<sub>5</sub>I and AgCN (Gauthier, Annalen, 151, 239), by distilling KCN with KC2H5SO4, propionitrile also being formed; by digesting ethylamine with chloroform and alcoholic potash (Hofmann, ibid. 147, 107).

It is a colouriess liquid having a very repulsive smell. It is transformed into propionitiile by heating at 240°, by heating with alcoholic H.S ethylthioformamide is produced; with sulphur and CS, ethylthiocarbimide; combines with CNCl, with C<sub>2</sub>H<sub>5</sub>Cl at -10° yields C<sub>2</sub>H<sub>5</sub>N(Cl)O C<sub>2</sub>H<sub>5</sub> (Nef, *ibid*. 280, 296). HgO oxidises it to C<sub>2</sub>H<sub>5</sub>N . C: O. Yields a chloride C<sub>2</sub>H<sub>5</sub>N (Cl<sub>2</sub>) by treatment with SO<sub>2</sub>Cl in ether at -15°, an oil, bp 102° (Nef, *lc*) Yields a bromide, C<sub>2</sub>H<sub>5</sub>N (Br<sub>2</sub>, with bromine in This gives ethylamine dibromide with water, ethyl isocyanide dibromide hydrobromide and ethylthicarbimide with H,S, ethyl isocyanide dibromide hydrochloride with dry HCl, an only ethnodide with ethyl rodide, and diphenylethylguanidine with aniline (Guillimand, Bull Soc chim 1904, in 31, 605, 1905, in 33, 652) Compounds with cobaltous, ferious, and ferric chlorides (v. Hofmann and Bugge, Ber. 1907, 40, 3759) (For further reactions, v. Nef, l.c)

Ethyl derivatives of cyanuric acid. Although cyanuric acid exists in only one modification, probably the 180-(11) esters derived from the tautomeric forms (I. and II.) are known.

Ethyl cyanurate (C<sub>2</sub>H<sub>5</sub>OCN)<sub>3</sub>, mp 29°, b p 275° (Claesson, J. pr Chem [2] 33, 131) By action of CNCl on C<sub>2</sub>H<sub>5</sub>ONa (Hofmann. By action of CNCI on C<sub>2</sub>H<sub>5</sub>ONa (Hofmann. Ber 19, 2061), also from C<sub>2</sub>H<sub>5</sub>ONa (3 mols) and trimethyl cyanurate (H), from CNI of CNBr and C<sub>2</sub>H<sub>5</sub>I (Ponomarew, Bull Soc chim [n] 41, 315), by heating the lead salt of the diethyl ester (P.), together with ethyl isocyanurate by treating silver cyanurate with C<sub>2</sub>H<sub>5</sub>I (C, P); from di-potassium cyanurate and C<sub>2</sub>H<sub>5</sub>I (P)

Oily liquid readily soluble in alcohol, ether, CHCl3 and CS2, sparingly so in water Converted into ethyl isocyanurate by long heating at  $180^{\circ}-200^{\circ}$ , yields cyanuric acid with HCl, cyanuric chloride with PCl<sub>5</sub>, melamine with strong ammonia and the diethyl ester with

baryta water

Diethyl cyanurate, Diethylcyanuric acid HO(CN)<sub>3</sub>(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> (Ponomarew, Ber 18, 3267, Hofmann, *ibid* 19, 2077) By warming ethyl cyanurate with concentrated baryta water, by treating methyl cyanulate or mono-potassium cyanurate with C2H5I

Thick plates from water, insoluble in ether, sparingly soluble in alcohol Decomposes on heating into diethyl isocyanurate, yields cyanuric acid on warming with HCl. Pb salt and  $C_2H_5I$  yield triethyl cyanurate, but if C<sub>2</sub>H<sub>5</sub>I contains free I, triethyl isocyanurate also formed.

Ethyl isocyanurate, Triethylcarbimide (C<sub>2</sub>H<sub>5</sub>NCO)<sub>3</sub>, mp 95°, bp 276°, absorption spectrum (Hartley, Dobbie and Walker, Chem. Soc Trans. 1901, 849), heat of formation (Lemoult, Compt rend. 125, 869) By polymerisation of  $C_2H_5NCO$  (H. D and W.); also from potassium cyanate or cyanurate, or from

Pb salt of the diethyl ester and KC<sub>2</sub>H<sub>5</sub>SO; parts of H<sub>2</sub>SO<sub>4</sub>, 5 parts H<sub>2</sub>O, and 15 parts of by heating ethyl cyanurate at 180°-200°; alcohol (85 pc) (Stinde, Dingl. poly. J 181, together with ethyl cyanurate from silver cyanurate and C2H I (Habich and Limpricht, Annalen, 109, 102)

Rhombic prisms (Rammelsberg, J. 1857, 273; Fock, Ber 19, 2076) moderately soluble in hot water, readily so in alcohol. KOH yields N(C<sub>2</sub>H<sub>5</sub>)H<sub>2</sub> and K<sub>2</sub>CO<sub>3</sub>.

Diethyl isocyanurate, Diethylcyanuric acid H(NCO)<sub>3</sub>(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>, mp 173° Obtained in preparing the triethyl ester (Habich and Limpricht, Lc); together with cyanuric acid by heating anhydrous mono-potassium cyanurate with  $C_2H_5I$  at  $170^\circ-180^\circ$  (Ponomarew, Ber 18, 3270); by heating diethyl cyanurate (Hofmann, ıbıd. 19, 2078)

Hexagonal columns, readily soluble in hot water, alcohol, and ether, sparingly so in cold water. Yields  ${\rm CO_2}$  and  ${\rm N(C_2H_5)H_2}$  by heating in a scaled tube at 100°. Pb salt and  ${\rm C_2H_5I}$ yield ethyl isocyanurate

Ethyl diketobutyrate v Ketones
Ethyl ferrocyanide (C<sub>2</sub>H<sub>7</sub>)<sub>4</sub>Fe(CN)<sub>6</sub> From
Ag<sub>s</sub>Fe(CN)<sub>6</sub> and C<sub>2</sub>H<sub>5</sub>I (Freund, Ber 21, 935)
Rhombic crystals from CHCl<sub>2</sub>, easily soluble in water and alcohol, insoluble in ether, ligroin, and  $\mathrm{CS}_2$  Decomposed at  $212^\circ-214^\circ$ , with formation of ethyl isocyanide. The aqueous solution gives a deep violet tint with FeCl3, and a white precipitate with HgCl<sub>2</sub> Molecular weight by eryoscopic method indicates the monomolecular formula (Buchbock, Zeitsch physikal Chem

Ethyl fluoride C,H,F Obtained impure by action of CaF, and H,SO, upon C, H,OH (Reinsch, J pr Chem 1840, 19, 314); by heating KC<sub>2</sub>H<sub>5</sub>S<sub>4</sub> and KFHF (Fremy, Compt rend 1854, 38, 393) Prepared pure from AgF and C,H, I (Moissan, Ann Chim Phys 1890, [6] 19, 272) Colourless gas with ethereal odour, liquefying at  $-32^{\circ}$  under atmospheric pressure Burns in air with a blue flame Readily soluble in  $C_2H_5Br$ ,  $C_2H_5I$ ,  $C_2H_5OH$ , and other Decomposed at  $100^\circ$  by heating with KOH in a scaled tube into KF, C, H, ()H, and ether

Ethyl formamide H CONHC, H<sub>5</sub>; bp 199°, sp gr 0 952 at 21° By distilling an aqueous solution of H COONH<sub>3</sub>(C<sub>2</sub>H<sub>5</sub>); separates from distillate upon addition of KOH (Linnemann). By action of NH<sub>2</sub>(C<sub>2</sub>H<sub>5</sub>) upon CCl<sub>3</sub> CHO (Hofmann, Ber. 5, 247); a thick colourless

Ethyl formate H CO<sub>2</sub>C<sub>2</sub>H<sub>5</sub>; b p 54 4° at 760 mm., sp.gr 0 9376 at 0°/4°; b p 53 4°-753.6° at 754.4 mm, sp.gr. 0.8731 at  $53.4^{\circ}/4^{\circ}$  (R. Schiff, Annalen, 220, 1063), b p at 760 mm 54.3°, sp.gr. 0.9480 at  $0^{\circ}/4^{\circ}$ , critical temperature, 235.3°; critical pressure, 35,550 mm (Young and Thomas, Chem. Soc. Trans. 1893, 1003) 1193). Capillarity constant at boiling-point, a2 = 4 528 (Schiff, Annalen, 223, 75); H C p 388 cals. (Berthelot, Ogier), 391 7 (Delépine)

By distilling a mixture of 6 parts alcohol (90 o c), 7 parts sodium formate and 10 parts (conc) H<sub>2</sub>SO<sub>4</sub> (Liebig), by distilling a mixture of ethyl oxalate with oxalic acid (Lowig, J 1861, 599), by heating a mixture of glycerol, oxalic acid, and alcohol in a reflux condenser, and then distilling (Lorin, Bull. Soc chim [ii ] 5, 12) On the large scale a mixture of 9 parts of starch and 29 parts of MnO<sub>2</sub> (of 85 pc) is heated with 20

- A mobile colourless liquid with a pleasant aromatic smell; is used for flavouring arrack and rum; is decomposed by water, for which it has strong affinity Sodium in absolute ether decomposes it into CO, H and C<sub>2</sub>H<sub>5</sub>ONa (Freer and Sherman, Amer Chem. J 18, 581) Cl forms with it in sunlight dichlorethyl formate H CO2C2H3Cl2, a colourless only liquid, decomposed on heating, and which by action of alkalis is decomposed into acetic, formic, and hydrochloric acids—By further action of (I in sunlight, perchlorethyl formate Cl CO2C2Cl5, b p 200°, sp gr 1 705 at 18°, is formed (Clove, Ann Chim Phys [3] 17, 297)

Ethyl hydrate v ALCOHOL

Ethyl hydride, Ethane, Dimethyl  $C_2H_6$  (Frankland and Kolbe, Chem Soc Trans 1, 60), m p. -171 4°; b p at 749 mm -85 4° (Ladenburg and Krugel, Ber 32, 1821), -172 4° and -84·1° (Cardoso and Bell, J Chim Phys 1912, 10, 497), -88 5° (Mass and McIntosh, J. Amer Chem. Soc. 1914, 36, 737), -89 3° (Burrell and Robertson). Gas: sp gr 1 036, condensed at 4° and 46 atmospheres pressure (Calletet, J Annalen, 282, 245; Olszewski, Ber 1894, 27, 3306, and Keunen, Chem Zentr 1897, 11 540; Cardoso and Bell, lc), heat of vaporisation 146+1010 ergs per mol; density at the bp 0 5490 (Maass and McIntosh, lc); sol in water at  $t^{\circ}$ 

(1) 
$$\frac{94556-035324t+0006278t^2}{100}$$
  
(2)  $8710-033242t+000603t^2$ 

(1) Schickendants (Annalen, 109, 116), (2) Bunsen (Gasometry) Sol in alcohol=1.5 (Berthelot, J 1867, 344); H (' p 373 3 ('als. (Th)=372 3 (Berthelot, Ann (him Phys [6] 30, 559); H.F (from amorphous C)=11.7Cals (B); occurs in crude petroleum

Pittsburg gas consists of ethane mixed with a little CH<sub>4</sub> and CO<sub>2</sub>, and is used for smelting

and lighting purposes.

By action of K upon C<sub>2</sub>H<sub>5</sub>(N, also by action of water upon Zn(C<sub>2</sub>H<sub>3</sub>), (Frankland and Kolbe, Chem Soc Trans 3, 338); by action of Zn upon C<sub>2</sub>H<sub>5</sub>I in presence of water; by electrolysis of acetic acid or acetates (Kolbe, Annalen, 69, 279), by heating 9 parts of  $C_2H_5I$  with 2.6 parts of AlCl<sub>3</sub> to 140° or 150° (Kohnlein, Ber 16 562); by action of  $Hg(C_2H_5)_2$  upon  $H_2SO_4$  (Schorlemmer, Annalen, 132, 234); by heating an excess of BaO2 with acetic anhydride and sand (Schutzenberger, Zeitsch Chem 1865, 703; Darling, Annalen, 150, 216), by the action of nascent H (from ZnCu couple or Zn dust) upon a mixture of C<sub>2</sub>H<sub>5</sub>I and C<sub>2</sub>H<sub>5</sub>OH (Sabanejeff, Ber 9, 810). By combining C<sub>2</sub>H<sub>4</sub> or C<sub>2</sub>H<sub>2</sub> with H in presence of reduced Ni (Sabatier and Senderens, Compt. rend 124, 1360; 128, 1173) Ethane is now produced on an industrial scale by means of this reaction carried out under pressure details of the process, see Sprent (J Soc Chem Ind 1913, 171) From EtI and potassium hydride in sealed tubes at 180°-200° (Moissan, ibid 134, 389) Reduced Ni at 325° breaks ethane up into C and CH4 (Berthelot)

Ethyl iodide  $\rm C_2H_5I$  (Gay-Lussac, Ann. Chim. Phys [1] 91, 89, Serullas, *ibid.* [2] 25, 323 and 42, 119; Frankland, Chem Soc Trans 2, 263; 3, 32), mp -118° (Schneider); bp 72·34° (Linnemann, 70.770), bp. 71·3° (Andrews), 72 57° (corr ) (Thorpe and Rodger), 71 9°-72° (Lanebarger); sp gr 1 9444 at 14·5° (L), 1 9755 at 0° (Pierre), 1 9309 at 15° (Mendeléeff), sp gr 1 1810 at 72 2°/4° (Schiff), sp gr 1 9653 at 4°, 1 9433 at 15°, 1 9243 at 25° (Perkin), V D 5 417 (Marchand)

From alcohol and HI (Gay-Lussae); from alcohol, iodine, and phosphorus (Sciullas). Personne (Compt rend 42, 468) suggested the use of red P, and, according to Beilstein (Annalen, 126, 250), I part 1cd P and 5 parts of alcohol (90 pc) are placed in a retort, and 10 parts of iodine slowly added After 24 hours the C2H5I is distilled off, washed with NaOH solution and with water, and dried over CaCl, Cusmer (Ber 1884, 649) dissolves I in liquid paraffin adds yellow P and then alcohol Walker (Chem Soc. Trans 1892, 717; cf ibid 1905, 1596) obtained a 93 pc yield from alcohol, iodine, and equal parts of ied and yellow phosphorus (cf Adams and Voorhees, J. Amer Chem Prepared in quantitative Soc 1919, 41, 789) yield by adding Et<sub>2</sub>SO<sub>4</sub> slowly to a warm con-centrated aqueous solution of KI (Weinland and Schmid, D. R. P. 175209). Also from action of HI upon ether (Cottrel Rogers), and together with iodoform and NaI by electrolysis of a solution of 20 grams C<sub>1</sub>H<sub>5</sub>COONa, and 20 grams KI in 20  $\epsilon \epsilon$  of water (Miller, Hofer, and Reindel)

C2H5I is a colourless, pleasantly smelling liquid, almost insoluble in water, but miscible with alcohol and ether. It precipitates silver from its solutions in the cold, easily forms double compounds with silver salts, metals, and ammonia Br displaces the I, and forms C, H, Br, Cl forms C<sub>2</sub>H<sub>3</sub>Cl (Dumas, Stas, Annalen, 35, 162) ICl forms C<sub>2</sub>H<sub>5</sub>Cl and I<sub>2</sub> HCl has no action, but, on the contrary, C<sub>2</sub>H<sub>5</sub>Cl is decomposed by HI into C<sub>2</sub>H<sub>5</sub>I and HCl (Lieben, Zeitsch ('hem 1868, 712) By action of HI at 150°, ethane and iodine are formed HNO3 also causes the separation of I (Marchand, J pr Chem 1884, 33, 186) Metallic Ag abstracts I, and leaves butane (C<sub>4</sub>H<sub>10</sub>) By heating with water to 150°, we get alcohol (Reynoso, J 1856, 567), with excess of alcohol yields ether and some C, H<sub>4</sub> (Lieben, Rossi, Annalen, 158, 166). Is gradually turned brown by exposure to light, owing to formation of free I and liberation of butane (Frankland, Chem Soc Trans 3, 322) In presence of mercury the reaction is much more rapid, owing to combination of the liberated I with Hg is used largely for the preparation of other ethyl compounds

Ethyl nitrate C<sub>2</sub>H<sub>5</sub>O NO<sub>2</sub>, Nitric ether; mp -112° (Schneider), bp 86 3° at 728°4 mm; sp gi 1 1322 at 0°, 1°1123 at 15 5° (Kopp, analen, 98, 367), bp 87 6°; sp gi. 1 1305 at 4°, 1 1159 at 15°, 1 1044 at 25° (Fekin), H F p = 40,870, H F v = 38,750, H C = 325, 690 (Th 4, 214) Obtained from alcohol by the action of nitric acid in presence of some substance which will destroy nitrous acid, eg. urea (Millon, Ann Chim. Phys [3] 8, 233).

Preparation —400 grams of pure mitric acid (sp gr 1 40, previously heated with 1 pc of urea in order to destroy lower exides of nitrogen)

are mixed with 300 grams absolute alcohol and 100 grams of urea nitrate, and distilled; when half the liquid has distilled off, a mixture of 400 grams of nitric acid and 300 grams of alcohol is allowed to drop into the retort and the distillation continued (Lossen, Annalen, Suppl. 6,

Silver nitrate, heated with ethyl iodide (or bromide) and alcohol, yields, not ethyl nitrate, but the nitrite, together with aldehyde (Bertrand, Bull Soc chim 33, [n ] 566) If, however, EtI be added gradually to powdered AgNO<sub>3</sub>, kept cool, a theoretical yield of EtNO<sub>3</sub> is formed (Von Biron, J Russ Phys Chem. Soc 30, 667).

Ethyl nitrate is a colourless liquid with pleasant odour and taste; almost insoluble in water, but miscible with alcohol and ether Ammonia forms ethylamine nitrate; nascent hydrogen yields hydroxylamine and other bases (Lossen). Sulphuietted hydrogen yields mercaptan (Kopp, Annalen, 64, 320). Alcoholic potash decomposes it with separation of crystals of potassium nitrate

Ethyl nitrite C<sub>2</sub>H<sub>5</sub> O NO, Nitrous ether, b p 16 4° (Liebig), 17° (Mohr, J 1854, 561, Brown, The Harm J 15, 400), 17 5° (Dunstan and Dymond, *ibid* 18, 861), sp gr. 0.90° at 15.5° (Br); 0.917 at 0°/0° (D and D), H.F.p. = 30,610, H.F.v. = 28,870 (Th. 4, 217).

This body was discovered in 1681 by Kunckel Obtained from alcohol by action of nitric acid, especially in presence of some oxidisable matter,

eg copper

Preparation —500 grams of potassium nitrite and 1 litre alcohol (45 pc) are mixed and cooled by means of ice, a mixture of sulphuric acid (500 grams), water (500 grams), and alcohol (500 grams) is then slowly dropped in, the heat produced volatilises the ether, which is con-densed in an efficient condenser (Feldhaus, Annalen, 126, 71) Dunstan and Dymond Dunstan and Dymond (lc.) recommend that 34 5 grams sodium nitrite in 120 grams water be slowly mixed with a mixture of 13 5 grams of sulphuric acid with 32 grams alcohol and about 75 c c water kept cool by ice The ethyl nitrite separates out as a layer floating on the surface As thus prepared, the liquid contains only traces of alcohol, from which it is freed by shaking with water Alkali ethyl sulphates react with alkali nitrites, yielding nitrous ester and nitroethane (Ray and Neogi, Also formed by Chem Soc Trans 1906, 1900) the interaction of MgSO<sub>4</sub>, NaNO<sub>2</sub>, and C<sub>2</sub>H<sub>5</sub>OH (Matuschek, Chem Zeit 1905, 29, 115)

Ethyl nitrite is a mobile liquid with a pleasant ethereal smell and taste, hable to undergo decomposition, especially in presence of water It can be preserved if mixed with alcohol and a small quantity of glycerol. It is decomposed by sulphides in accordance with the following

equation:

 $C_2H_5NO_2+3H_2S=NH_3+C_2H_6O+H_2O+3S$ 

(Kopp, Annalen, 64, 321)

It is slightly soluble in water and miscible with alcohol Mixed with alcohol it constitutes the 'sweet spirit of nitre,' spiritus ætheris nitrosi, of the British Pharmacopæia, which is thus prepared. To 1000 millilitres of alcohol (90 p.c.) add gradually 100 millilitres of sulphuric acid, and then 125 millilitres of nitric acid, stirring Transfer the mixture to a retort or constantly

flask, in which 100 grams of copper in fragments have been placed, and to which is attached an efficient condenser with a receiver containing 1000 millultres of 90 p c alcohol Surround the receiver with ice-cold water and distil gently at a temperature which is at first about 77°, and rises to 80°, but does not exceed 82°, until the volume of liquid in the receiver has been increased to 1600 millilitres Then allow the contents of the retort to cool, add 25 millilitres of nitric acid, and resume the distillation until the liquid in the receiver is increased to 1700 millilitres. Mix this liquid with 1000 millilitres of the alcohol so as to make the whole contain 2 66 p c. of ethyl nitrite.

Ethyl oxalylsuccinate v Ketones

Ethyl oxide  $(C_2H_5)_2O$ , Ether, Ethyl ether, Vinic ether, formerly called Sulphuric ether, Phosphone ether, &c., according to the acid used in its preparation, mp = 117.6° (Archibald and Melntosh), mp = -112.6° (Ladenburg, and Krugel), bp 34.97° (Regnault), 34.6° at 762 mm (Schiff, Annalen, 220, 332), 34.9° (Kopp), sp gr 0.7360 at  $0^\circ$ , 0.7185 at 17.5° (Hager), 0.6950 at 34.6°/4° (Schift), 0.7024 at 15°, 0.7099 at 25°/25°, 0.7201 at 15°/15° (Perkin, Chem S.c. Trans 45, 474), sp gr 0.71982 at 15°/15° (Wade and Finnemore), sp gr 0.7183 at 17.1° (Bruhl), sp gr 0.70942 at 25° (Linebarger), MM = 4.777 at 20°, freezes at -129° to a crystalline mass, which melts at -117.4° (Olzewski, Monatsh 5, 128), capillarity constant at bp  $a^2 = 4.521$  (Schiff), S at 17.5° = 8, critical temperature, 194°, critical pressure, 35.61 atmospheres (Ramsay and Young) Vapour tension 67.49 mm at  $-20^\circ$ ; 182.34 mm at  $0^\circ$ , 286.4 mm at  $10^\circ$ ; 433.2 at 20°, 636.3 at 30°.

The preparation of ether from alcohol and sulphuric acid was first described by Valcrus Cordus (1540), and the method of making this 'oleum vitroli dulce' was published in 1552 by Conrad Gessner Frobenius, 1730, named it sulphuric ether Val Rose (Scher. J. 4, 253) showed that it contained no sulphur, but its composition was first made out by Saussure and also by Dumas and Boullay (Ann Chim Phys [2] 36, 294) Its constitution was first studied by Liebig (Annalen, 60, 31, 23, 39) and Regnault (Ann Chim Phys [2] 71, 352) Williamson, in 1850-51 (B. A. 1850, 65, and Phil Mag. [3] 37, 350), established the views now held as to its constitution and formation.

Formation — From alcohol, by action of phosphoric or arsenic acid (Boullay), by action of boron fluoride (Desfosses, Ann. Chim Phys. [2] 36, 294), of ZnCl<sub>2</sub> (Masson, Annalen, 31, 63), of SnCl<sub>4</sub>, and other metallic chlorides (Kuhlmann, *ibid* 33, 97, 192) From alcohol by heating with dry NH<sub>4</sub>Cl to  $260^{\circ}$ –400° (Berthelot, Annalen, 83, 110) From C<sub>2</sub>H<sub>5</sub>NaO and C<sub>2</sub>H<sub>5</sub>I (Williamson) From alcohol and HCl, HBr, or HI at 200° or 240°, or by heating alcohol with ZnCl<sub>2</sub>, SnCl<sub>4</sub>, HgCl<sub>2</sub>, CaCl<sub>2</sub>, MgSO<sub>4</sub>, or chrome alum to 300° (Reynoso, Ann Chim Phys [3] 48, 385) Also from C<sub>2</sub>H<sub>5</sub>I and Na<sub>2</sub>O (Green, Bull. Soc. chim [1,] 29, 458)

The continuous method now adopted is due to Boullay (J. Pharm Chim. 1, 97), and the true explanation of the action was first given by Williamson (l.c.). The alcohol and sulphuric acid

first form  $\rm C_2H_5HSO_4$  and  $\rm H_2O$ , and then, by the action of  $\rm C_2H_5HSO_4$  upon more alcohol,  $\rm (C_2H_5)_2O$  and  $\rm H_2SO_4$  are formed. That this is true Williamson proved by using amyl sulphunic acid and ethyl alcohol, when amyl-ethyl ether was produced (cf. Prunier, J. Pharm. Chim. 1897, 5, 513). Addition of  $\rm Al_2(SO_4)_3$  increases rate of production of ether owing to catalytic action (Senderens, Compt. rend. 1910, 151, 392).

Preparation -Boullay's method is usually A mixture of 9 parts H<sub>2</sub>SO<sub>4</sub> with 5 employed parts of alcohol (90 pc) is placed in a retort, and alcohol is slowly dropped in and the temperature is maintained between 130° and 140°. An iron retort lined with lead is usually employed, and the ordinary mercurial thermometer, which is, of course, liable to fracture, is replaced by a bulbed tube containing some non-drying oil. The tube is then either exhausted by the airpump, and hermetically scaled, or its open end is closed by a plug of cotton wool, and two marks are made on the tube corresponding to positions of the surface of the oil at 130° and 140° respec-In order to avoid risk of explosion by contact of the vapour with direct flame, coils of lead tubing, conveying superheated steam or the vapour of some liquid of high boiling-point (e g coal-tar phenol), are used as a source of heat The distillate is treated with milk of lime or solution of soda in order to remove the SO, which is always simultaneously formed. It is then rectified in an apparatus devised by Mohr, which consists of a still from which the vapour is led through a vessel kept at 38° by warm water Here the alcohol and water vapours are condensed, and the ether passes over, and is condensed in an efficient condenser

By means of an apparatus devised by Soubeiran, ether can be prepared in a fairly pure state by one operation. A mixture of about 30 lbs of H<sub>2</sub>SO<sub>4</sub> with 20 lbs of alcohol of 85 p c is heated rapidly to 130° in a copper still, to the bottom of which two tubes convey alcohol from a tinned copper reservoir. The neck of the retort (which is of lead) is connected with the first condenser, which is a copper vessel kept warm by allowing the waste water from the worm tub (where the ether is condensed) to flow over the outside of it Here the steam and vapour of alcohol are condensed, and the liquid formed can be drawn off from below by means of a stopcock. The ether vapour then passes on to the purifier, which consists of a vessel filled with wood charcoal saturated with a solution of caustic soda, which not only removes the SO<sub>2</sub>, but also absorbs the oil of wine The pure ether passes on, and is condensed in a well-cooled worm greatest yield of other is obtained at 140°-145°; below this temperature the yield is less, and above this much SO, is evolved (Prescott and Norton, Amer Chem J 6, 243) Other apparatus have been described by Annaratone (Fr Pat 408089; J Soc Chem 1910, 592), Fritzsche (Zeitsch anal Chem 1897, 36, 298), Barbet et fils et Cie (Fr. Pat 479435, 1914). Sulphune and has been largely replaced by benzenesulphonic acid in this preparation (Krafft, Ber 26, 2831; D. R 69115, Frdl. m. 11).

Commercial ether contains water, alcohol, aldehyde, methyl compounds, ketones, and vinyl Llcohol. A. J. Jones (Pharm. J. 1919, 103, 71)

found that in commercial samples, methyl compounds range from 0.02 to 0.06 p.c., sp.gr. 0.7182-0.7211, and ketones (as acctone) from 0.09 to 5.0 pts per 10,000 Vinyl alcohol may be removed by shaking with water or treatment with bromine, phenylhydrazine, or potassium hydroxide (Poleck and Thummel, Ber. 22, 2863), and the other impurities by treatment with dry Fe(OH)<sub>2</sub>, prepared from crystallised FeSO<sub>4</sub>, and an equimolecular weight of powdered lime (Gaborini, Bull Assoc Chim Sucr Dist 1909, 26, 1165); by treatment with potassium hydroxide and powdered potassium permanganate, and finally drying with calcium chloride (Fierz; Wade and Finnemore, Chem. Soc Trans 1909, 1842, François, Chem Zent 1897, n 144; Fritsch, Chem Zeit 1909, 33, 759) Phosphorus pentoxide may be substituted for calcium chloride (Lieben, Annalen, Suppl 7, 218) (For other methods, v Guigues, J. Pharm. Chim 1906, 24, 204, and Ekenberg, Zeitsch anal Chom 36, 245)

According to the BP, 1914, ordinary ether should have a sp gr of 0.726, 15°/15°, and boil between 34° and 36°. Purified ether (Æether purificatus of the BP) should give no yellow colouration with solid potassium hydroxide in the dark, or with a solution of freshly prepared solution of potassium iodide To test for presence of methyl compounds shake 2 vols of the ether with I vol of 20 pc alcohol and I vol. of water, allow the mixture to separate, and draw off the lower layer Mix 5 millilitres of this lower layer with 2.5 millimetres of an aqueous solution (1 in 50) of potassium permanganate and 0.2 millilitre of sulphuric acid At the end of 3 minutes add 0.5 millilitre of an aqueous solution (96 in 100) of oxalic acid, followed by I millilitre of sulphuric acid, and then by 5 millilitres of decolourised solution of fuchsin, and mix thoroughly. No violet colour should be produced within 20 minutes

Wade and Finnemore (lc) find that ether and water form a binary mixture, b p 34 15°, containing 1 3 p c water, and that slight traces of alcohol greatly increase the solubility of water in other 1 gram ether dissolves 0 023 gram water at 15°-20° and 0 019 at 10° (cf. Schunke, Zeitsch physikal Chem 14, 331; Napier, Bull Soc chim. 29 [11] 129); 1 gram water absorbs at 0°, 0 12465, at 10°, 0 09599, at 20°, 0 07487, at 30°, 0 06370 gram ether (Schunke, lc; Tolloczko, Ber 28, 808; Klobbie, Zeitsch physikal Chem 24, 615; Osaka, J. Soc Chem Ind 1909, 625). If ether be shaken with an equal volume of CS<sub>2</sub>, a turbidity is produced if water be present. A better test is with anhydrous copper sulphate or amalgamated alumınıum.

Decompositions—Pt black, CrO<sub>3</sub> or HNO<sub>3</sub> oxidise ether to acetic acid; ozone produces ethyl peroxide Ether vapour and air at 100°, in the presence of a copper catalyser and platinum-black, yield acetaldehyde and formaldehyde (Orlow, J. Russ. Phys. Chem. Soc. 1908, 40, 799; cf. Legler, Annalen, 217, 392). When ozonised oxygen is passed into ether, a solution is obtained containing  $C_2H_2O_4$ ,  $C_2H_4O_2$ , and  $H_2O_2$ , also a small quantity of  $CH_2O_2$  (A. W. Wright). Ether combines with  $H_2SO_4$  to form  $C_2H_5LSO_4$ ; by action of SO<sub>3</sub>, we first get (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>SO<sub>4</sub>, but by excess of SO<sub>3</sub>, C<sub>2</sub>H<sub>5</sub>HS<sub>2</sub>O<sub>7</sub> and a small quantity

of, a body of the composition  $CH_2(SO_3C_2H_5)_2$ are formed. When ether is heated with water and a small quantity of H<sub>2</sub>SO<sub>4</sub> to 150°-180°, alcohol is formed (Erlenmeyer, Zeitsch. Chem. 1868, 343) According to Lieben (Annalen, 165, 136), the reaction goes on, though very slowly, without H2SO4, and at the ordinary temperature Ether combines easily with HI and yields CoH, I (Silva, Ber 8, 903), and is decomposed by heating with zinc-dust into C2H4 and water (Jahn, Monatsh 1, 675), bromine and aqueous ether yield bromacetaldehyde (Maugin, Compt rend 1908, 147, 747).

Instances of the spontaneous explosion of ether on heating are not unknown, due probably to the presence of ethyl peroxide produced by autoxidation Ether occasionally contains hydrogen peroxide and acctaldelyde and a relatively large amount of vinyl alcohol (Kassner, Arch. Pharm 1912, 250, 436). Hydrogen peroxide may be detected by the immediate red colouration produced when 5 c.c is treated with 1 c c of N/10 potassium thiocyanate solution and 2 drops of a 5 pc freshly prepared acidified solution of ferrous ammonium sulphe to (Dietze, Apoth Zeit 1915, 30, 165) There should be no liberation of iodine when 2 cc. of a 10 pc solution of cadmium potassium iodide are shaken with 10 cc of the sample. Per-oxides or peroxidised compounds may be formed in ether when improperly stored. The degree of oxidation is dependent upon the nature of the container, the purity of the ether, the amount of air present, and, in the case of glass containers, the intensity of the light which accelerates the oxidation Peroxides may be removed by means of ferrous hydroxide or by shaking with mercury

Mixtures of ether vapour and air explode when heated to about 190° if the amount of ether in the gaseous mixture reaches 1 gram

A hydrate  $(C_2H_5)_2O$ ,  $2H_2O$  is known; it is a solid body, which only exists below  $-3.5^{\circ}$ , and is obtained by the rapid evaporation of aqueous obtained by the rapid evaporation of aqueous ether on filter paper (Tanret, Bull Soc chim 30, 505; Compt rend 87, 765) Dry ether and chlorine at  $-80^{\circ}$  yield a white crystalline chloride  $(C_2H_5)_2OCl_2$ , mp  $-51^{\circ}$ ; bromine similarly yields a reddish-yellow bromide  $(C_2H_5)_2OBr_2$ , m.p.  $-40^{\circ}$  (McIntosh, Chem. Soc. Trans 1905, 789) A bromide  $(C_2H_5)_2OBr_3$ , ied plates, mp 22°, is also known (Schutzenberger, Annalen, 167, 86).

berger, Annalen, 167, 86).

Ether combines with various metallic salts and forms crystalline bodies, eg BeCl<sub>2</sub>, 2(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>O, large prisms (Atterberg, Ber 9, 856); HgBr<sub>2</sub>,3(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>O (Nicklès, J. 1861, 200); AlBr<sub>3</sub>,(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>O (N.). TiCl<sub>4</sub>,(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>O; crystalline, mp 42°-45°; bp 118°-120°, decomposes into TiCl<sub>3</sub>(Oc<sub>2</sub>H<sub>5</sub>) (Bedson, Annalen, 180, 236; Chem Soc. Trans 1876, 1, 311)

Procentees—A colourless mobile bound with

Properties —A colourless mobile liquid with asant smell Volatilises very quickly, and pleasant smell by so doing produces great cold "It is extremely inflammable, and its vapour, which is very heavy, forms an explosive mixture with air Ether is readily soluble in concentrated HCl solution (Draper, Chem. News, 35, 87), and in concentrated H<sub>2</sub>SO<sub>4</sub>, from which it is separated by addition of ice (Riedel, D R P. 52982, Frdl n 551) It is miscible with almost all

organic liquids, and with liquid  ${\rm CO}_2$ . It is a good solvent for resnns, fats, alkaloids, &c., and sulphur and phosphorus dissolve in it to a small extent. It also dissolves I and many salts, e q Fe<sub>2</sub>Cl<sub>6</sub>, HgCl<sub>2</sub>, PtCl<sub>4</sub>, and many gases, not-

ably ammonia

In laboratories ether should always be kept over mercury or sodium in completely filled, well-stoppered bottles, preferably made of blue, green, or brown glass, in cool places excluded from the light (cf Baskerville and Hamor, J Ind Eng Chem 1911, 3, 301 et seq; J Soc Chem Ind 1911, 830)

Its vapour when inhaled produces insensibility (Faraday, 1818), and it is used as an anæsthetic in surgery It is also occasionally used in surgery for producing local anæsthesia, this is done by directing a spray of ether upon the skin, when the extreme cold produced by evaporation produces complete insensibility.

It is also used as a solvent in the preparation of collodion, in the extraction of tannic acids, of

several alkaloids, &c

Chlorine acts violently upon ether, setting fire to it, and liberating carbon (Cruikshank) ether be kept cool by icc, and in the dark, substitution, roducts are obtained. The Clreplaces the H atom by atom from one ethyl group first, CHHHCHHOC<sub>2</sub>H<sub>5</sub> in the following order.

(Lieben, Annalen, 111, 121; 146, 180; Abeljanz, 164, 197, Jacobsen, Ber 4, 215, also Liebig, Annalen, 1, 220; Malaguti, Ann Chim Phys [2] 70, 338; [3] 16, 5; Fritsch and Schumacher, Annalen, 279, 302)

# Monochlorether, Monochlorethyl oxide

CH, CHCl O C, H,;

bp 97°-98°, by the chlorination of ether (Lieben); by saturating a mixture of aldehyde and alcohol with HCl (Frapolli, Wurtz, Annalen, 108, 226); by the action of PCl<sub>5</sub> upon acetal (Bachmann, ibid 218, 39) It is decomposed by H<sub>2</sub>SO<sub>4</sub>into HCl<sub>7</sub>C<sub>2</sub>H<sub>4</sub>O, and C<sub>2</sub>H<sub>5</sub> OH C<sub>2</sub>H<sub>5</sub>ONa forms NaCl and acetal; water decomposes it into HCl. aldehyde, and alcohol (Laatsch, Annalen, 218, 36)

#### Dichlorether, Dichlorethyl oxide

#### CH,Cl CHCl O C,H,;

b p 140°-145°, sp gr 1 174 at 23°; by action of Clupon ether (Malaguti, Annalen, 32, 15; Wildman and Gray, J Amer Chem Soc 1919, 41, 1122); by action of HCl upon a mixture of chloraldehyde and C<sub>2</sub>H<sub>5</sub> OH (Natterer, Monatsh 5,496), by action of HCl upon chloracetal (N)

Dichlorether is decomposed on heating in a tube into  $C_2H_5Cl$  and other products  $C_2H_5ONa$  forms first *chloracetal*  $CH_2Cl$   $CH(OC_2H_5)_2$ . By heating with excess of C2H5ONa in sealed tubes, ethyl glycol acetal CH<sub>2</sub>(OC<sub>2</sub>H<sub>5</sub>)CH(OC<sub>2</sub>H<sub>5</sub>)<sub>2</sub> is formed In ethereal solution, Zn(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> yields ethyl chlorether CH<sub>2</sub>Cl CH(C<sub>2</sub>H<sub>4</sub>)OC<sub>2</sub>H<sub>5</sub>; b p 141°, sp gr 0 9735 at 0° With excess of 141°, sp gr 0.9735 at 0° With excess of Zn(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> we get CH<sub>2</sub>(C<sub>2</sub>H<sub>5</sub>)CH(C<sub>2</sub>H<sub>5</sub>)OC<sub>2</sub>H<sub>5</sub>; bp 131 4° at 749 6 mm; sp gr 0.7865 at 0° (Lieben, Annalen, 178, 14) Strong caustic potash forms alcohol, a body C<sub>8</sub>H<sub>16</sub>Cl<sub>2</sub>O<sub>3</sub>, a little glycollic acid, and two isomeric bodies of CHCCO (Abdustry 31, 164) the composition C<sub>4</sub>H<sub>9</sub>ClO<sub>2</sub> (Abeljanz, ibid. 164, 218) · α-C<sub>4</sub>H<sub>9</sub>ClO<sub>2</sub>, chloraldehyde alcoholate CH<sub>2</sub>Cl CH(OH)O·C<sub>2</sub>H<sub>5</sub>, bp 93°-95°; and β-C<sub>4</sub>H<sub>4</sub>ClO<sub>-</sub> oxychlorater CH<sub>2</sub>OH·CHCl·O·C<sub>2</sub>H<sub>5</sub>,

also formed by chlorination of ether (Jacobsen, Ber 4,217), bp 151°-155°. With NH<sub>2</sub> OH yields glyoxime (Hantzsch and Wild, Annalen, 289, 293). It is decomposed by water, and in presence of marble yields monochloracetaldehyde alcoholate, which, on distillation, gives monochloraldehyde and monochloracetal (Fritsch

Trichlorether CHCl<sub>2</sub> CHCl O C<sub>2</sub>H<sub>5</sub>; b p 167°-168°, 155°-158° (Copaux), 170°-175° (Oddo and Mameli); sp gr. 1 3303 at 14° (O and M). By the action of PCl<sub>5</sub> upon dichloracetal CHCl<sub>2</sub> CH(OC<sub>2</sub>H<sub>5</sub>)<sub>2</sub> (Krey, J 1876, 475), by hydrolysis of the compound formed by action of chlorine on triethyl boric ester (Copaux, Compt. rend 127, 721), by chlorinating ab-dichloroethyl ether with I molecule of Cl at temperature of boiling saturated salt solution At 230°-240° in a scaled tube, yields dichloroaldehyde and  $\rm C_2H_5Cl$  HCl at 110° for 6 hours, and distillation with concentrated H<sub>2</sub>SO<sub>4</sub>, yield the same products Conversely, dichloroaldehyde in alcohol with HCl yields trichloroether Boiled with water, trichloroether yields acctaldehyde, di-chloroacetaldehyde hydrate (m p 55°-56°, bp 965°-975°), dichloroacetal, and other very complex compounds (Oddo and Mameli, Gazz chim ital 33, ii 373; also ibid 36, 1 480), decomposed by heating with C.H.ONa, yielding dichloracetal

Tetrachlorether CCl<sub>2</sub> ('HCl O C<sub>2</sub>H<sub>5</sub>; b p. 189 4° at 749 1 mm, 79° at 16 mm, 189 7° at 758 7 mm.; sp gr 1 4225 at  $18^{\circ}/4^{\circ}$  (Weber and Foster, J Amer Chem. Soc 31, 1410), sp gr 1 4379 at 0°, 1.4182 at 15 2°. Formed by action of Cl upon monochlorether in contact with I (Wurtz, Vogt, Zeitsch Chem. 1871, 689), or of chloral alcoholate CCl<sub>3</sub> CH(OH)O C<sub>2</sub>H<sub>5</sub> upon PCl<sub>5</sub> (Henry, Ber 5, 101, 435, Paternò, Pisati, J 1872, 303) From trichlorvinyl ethyl ether and chlorine (Godefroy) A liquid with a camphorlike smell, decomposed by heating with water into C<sub>2</sub>H<sub>5</sub>OH, HCl, and chloral Alcoholic KOH forms with it trichlorunal ethal ether CCl<sub>2</sub> CCl O C<sub>2</sub>H<sub>5</sub> Heated with alcohol, forms trichloracetal (Pergami).

Pentachlorether. Two isomerides:

(1) CCl, CCl, O C<sub>2</sub>H<sub>5</sub>, bp 190°-210° with decomposition; spgr 1 645 (Jacobsen, Ber 4, 217); by action of Cl upon trichlorvinyl ethyl ether (r supra) (Busch, Ber 11, 445)

(2) CCl<sub>1</sub> CHCl O CH<sub>2</sub> CH<sub>2</sub>Cl; b p 235°; sp gr 1 577 at 80° By action of PCl<sub>5</sub> on a compound of chloral and glycol chlorohydrin

#### CCl<sub>3</sub> CH(OH)O CH<sub>2</sub> CH<sub>2</sub>Cl

(Henry, Ber 7, 763)

Hexachlorether  $CHCl_2$  CHCl O CHCl  $CHCl_2$ ; b p  $250^{\circ}$ , by action of PCl<sub>5</sub> upon dichloral dehyde saturated with HCl (Paterno, Pisati, J 1871, 508)

Octochlorether C4H2Cl8O, from ethylidene oxychloride and Cl in sunlight (Roth, Ber 8, Camphor-like smelling, volatile crystals

Perchlorether (C<sub>2</sub>Cl<sub>5</sub>)<sub>2</sub>O (Regnault, Annalen, 34, 27); sp gr 1 900 at 14 5° (Malaguti, Ann Chim Phys [3] 16, 4); the ultimate product of the action of CI upon ether in sunlight, is a solid, forming orthorhombic scales, m p. 69°, which possesses a smell like that of camphor Decomposed by heating at 300° into C2Cl6 and CCl3 COCl; with K2S yields perchlorvinyl ether

(C<sub>2</sub>Cl<sub>3</sub>)<sub>2</sub>O, with liberation of S (Malaguti, Ann. Chim Phys [3] 16, 19) This body is a liquid, b p 210°, sp gr 1 652 at 21°, which combines with Cl in sunlight to form (C<sub>2</sub>Cl<sub>2</sub>)<sub>2</sub>O, or with Br

vielding (C2Cl3Br2)2O

Ethyl peroxide (C<sub>2</sub>H<sub>5</sub>)<sub>4</sub>O<sub>3</sub>, produced by leading dry ozone into absolute ether (Berthelot, Bull Soc chim ii 36, 72), is a thick syrup which does not solidify at - 40°, is partially volatile on heating, but easily explodes, is miscible with water, by which it is decomposed into C2H5OH and H<sub>2</sub>O<sub>2</sub>

Ethyl phosphates.

1 . Normal ethyl phosphate (C2H5)3PO4, b p  $215^{\circ}$  , sp gr 1 072 at 12°. By action of heat on lead diethyl phosphate Pb(C<sub>2</sub>H<sub>2</sub>)<sub>4</sub>(PO<sub>4</sub>)<sub>2</sub> (Vogeli, Annalen, 69, 190), from C<sub>2</sub>H<sub>3</sub>I and Ag<sub>3</sub>PO<sub>4</sub> (Clermont, Ann Chum Phys [3] 42, 330), from PO(I<sub>3</sub> and C<sub>2</sub>H<sub>2</sub>ONa (Limpitcht, Annalen, 124, 213), from PO(I<sub>3</sub> and C<sub>4</sub>H<sub>2</sub>ONa (Limpitcht, Annalen, 124, 213), from PO(I 134, 317), from  $\stackrel{\circ}{1}{1}{20}_{5}$  and absolute elcohol (Carius, ibid 137, 121) Colourless liquid, miscible with and slowly decomposed by water, forming diethyl phosphoric acid

2 Diethyl phosphoric acid (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>HPO<sub>4</sub>, a syrupy liquid obtained by action of P<sub>2</sub>O<sub>5</sub> upon It is a monobasic acid, and forms wellmarked salts, eg  $\text{Ca}[(\text{C}_2\text{H}_5)_2\text{PO}_4]_2$ , crystalline needles . Pb[(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>PO<sub>4</sub>]<sub>2</sub>, needles , m p 180°,

soluble in water

3 Ethyl phosphoric acid H<sub>2</sub>(C<sub>2</sub>H<sub>5</sub>)PO<sub>4</sub>, an oily liquid decomposed by heating, evolving (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>O, C<sub>2</sub>H<sub>5</sub>OH, and C<sub>2</sub>H<sub>4</sub> Equal parts of alcohol (95 p c) and syrupy H<sub>3</sub>PO<sub>4</sub> are heated to 60° or 80°, diluted with water and neutralised with BaCO3, filtered, the Ba salt allowed to crystallise, and then decomposed by H2SO4 (Pelouze, Ann Chim Phys [2] 52, 37)

Also produced by action of P2O5 upon ether or alcohol or of syrupy  $\rm H_3PO_4$  upon ether (Vogeli, J 1847-48, 694) Forms crystalline salts with the metals, of these the lead salt is least soluble

Ethyl phosphites.

Triethyl phosphite (C2H5)3PO3; bp 191° (or 188° in stream of H); sp gr 1 075 at 15 5° (Railton, Chem Soc Trans 1855, 7, 216), from

PCl<sub>3</sub> and alcohol or sodium ethoxide

An ethereal-smelling liquid, which absorbs O and is converted by PCl<sub>5</sub> into PO(OC<sub>2</sub>H<sub>5</sub>)Cl<sub>3</sub>, PCl<sub>3</sub>, and C<sub>2</sub>H<sub>5</sub>Cl (Geuther, Hertz J 1876, 207) By heating with NaOC<sub>2</sub>H<sub>5</sub> yields Na(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>PO<sub>3</sub>; with (C<sub>2</sub>H<sub>5</sub>O)<sub>2</sub>O, gives

H<sub>2</sub>(C<sub>2</sub>H<sub>5</sub>)PO<sub>3</sub>

(Jaehne, Annalen, 256, 269).

2 Duthyl-phosphorous acid H(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>PO<sub>3</sub>; b p 184°-185°, sp gr 1 0749 (15 5°/4°) From P<sub>4</sub>O<sub>6</sub> and C<sub>2</sub>H<sub>3</sub>OH (Thorpe and North, Chem Soc Trans 1890, 634); from PCl<sub>3</sub> and C<sub>2</sub>H<sub>5</sub>OH (Levitsky, J Russ Phys Chem Soc 1903, 35, 211, Milobendzi and Sachnowski, Chem Soc Abst 1918, 1 477), from  ${\rm C_2H}_5{\rm I}$  and  ${\rm Pb_3(PO_3)_2}$  (Michaelis and Becker, Ber 1897, 1005). Colourless mobile liquid with an alliaceous odour

3 Ethyl-phosphorous acid  $H_2(C_2H_5)PO_3$ , very unstable syrupy liquid; obtained by action of PCl<sub>3</sub> upon weak alcohol (Wurtz, Ann Chim Phys [3] 16, 218). The salts do not crystallise well, but are more stable than the acid

Chlorule of ethyl-phosphorous acid C<sub>2</sub>H<sub>5</sub>POCl.; b p 117 5° (corr); sp gr 1·30526 at 0°/4° (Thorpe, Chem Soc. Trans. 37, 346); from PCl<sub>3</sub>

and C<sub>2</sub>H<sub>5</sub>·OH (Menschutkin, Annalen, 139, 343); decomposed by water into HCl, C<sub>2</sub>H<sub>5</sub> OH, and H<sub>3</sub>PO<sub>3</sub>; also by heating to 165° into C<sub>2</sub>H<sub>5</sub>Cl, P, PCl<sub>3</sub>, and P<sub>2</sub>O<sub>5</sub> (Chambon, J 1876, 205)

Diethyl pyro-phosphorous acid is not known, but the zinc salt  $(C_2H_5)_2P_2O_5Zn$  is not known, but the zinc salt  $(C_2H_5)_2P_2O_5Zn$  is produced when  $Zn(C_2H_5)_2$  is heated with  $P_2O_5$  to 140° (Dilling, Zeitsch Chem 1876, 266)

Ethyl selenic acid C<sub>2</sub>H<sub>5</sub>HSeO<sub>4</sub>, very unstable, produced from H<sub>2</sub>SeO<sub>4</sub> and C<sub>2</sub>H<sub>5</sub>OH (Fabian, Annalen, Suppl 1, 244). The salts are also unstable, the most permanent being the strontium salt, they can be crystallised with the ethyl-sulphuric acid salts

Ethyl selenhydrate, Ethyl selenomercaptan  ${
m C_2H_5SeH}$  , b p 53 5°; sp gr 24°/4° 1 3954 (Tschugaeff, Ber 1909, 42, 49) From ethyl iodide and sodium hydroselenide Nauscous-

smelling liquid

Ethyl selenide, Selenethyl  $(C_2H_5)_2Se$ : b p 108°, discovered by Lowig (Pogg Ann 37, 552) By action of  $K_2Se$  upon  $(C_2H_5)_2C_2O_4$ (L), by action of K('2H5SO4 upon K2Se (Joy, Annalen, 86, 35; Rathke, ibid 152, 210), crude product is then distilled again with KOH, C<sub>2</sub>H<sub>5</sub>HSO<sub>4</sub>, and a small piece of P or S (Pieverling, ibid 185, 331, Ber 9, 1469) A colourless mobile liquid with a not unpleasant smell, is insoluble in water, acts as a base . H(I precipitates from a solution in dilute  ${\rm HNO_3}$  an oily liquid (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>SeCl<sub>2</sub>, which gives with aqueous  $NH_3$  a crystalline oxychloride  $[(C_2H_5)_2Se]_2OCl_2$ . Combines with  $C_2H_5I$  to form crystalline  $(C_2H_5)_3Sel$  (Pieverling) This is a white substance resembling Epsom salts in appearance. The (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>SeCl<sub>2</sub> forms double salts with several metallic chlorides, e g

## [(C,H5)aSeCl],ZnCl2

Ethyl diselenide  $(C_2H_5)_2Se_2$ ; b p  $186^\circ$ ; formed as a by-product in the preparation of (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>Se, was first obtained by Wohler and Dean (Annalen, 97, 1) from KC<sub>2</sub>H<sub>5</sub>SO<sub>4</sub> and K<sub>2</sub>Se<sub>2</sub> (Rathke, *ibid* 152, 212), has an intensely disagreeable smell, and acts as a poison (Pieverling) A solution in dilute HNO<sub>3</sub> gives with HCl monoclinic crystals of  $(C_2H_5)_2Sc_2O_2(OH)_2Cl_2$ , which are soluble in water, and are reduced by SO, to ethyl diselenide

Ethoxy-selenyl chloride C<sub>2</sub>H<sub>5</sub>O SeOCl, m p. 10°; bp 175°, not without decomposition. From SeOCl<sub>2</sub> and absolute alcohol Heated in a tube to 200° yields Se, C<sub>2</sub>H<sub>5</sub>Cl, HCl, and H<sub>2</sub>O (Michaelis and Landmann, Annalen, 241,

156Diethylselenite SeO(OEt)<sub>2</sub>; bp 183°-185°, not without decomposition, sp gr 149 at 165°. From ScoCl<sub>2</sub> and NaOEt in dry ether at 180°-190°, also from Ag<sub>2</sub>SeO<sub>3</sub>, and C<sub>2</sub>H<sub>5</sub>I at 85° m sealed tube A thick liquid, decomposed by water into C<sub>2</sub>H<sub>5</sub>OH and H<sub>2</sub>SeO<sub>3</sub> Decomposed by heating in a tube at 200° with separation of Se (M and L.)

Ammonium monoethylselenite

#### C<sub>2</sub>H<sub>5</sub>O SeO ONH<sub>4</sub>;

a crystalline, very hygroscopic acid, formed by action of alcohol and ammonia upon SeO2 at temperature of melting ice. It is soluble in alcohol, insoluble in ether (Divers and Hada, Chem Soc. Trans. 75, 538).

Ethyl sulphates.

Mono-ethyl sulphate  $C_2H_5HSO_4$  (Ethyl-sulphu) ic acid; Sulphethylic acid; Sulphovinic

acid); sp gr 1 316 at 16°

First noticed by Dabit (Crell's Ann [1802] 1, 394); and again by Serturner (Gilb Ann 60, 53; 64, 67, [1818-1820]; see also Heeren, Pogg. Ann. 7, 193; Hennel, Trans. Roy Soc 1826; 240, 1828, 365, Serullas, Ann Chim Phys [2] 39, 153; Liebig and Wohler, Pogg Ann 22, 487, Liebig, Annalen, 9, 17, 32, 13, 32, 38; Dumas and Boullay, Ann Chim Phys [2] 36, 300)

Formed by action of sulphuric acid upon alcohol (Dabit, Serturner, Serullas), also by absorption of ethylene in sulphuric acid (Hennel, Berthelot, Ann Chim, Phys [3] 43, 385), by heating ether with strong H<sub>2</sub>SO<sub>4</sub> (Hennel, Magnus, Pogg Ann 27, 386), from S<sub>2</sub>Cl<sub>2</sub> and alcohol (Heusser, Annalen, 151, 249), from HO SO, Cl and alcohol in the cold (on heating, this gives C<sub>2</sub>H<sub>5</sub>O SO<sub>2</sub>Cl, Claesson, J pr Chem.

[2] 19, 245)

Preparation -A mixture of equal parts of absolute alcohol and strong sulphure acid is heated for 4 hours on the water-bath, by this treatment 59 p.c. of the H2SO4 used is converted into mono-ethyl sulphate (Berthelot, Bull Soc chim ii 19, 295) By using 3 molecules alcohol and 1 molecule H<sub>2</sub>SO<sub>4</sub> (ie 3 to 2 by weight), 77 p c of the sulphuric acid is utilised (Claesson, J pr Chem [2] 19, 246) The mixture is diluted with water and neutralised with lead or barium carbonate, filtered, evaporated to crystallisation, the crystals dissolved in water, and the acid set free by means of H<sub>2</sub>SO<sub>4</sub>, or, when lead carbonate is used, by means of H<sub>2</sub>S. The piecipitated BaSO4, PbSO4, or PbS is removed by filtration, and the liquid evaporated in vacuo over sulphuric acid Mono-ethyl sulphate is a syrupy liquid, very soluble in water, soluble also in alcohol, but insoluble in ether

Heated with water, yields alcohol and sulphuric acid; on heating with alcohol to 140°, ether and H<sub>2</sub>SO<sub>4</sub> are formed Oxidising agents, e q MnO<sub>2</sub> or K<sub>2</sub>CrO<sub>4</sub>, give aldehyde (Jacquemin and Lies-Bodard, J. 1857, 345). The salts are very soluble in water, and can be heated in dilute solutions without decomposition, though in strong solution, or by prolonged heating, they are decomposed with formation of alcohol, a sulphate, and free H<sub>2</sub>SO<sub>4</sub> This decomposition may be diminished by the addition of an alkali hydroxide or carbonate By dry distillation, the salts yield 'heavy oil of wine,' a liquid containing diethyl sulphate and olefines (c) Kremann, Monatsh. 1917, 38, 53) HCl gas yields C<sub>2</sub>H<sub>5</sub>Cl and a metallic sulphate (Kohler, Ber 19, 11,

1929)

By distilling sodium ethyl sulphate in a vacuum, Lilienfeld (Austrian Pat 63526) obtains

Vacuum, Imenied (Austrian Fat 65526) obtains ethyl sulphate in 83-90 p c yield.

Salts (v. Marchand, Pogg Ann 32, 456, 41, 595). LiC<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>, H<sub>2</sub>O; NaC<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>, H<sub>2</sub>O, KC<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>, crystallises in anhydrous monoclinic plates, soluble in 0.8 part H<sub>2</sub>O at 17°, (Schabus, J. 1854, 560; Marignac, J. 1855, 608)

 $Mg(C_2H_5SO_4)_2,4H_2O$ ,  $Ca(C_2H_5SO_4)_2,2H$ ,O

forms monoclinic laminæ, soluble in 0.8 part water at 17° (M). Ba( $\rm C_2H_5SO_4$ )<sub>2</sub>,2H<sub>2</sub>O, monoclinic plates, sp gr. 2.080 at 21.7°, soluble in 0.32

parts of water at  $17^{\circ}$  (M.); Pb(C<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>)<sub>2</sub>,2H<sub>2</sub>O; Harge rhombic tables —  $Pb(C_2H_5SO_4)_2$ ,  $PbO_5$ amorphous; soluble in 0 54 part H,O at 17°

amorphous; soluble in 0.54 part  $H_2O$  at 17° Diethyl sulphate  $(C_2H_5)_2SO_4$ , sp gr. 1.1837 at 19° (Claesson, J. pr. Chem. [2] 19, 257), b.p. 208° (with decomposition), 113.5° at 31 mm, 118° at 40 mm, 120.5° at 45 mm. (Villers, Bull. Soc. chim. ii. 34, 26); m.p. about  $-24.5^\circ$  (V), occurs in 'heavy oil of wine' Formed by leading  $SO_3$  vapour into absolute ether (Wetherill. Annalen. 66, 117), ii. small ether (Wetherill, Annalen, 66, 117). in small quantity by distillation of C2H5HSO4; by dropping alcohol into chloride of ethyl sulphuric acid C<sub>2</sub>H<sub>5</sub>O SO<sub>2</sub>Cl, or by action of H<sub>2</sub>SO<sub>4</sub> upon alcohol (Claesson), from Ag<sub>2</sub>SO<sub>4</sub> and C<sub>2</sub>H<sub>5</sub>I (Stempnewsky, Ber 11, 514) A nuxture of 1 vol absolute alcohol and 2 vols H<sub>2</sub>SO<sub>4</sub> ıs dıstılled slowly *in racuó* (Vilhers) Absolute alcohol is mixed with Nordhausen sulphuric acid, the ether separated by means of CHCl, and the product distilled in vacuo (Claesson and Lundvall, Ber 13, 1699)

Is an oily liquid, with an odour like that of peppermint, insoluble in water, and slowly decomposed by that liquid even in the cold, when heated with water, yields alcohol,  $\rm H_2SO_4$  and  $\rm C_2H_5HSO_4$  Heated with alcohol, forms ether  $\mathrm{C_2H_5HSO_4}$ and C<sub>1</sub>H<sub>5</sub>HSO<sub>4</sub>, warm baryta water forms alcohol and Ba(C<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>)<sub>2</sub> (Vilhers)

Unsaturated hydrocarbons are present to

the extent of about 5 pc in 'heavy oil of

wine

Chloride of ethyl sulphuric acid (1, H<sub>3</sub>O SO, C1; b p  $151^{\circ}$ - $154^{\circ}$  (corr.) (Claesson, J. pr. Chem. [2] 19, 248), with slight decomposition.  $93^{\circ}$ - $95^{\circ}$  at 100 mm (Muller, Ber 6, 227) From C<sub>2</sub>H<sub>5</sub>Cl and SO<sub>3</sub>, together with isomerides (v Ethyl chloride), by dropping alcohol into SO<sub>2</sub>Cl<sub>2</sub> (not ruce versa, diethyl sulphate is then formed) (Behrend, J. pr. Chem. [2] 15, 28), from a salt of ethyl sulphure acid and PCl<sub>5</sub> (Purgold, Ber 6, 505), from ethyl chloroformate Cl CO<sub>2</sub>C<sub>2</sub>H<sub>5</sub> and fuming sulphuric acid (Wilm, Ber 6, 505), by passing C<sub>2</sub>H<sub>4</sub> into HSO<sub>3</sub>Cl, SO<sub>4</sub>H C<sub>2</sub>H<sub>4</sub> SO<sub>2</sub>Cl is also produced (Muller, *ibid*. 6, 227)

A liquid with an irritating smell, exciting tears, and decomposed by contact with water into HCl, H2SO4 and alcohol When the chloride is added to methyl alcohol or ethyl alcohol, ethyl sulphuric acid and CH3Cl or C2HaCl are produced, with amyl alcohol, amyl sulphuric acid and ethyl chloride are formed If, on the other hand, absolute al-(Muller) cohol is dropped into the chloride, diethyl sulphate is produced (Claesson)

Bromethyl sulphuric acid

 $CH_2Br\ CH_2\ OSO_2OH(?)$ ;

from ethylene bromide and SO<sub>3</sub> (Wroblewski, Zeitsch Chem 1868, 563) The barium salt is anhydrous, and is decomposed by continued heating with water, with separation of BaSO4 and formation of glycol (Beilstein and Wiegand, Ber 15, 1370) An isomeric body

CH<sub>3</sub> CHBr OSO, OH(?)

is formed by acting upon ethylene bromide with Ag<sub>2</sub>SO<sub>4</sub> and water (B and W), the barium salt is very soluble in water, and its solution decompose on warming into BaSO<sub>4</sub>, HBr, and glycol **Dibromo-diethyl sulphate** (CH<sub>2</sub>Br CH<sub>2</sub>)<sub>2</sub>SO<sub>4</sub>,

by action of ethylene bromide upon Ag<sub>2</sub>SO<sub>4</sub> in

presence of benzene (Beilstein and Wiegand, Annalen, 15, 1369); a heavy oil insoluble in water, soluble in benzene and ether, decomposed on heating. Heated with water, yields bromide of ethyl sulphuric acid, and finally HBr, H<sub>2</sub>SO<sub>4</sub>, and glycol.

Ethyl sulphites.

Mono-cthyl sulphite C<sub>2</sub>H<sub>5</sub>O SO OH, Ethyl sulphirous acid, Hyposulphethylic acid. The potassium salt KC<sub>2</sub>H<sub>5</sub>SO<sub>3</sub> is obtained by passing SO, into a well-cooled solution of NaOC, H5 in absolute alcohol (Rosenheim and Liebknecht, Ber 1898, 408) The ammonium salt is prepared by passing NH<sub>3</sub> followed by SO<sub>2</sub> into absolute alcohol (Divers and Ogawa, Chem Soc Trans 1899, 535) The alkali salts are very unstable in the solid state decomposing with evolution of SO2. Dilute mineral acids bring about this change in solution; ethyl iodide and alcohol at  $150^{\circ}$  yield ethyl sulphonate (q v)By treatment with PCI, diethyl sulphite yields the chloride of ethyl sulphurous acid C2H5O SOCI which boils at 122°, is decomposed by water into HCl, SO<sub>2</sub>, and alcohol, and gives, by further action of PCl<sub>5</sub> at 180°, thionyl chloride,  $\rm C_2H_5Cl$ , and POCI, (Michaelis and Wagner, Ber 7, 1074) Ethyl sulphurous acid is isomeric with ethyl

Delivity supintious with is sense in the single sulphone and C<sub>2</sub>H<sub>5</sub> SO<sub>2</sub> OH (q v ).

Diethyl sulphite C<sub>2</sub>H<sub>5</sub>O SO OC<sub>2</sub>H<sub>5</sub>; sp gr
1 1063 at 0° (Carius, J pr Chem [2] 2, 279); b p 161 3° From alcohol and S<sub>2</sub>Cl<sub>2</sub>; 18 parts of absolute alcohol are mixed with 50 parts of S<sub>2</sub>Cl<sub>2</sub>, previously warmed to 60°, the mixture is kept at this temperature for an hour, and then distilled, the portion boiling above 150° is redistilled (Warlitz, Annalen, 143, 74)

A colourless liquid, with mint-like odour, miscible with alcohol and ether, insoluble in water Decomposed by water; with PCl<sub>5</sub>, yields a chloride C<sub>2</sub>H<sub>5</sub>OSOCl, which, on distillation, splits up into C<sub>2</sub>H<sub>5</sub>Cl and SO<sub>2</sub> (Geuther, Annalen, 224, 223; Michaelis and Wagner, Ber 7, 1074). Decomposed by KOH into potassium ethyl sulphonate (Rosenheim and Liebknecht, ibid. 31, 405) Decomposes at 200° into SO<sub>2</sub> and ether (Prinz, Annalen, 223, 374), or by heating with SOCl<sub>2</sub>, to 120°, into SO<sub>2</sub> and C<sub>2</sub>H<sub>5</sub>Cl (Geuther).

Ethyl sulphydrate C<sub>2</sub>H<sub>5</sub>SH. Mercaptan, Ethyl mercaptan; b p. 36 2° (Nasım, Ber 15, 2882), sp gr 0 83907 at 20°/4° (N), 0 835 at 21°. By distilling Ba(C<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>)<sub>2</sub> with Ba(HS)<sub>2</sub> (Zeise, Annalen, 11, 1), by action of KHS upon C<sub>2</sub>H<sub>5</sub>Cl (Regnault, Ann. Chim Phys [2] 71, 390); by heating absolute alcohol saturated with SO<sub>2</sub> in a scaled tube, there are also formed C<sub>2</sub>H<sub>5</sub>HSO<sub>4</sub>, (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>O, and H<sub>2</sub>SO<sub>4</sub> (Endemann, Annalen, 140, 336), from P<sub>2</sub>S<sub>5</sub> and alcohol (Kekulé, Annalen, 90, 310) It is best prepared by saturating a solution of KOH, sp gr 1 3, with H<sub>2</sub>S, mixing with a solution of Ca(C<sub>2</sub>H<sub>5</sub>SO<sub>4</sub>)<sub>2</sub> (also of sp gr. 13), and distilling on water-bath (Liebig, Annalen, 11, 14); according to Claesson (J pr. Chem [2] 15, 193), (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>S is also formed; NaC<sub>2</sub>H<sub>5</sub>S is prepared from the product of this action, the alcoholic solution evaporated to dryness, the (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>S removed by means of benzone, and the C<sub>2</sub>H<sub>5</sub>NaS decomposed by dilute H<sub>2</sub>SO<sub>4</sub>

It is a colourless liquid with a penetr ting garlic-like smell, slightly soluble in water, from which it crystallises on evaporation with 18H<sub>2</sub>O,

m.p. 12° (Claesson). It gives with bromine  $C_2H_5Br$ , HBr, and BrS (Friedel, Ladenburg, Annalen, 145, 189) HNO<sub>3</sub> forms  $C_2H_5SO_2$  SC<sub>2</sub>H<sub>5</sub>, or, if the acid be stronger, ethyl sulphonic acid Treated with Cu powder, loses its disagreeable odour, but is considerably decomposed thereby (Finish)

It forms crystalline compounds with S<sup>Cl</sup><sub>4</sub> (Demarcay, Bull. Soc chim [2] 20, 127). It absorbs NO, forming a dark-red solution

The hydrogen of mercaptan is replaceable by metals forming mercaptides; e.g.  $C_2H_5KS$  and  $Hg(C_2H_5S)_2$ , transparent plates, m.p.  $76^\circ$ – $77^\circ$  (Otto, Ber 13, 1290, 15, 125), very slightly soluble in cold alcohol, soluble in 12–15 parts hot alcohol (Liebig, Annalen, 11, 17). gives with HNO<sub>3</sub> the mitrate  $Hg(C_2H_7S)NO_3$  (Hofmann and Rabe, Zeitsch anorg Chem 17, 26),  $Pb(C_2H_5S)_2$ , yellow precipitate, formed when  $Pb(C_2H_5O_{22})_2$  and  $C_2H_5HS$  are mixed in alcoholic solutions  $As(C_2H_5S)_3$ , a foul-smelling oil formed from  $As(C_3H_3C_2)_2$  and  $C_2H_5NaS$ , decomposed by heat into As and  $(C_2H_5)_2S_2$   $Pt(C_2H_5S)_2$  pale-yellow precipitate (Zeise).

precipitate (Zeise). Ethyl sulphide ( $\rm C_2H_5)_2S$ ; b p 91° (Pierre, J 1851, 51), 91 9° at 754'7 mm (Beckmann, J. pr. Chem [2] 17, 451), 92·2°-93° ( $^{\circ}$  corr.) at 754 mm. (Nasim, Ber 15, 2282), 92·1° (corr.) (Thorpe and Rodger); sp gr 0·8367 at 0° (Pierre), 0 83676 at 20°/4° (N) From K $_2$ S and C $_2$ H $_5$ Cl (Regnault, Ann Chim Phys [2] 71, 387); from Zn(C $_2$ H $_5$ l $_2$  and SOCl $_2$  (Gauhe, Annalen, 143, 266), from KHS and KC $_2$ H $_5$ SQ $_4$  in alcohol (Hobson, Chem Soc Trans 10, 56), also from P $_2$ S $_5$  and (C $_2$ H $_5$ ) $_2$ O (Beckmann) To prepare the pure sulphide, heat the crude sulphide with Cu powder to 260°-280° (Finckh, Ber 1894, 1239)

It is a colourless liquid with strong garlic-like smell, insoluble in water. Bruhl states that in the pure state it has an ethereal odour. Chlorine acts upon it in the dark, forming substitution products: (1) (C<sub>2</sub>H<sub>3</sub>(I<sub>2</sub>)<sub>2</sub>S, vellow liquid, b.p. 167°-172°, sp.gr. 1.547 at 12°, (2) (C<sub>2</sub>H<sub>3</sub>(I<sub>3</sub>)<sub>2</sub>S, b.p. 189°-192°, sp.gr. 1.219 at 13.5°; (3) (C<sub>2</sub>H(I<sub>4</sub>)<sub>2</sub>S, b.p. 217°-222° By prolonged action of chlorine, C<sub>2</sub>Cl<sub>4</sub> is formed, and possibly (C<sub>2</sub>Cl<sub>5</sub>)<sub>2</sub>S (Riche, Ann Chim. Phys. [3] 43, 283; Annalen, 92, 358) (C<sub>2</sub>H<sub>2</sub>Cl<sub>3</sub>)<sub>2</sub>S also results from action of chlorine upon (C<sub>2</sub>H<sub>3</sub>Cl<sub>2</sub>)<sub>2</sub>S, which can be obtained from C<sub>2</sub>H<sub>4</sub> and Cl<sub>3</sub>S<sub>2</sub> (Guthrie, Annalen, 116, 241) Bromine forms (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>SBr<sub>2</sub>, a yellowish-red unstable body, which, by the action of KI, yields (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>SI<sub>2</sub>, a black liquid (Rathke, Annalen, 152, 214)

Ethyl sulphide combines with many metallic chlorides to form crystalline compounds, e.g.  $(C_2H_5)_2S$  HgCl<sub>2</sub>, white crystals, soluble in alcohol and ether, mp 119°,  $(C_2H_5)_2S$  HgI<sub>2</sub>, yellow needles, mp 110°;  $2(C_2H_5)_2S$  TiCl<sub>3</sub>, dark-red crystals (Demarcay) (For addition compounds, see Abel, Zeitsch physiol Chem 20, 268; Werner, Zeitsch anorg Chem. 15, 14; 17, 101; Smiles, Chem Soc Trans 1900, 164.)

Nitric acid (of sp gr 1 2) forms ethyl sulphoxide or diethyl sulphine oxide  $(C_2H_5)_2SO$ , a soluble oily liquid, solid at low temperatures, and decomposed by heating. Fuming intric acid converts this into diethyl sulphone  $(C_2H_5)_2SO_2$ ; bp. 248°; mp. 70°-72° (Oefele, Annalen, 127, 370; 132, 88);  $R\infty = 47.53$  (Kanonikow, J Russ. Ph.s Chem. Soc. 15

451); also formed from  $Pb(C_2H_b)_4$  and  $SO_2$ (Frankland and Lawrence, Chem. Soc. Trans 35, 244), and from (C2H5)2S, and a solution of KMnO<sub>4</sub> (O) Rhombic plates, soluble in 6.4 parts water at 16°

Triethyl sulphine (C2H5)3S forms compounds

C,H,HS (Cahours, ibid 135, 352, 136, 151), forms rhombic plates of disagreeable odour, and soluble in water By action of Ag<sub>2</sub>O, yields triethy, sulphine hydroxide (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>SOH, a strong base, displaces NH4, and has caustic action on the skin, it forms a crystalline deliquescent mass, which unites with acids to form deliquescent salts yielding double compounds with many metallic salts;  $e\ g$ :

## PtCl<sub>4</sub>·2(C,H<sub>5</sub>)<sub>3</sub>SCl

dark-reddish prisms, soluble at 20  $7^{\circ}$  in 30 parts of water (Dehn, Annalen, Suppl 4, 90; Jorgensen, J pr Chem [2] 6, 82, Kraut, Annalen,

210, 321)
When  $(C_2H_5)_2S$  is heated with  $CH_3I$ , diethylmethyl sulphine rodide (C2H5)2CH3SI, an unstable non-crystalline body, is formed, from which other salts can be obtained; the chloride (C2H5)2CH3SCl forms many double salts (Kruger, J pr Chem The isomeride, ethyl-methylethyl [2] 14, 195) sulphine iodide, prepared from C<sub>2</sub>H<sub>5</sub>CH<sub>3</sub>S and C<sub>2</sub>H<sub>5</sub>I, is crystalline (Kruger)

Ethyl disulphide  $(C_2H_2)_2S_2$ , bp 152 8°-153.4° (corr) at 730 mm (Nasm, Ber 15, 2882), sp gr 0 99267 at 20°/4° (N) By distillation of KC<sub>2</sub>H<sub>5</sub>SO<sub>4</sub> with K<sub>2</sub>S<sub>2</sub> and water (Zoise, Annalen, 11, 1, Morin, ibid 32, 267, Lowig, Kopp, ibid. 35, 345, ('ahours, ibid 61, 98), by action of I upon a slight excess of a solution of C2H5NaS (Kekulė; Linnemann, *ibid* 123, 279), by action of S upon C<sub>2</sub>H<sub>5</sub>SNa (Bottger, *ibid* 223, 348); by distilling liquid thioacetaldehyde (Klinger,

Ber 32, 2195)

A colourless liquid, with garlic-like smell, very slightly soluble in water, with dilute HNO3, gives  $(C_2H_5)_2S_2O_2$ , an only liquid, which may be regarded as the ethyl salt of ethyl thiosulphonic acid C2H5SO3SC2H5.

Ethyl trisulphide  $(C_2H_5)_2S_3$ , from  $K_2S_3$  and  $KC_2H_5SO_4$  (Cahours, Bull. Soc chun. [2] 25, 184); also from (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>S<sub>2</sub> and S (H Muller); a colourless liquid, with unpleasant smell.

Ethyl tetrasulphide  $(C_2H_5)_2S_4$ , from  $S_2Cl_2$  and  $C_2H_5SH$  (Claesson, J pr Chem [2] 15, 214), a heavy oily liquid, with disagreeable odour

Ethyl pentasulphide  $(C_2H_5)_2S_5$ ; by heating  $(C_3H_5)_2S_4$  and S at 150°; a tough elastic solid

Ethyl sulphinic acid  $C_2H_5HSO_2$ , by action of Zn(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> upon SO<sub>2</sub> (Wischin, Annalen, 139, 364; Hobson, Chem Soc Trans 1858, 10, 58), the sodium salt is produced by oxidation of sodium mercaptide by dry oxygen (Claesson, J. pr. Chem. [2] 15, 199) The free acid is a syrupy liquid with a sweet taste, by action of HNO3, yields ethyl sulphonic acid and (C<sub>1</sub>H<sub>5</sub>SO<sub>2</sub>)<sub>3</sub>NO, crystals, m p 81 5°, very slightly soluble in water (Zuckschwerdt, Annalen, 174, 308) Forms salts, of which NaC<sub>2</sub>H<sub>6</sub>SO<sub>2</sub> crystallises from alcohol in anhydrous crystals (C.); the lead salt was prepared from Pb(C<sub>2</sub>H<sub>5</sub>)<sub>4</sub>

and SO<sub>2</sub> by Frankland and Lawrence (Chem. Soc Trans 35, 244)

Ethyl chlorosulphinate Cl SO, C<sub>2</sub>H<sub>5</sub>. A faintly yellow hquid, b p 29°/13 mm, which decomposes at its bp, 122°, under ordinary pressure, into sulphui dioxide and ethyl chloride, formed by treating well-cooled ethyl alcohol with thionyl chloride (Stahler and Schiim, Bei 1911, 44, 319)

Ethyl sulphonic acid C<sub>2</sub>H<sub>5</sub> SO<sub>2</sub> OH by the oxidation of C2H5SH (Lowig and Weidmann, Pogg Ann 49, 329, Kopp, Annalen, 35, 346), C<sub>2</sub>H<sub>3</sub>CNS or of (C<sub>2</sub>H<sub>3</sub>)<sub>2</sub>S<sub>2</sub> (Muspratt, Chem. Soc Trans 1849, 1, 45) by HNO<sub>3</sub>, from C<sub>2</sub>H<sub>3</sub>I and K<sub>2</sub>SO<sub>3</sub> (Graebe, Annalen, 146, 37) By heating ethylene sulphonic acid with P and HI at 170° (Kohler, Amer Chem J 20, 688), by oxidation of C<sub>2</sub>H<sub>5</sub>CNS with hypochlorites (De Coninck, Compt. rend 126, 838), by action of cone HNO3 upon mercury mercaptide nitrate (Hofmann and Rabe, Zeitsch anorg Chem 17, 26) The acid is a crystalline deliquescent body; by action of ICI, at 150°, we get dichlorethyl sulphonic acid, excess of ICl<sub>3</sub> gives C<sub>2</sub>Cl<sub>6</sub> (Spring and Wessinger, Ber 15, 445), unites with bases to form salts (For halogen derivatives, see Kohler, Amer Chem J 19, 737, 20, 690, 21, 361 For salt Rosenheim and Liebknecht, Ber 31, 412) For salts, see

Ethyl sulphonate  $C_2H_5$  SO<sub>2</sub> OC<sub>2</sub>H<sub>5</sub>, bp 213 4° (corr), sp gr 1 1712 at 0°/0° 1 1452 at 20°/4° (Nasm, Ber 15, 2884), by action of ethyl sulphonic chloride  $C_2H_5$ SO<sub>2</sub>Cl and  $C_2H_5$ NaO (Carius, J 1870, 726, J pi Chem [2] 2, 262), from  $C_2H_5$ I and silver sulphite (archive sulphite (archive))

sodium ethyl sulphite (q v)

Ethyl sulphonic chloride  ${\rm C_2H_{2}SO_2Cl}$ , b p 177 5° (corr ) (Carius), 171° (Otto, Ber 15, 122), sp gr 1 357 at 22 5° (C), by action of PCL on NaC2H5SO3 (Gerhardt and Chancel, Compt rend 35, 690), by action of Cl upon ethyl oxysulphide (S and W lc) Colourless liquid,

with unpleasant smell

Ethyl thiocyanate C<sub>2</sub>H<sub>3</sub>SCN, bp 143° (Berthelot, Compt rend 130, 444), 146° (corr) (Buff, Ber 1, 206), sp gr 1 033 at 0°, 1 0126 at 19°, 0 8698 at 146° (B), by action of KCNS upon KC<sub>2</sub>H<sub>5</sub>SO<sub>4</sub> (Cahours, Ann Chim Phys [3] 18, 264, Annalen, 6<sub>5</sub>1, 95), or C<sub>2</sub>H<sub>5</sub>Cl (Lowig, Pogg Ann 67, 101), or C<sub>2</sub>H<sub>5</sub>I (Johnson and Levy Amer Chem J 1907, 38, 456), from Et<sub>2</sub>SO<sub>4</sub> and KCNS, yield 87 pc (Walden, Ber. 1907,

A mobile liquid with unpleasant odour, insoluble in water, miscible with alcohol or ether, by action of sodium forms NaCN and (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>S (Hofmann, Ber 1, 184), by heating with solution of KOH, yields (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>S<sub>2</sub>, KCN, and KCNO (Bruning, Annalen, 104, 198), with alcoholic KOH, forms (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>S<sub>2</sub>, CO<sub>2</sub>, NH<sub>3</sub>, but no KCNS (Lowig), but with alcoholic KHS yields C<sub>2</sub>H<sub>5</sub>HS and KCNS (L) Decomposed by hot solution of bleaching powder, yielding CO2, hot, yield (EtO)<sub>2</sub>SO<sub>2</sub> and NaCN Further action gives Et<sub>2</sub>S<sub>2</sub>, NaCN, and NaCNO, if all the hypochlorite is used up By action of aqueous  $NH_3$  at  $100^\circ$ , it yields  $(C_2H_5)_2S_2$ ,  $NH_4CN$ , urea, oxalic acid, and other products (Kremer, J. 1858, 401; Jeanjean, J. 1862, 364) Py passing Cl into it, there results (CNCl)<sub>3</sub> and a liquid C<sub>2</sub>H<sub>3</sub>SCl<sub>3</sub>, bp. 134°-135° (James, J. pr.

Chem [2] 30, 316) A chlorine substitution product  $C_2H_4\text{ClSCN}$  was obtained by James (viul [2] 20, 352) by heating  $C_2H_4\text{ClBr}$  with KCNS and alcohol, an oil heavier than water, with unpleasant smell, bp. 202°-203°; mp below --20°

Ethyl thiocyanate forms compounds with HCl, HBr, and HI (Henry, J 1868, 652; Glutz, Annalen, 153, 312) (For many other compounds, see Wheeler and Johnson, Amer Chem. J 26, 345, J Amer Chem Soc 24, 680, Wheeler and Jamieson, *ibid* 24, 743, Wheeler

and Mernam, ibid 24, 439)

Ethyl isothiocyanate C<sub>2</sub>H<sub>5</sub>NCS (L), Ethylthrocarbinide, mustard oil, b p 134°, sp gr 1 0192 at 0°, 0 9972 at 22°, 0 8763 at 133 2° (Buft, Ber I, 206), by action of C<sub>2</sub>H<sub>5</sub>NCO upon P<sub>2</sub>S<sub>5</sub> (Michael and Palmer, Amer Chem J 6, 259), also in very small quantity when Hg(CNS)<sub>2</sub> is heated with C<sub>2</sub>H<sub>5</sub>I (Michael, ibid. 1, 417), also by heating CSCl<sub>2</sub> and (C<sub>2</sub>H<sub>5</sub>)NH<sub>2</sub> (Rathke, Annalen, 167, 211) A solution of ethylamine in alcohol is treated with CS2, when crystals of ethyl ammonium ethyl dithiocarbamate separate out,  $2(C_2H_5)NH_2+CS_2=(C_3H_5)NHCSSNH_3(C_2H_5)$ A solution of this body is then treated with HgCl2, when the mercury compound is precipitated.

 $\begin{array}{l} (\mathrm{C_2H_5})\mathrm{NH} \times \mathrm{S} \times \mathrm{NH_3}(\mathrm{C_2H_5}) + \mathrm{Hg}(\mathrm{T_2} \\ = 2(\mathrm{C_2H_5})\mathrm{H_3}\mathrm{N}\mathrm{C1} + [\mathrm{NH}(\mathrm{C_2H_5})\mathrm{CS_2}]_2\mathrm{Hg} \end{array}$ 

On distillation, this body yields the mustard oil, HgS and H<sub>2</sub>S (Hofmann, Ber 1, 171, 2, 452) Delépine (Compt. 1end. 144, 1125) improves the yield of dithiocarbamate by using I molecule each of CS,, amine, and soda, and then distilling with basic lead acetate in place of HgCl2. Mustard oil is a liquid with very disagreeable smell, and in contact with the skin produces a burning sensation (Hofmann, Ber 1, 26), with absolute alcohol forms monoethyl throurethane (C<sub>2</sub>H<sub>5</sub>)NH CS OC<sub>2</sub>H<sub>5</sub>, a liquid, bp 204°-208°, with aldehyde ammonia yields the compound C<sub>2</sub>H<sub>15</sub>N<sub>5</sub>S, mp 135°-136° (Dixon, Chem. Soc. Trans. 1888, 414)

Thiocarbimides react with phenylhydrazine, yielding thiosemical bazides (Marckwald) Br in chloroform a ring compound, C2OS2(NEt)2, melting at 45°, is formed (Freund and Bachrach, Annalen, 285, 184)

Ethyl thiophens  $C_4SH_3(C_2H_5)$ 2-Ethyl theophen, bp 132°-134° (corr), sp gr 0 990 at 24° By action of  $C_2H_5Br$  and Na upon C4SH3I (Meyer and Kieis, Ber 17, 1560), also by action of Br upon thiophen, C<sub>2</sub>H<sub>5</sub>Br and Na (Schleicher, *ibid* 18, 3015, *ibid* 19, 671).

3-Ethyl throphen, bp. 135°-136°; spg1 1 0012 at 16°. By heating ethyl succinic acid with P<sub>2</sub>S<sub>3</sub> (Damsky, Ber 19, 3284, Gerlach, Annalen, 267, 146)

Di-ethylthiophen, bp 181°, sp gr 0 962 at 14°/14° An oil obtained by action of Na upon (',H<sub>5</sub>I and 10doethylth10phen (Muhlert, Ber

19, 633).

Ethyl telluride (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>Te, Tellurethyl; b p (°-138° (Marquardt and Michaelis, Ber 137°-138° 21, 2045; Heeren, J 1861, 565), from K,Te and KC,H,SO<sub>4</sub> (Wohler, Annalen, 84, 69; 35, 111; Mallet, Chem Soc. Trans 1853, 5, 71) A heavy, viscid, reddish-yellow liquid, with a very unpleasant smell, burns in air with blue flame, evolving fumes of TeO,; hardly soluble in water, and oxidised by exposure to air, poisonous  $\frac{\mathrm{HNO_3}}{\mathrm{(monoclinic\ prisms)}}$  forms  $\frac{(\mathrm{C_2H_5})_2\mathrm{Te},\mathrm{HNO_5}}{\mathrm{Strong\ HCl\ precipitate_3}}$  the oily compound  $(\mathrm{C_2H_5})_2\mathrm{TeCl_2}$  from a solution of the nitrate, ammonia converts this into [(('2H<sub>5</sub>)<sub>2</sub>Tc]<sub>2</sub>('l<sub>2</sub>O (hexagonal pusms), which, when treated with Ag<sub>2</sub>SO<sub>4</sub>, yields

 $[(C_2H_5)_2Te]_2,H_2SO_4$ 

(colourless pusms) By action of Ag,O upon a solution of the chloride, (C2H5)2TeO is produced,

which decomposes on concentration

When  $(C_2H_5)_2$ Te is acted upon by  $C_2H_5I$ , triethyl tellurium rodide (C, $H_5$ )<sub>3</sub>Te1 is formed, m p 90°-92° (Cahours, Bull Soc. chim. [2] 4, 40), which crystallises in yellow prisms

Ethyl ditelluride  $(({}^{\iota}_{2}H_{5})_{2}Te_{2}^{-1}$  is said to be formed in the preparation of  $({}^{\iota}_{2}H_{5})_{2}Te_{3}$  and to be a dark-red liquid, with high boiling-point

#### ETHY LAMINES

Compounds in which one or more atoms of

H in NH<sub>3</sub> are replaced by C<sub>2</sub>H<sub>5</sub>

Ethylamine C<sub>2</sub>H<sub>5</sub> NH<sub>2</sub>, b p 18 7°, sp gr
0 6964 at 8°, 0 708 at 2° (Hofmann, Ber 22, 699); mp -852°, bp 19° to 20° (Ladenburg and Krugel), sp gr 0 7013 at 4°, 0 6892 at 15° (Perkin), cut. temp 1852° (Schmidt), 1832° and cut piess 554 atm. (Berthoud), H C=4085 Cals (Berthelot, Ann Chim. Phys [5] 23, 244) From ethyl carbinide and KOH (Wurtz, Annalen, 71, 330, also Compt 1end 28, 223), from C<sub>2</sub>H<sub>5</sub>Br and NH<sub>3</sub> (Hofmann, Annalen, 74, 159), by the putrefaction of yeast and of flour (Hesse, J. 1857, 403, Sullivan, J. 1858, 231), by heating alcohol with NH<sub>4</sub>Cl at 300° (Berthelot, Ann Chim Phys [3] 38, 63), by action of nascent H upon acetomtrile (Mendius, Annalen, 121, 142) It is also produced in the dry distillation of the residues from beet-root in sugar manufacture (Duvillier and Buisine, Ann Chim Phys [5] 23, 317), by action of KC<sub>2</sub>H SO<sub>4</sub> upon alcoholic NH<sub>3</sub> at 120° (Eilenmeyer and Cail, J. 1875, 617), by action of Na upon CH<sub>3</sub> CONH<sub>2</sub> in boiling amyl alcohol (Gucibet, Compt 1end 129, 62), from EtOH and phospham at 225°-250° (Vidal, D. R. P. 64346), by action of Zn filings and HCl in the cold on aldehyde ammonia (Trillat and Fayollat) (Jean), by electrolytic reduction of nitroethane in H<sub>2</sub>SO<sub>4</sub> at 70°-75° (Pieron, Bull Soc chim [3], 21,784)

Preparation -(1) 1 volume of ethyl nitrate C<sub>2</sub>H<sub>5</sub>NO<sub>3</sub> is treated with 3 volumes of alcoholic ammonia for 12 hours at 100°, the free bases are separated from the NH<sub>3</sub> by neutralising with H<sub>2</sub>SO<sub>4</sub> or HCl and extracting with alcohol; the sulphates or chlorides are then decomposed by NaOH, and the free bases combined with pierre acid and crystallised The pierate of (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>N separates first, in yellow needles, then the C2H5NH2 salt in blown prisms, the picrates are then separated and decomposed by HCl, and the bases liberated by KOH (Carey Lea, Chem. News, 5, 118).

(2) Crude & C, H, Cl, from manufacture of chloral, is heated for an hour with 3 times its volume of alcohol (95 p c ) previously saturated with ammonia, in an iron vessel heated by a On cooling, the NH<sub>4</sub>Cl is filtered water-bath off, and the remainder distilled until free from NH<sub>3</sub> and alcohol, the residue (hydrochlorides of

mon-, di-, and tri-ethylamine, mixed with a little NH<sub>4</sub>(I) is treated with a strong solution of NaOH, and the liquid drawn off and dried by means of solid NaOH; it consists of a mixture of the three bases, ethyl oxalate is then added, and the  $({\rm C_2H_5})_3{\rm N}$ , which is unacted upon, is distilled off, the residue consists of a mixture of solid diethyl oxamide  ${\rm C_2O_2(NHC_2H_5)_2}$  and liquid ethyl diethyloxamate  ${\rm C_2O_2N(C_2H_5)_2}$  over which are separated and the diethyl oxamide, after recrystallising from hot water, decomposed with KOH (Hofmann, Ber 3, 109, 776, also Duvillier and Buisine, Compt rend 88, 31)

According to Garner and Tyrer (Chem Soc Trans 1916, 109, 174), a mixture of mono-, di-, and tri-ethylamine can be separated by fraction-

ating with a 10-bulb column.

(3) By the interaction of ethyl bromide and excess of ammonia in alcoholic solution. By regulating the addition of the ethyl bromide to the ammoniacal solution it is possible to obtain the primary and secondary bases without any sensible admixture of the tertiary base (see Werner, Chem Soc. Trans 1918, 113, £)9)

Properties—Is a mobile liquid, with strong ammoniacal odour, is strongly caustic, and has an alkaline reaction, burns with yellow flame, is miscible in all proportions with water, displaces NH<sub>3</sub> from its salts, and, like ammonia, precipitates metallic hydroxides and oxides from salts It. however, dissolves the hydroxides of Al (Wurz), Au, and Ru (Carey Lea), and does not dissolve those of Cd, Ni, and Co. The chloride is decomposed on distillation into C<sub>2</sub>H<sub>3</sub>/NH, NH<sub>3</sub>, C<sub>2</sub>H<sub>4</sub>, and C<sub>2</sub>H<sub>5</sub>(T (Fileti and Piccini, Ber. 12, 1508). CrO<sub>4</sub> oxidises ethylamine to aldehyde and N (Carstanjen, J. 1862, 330).

Caro's acid oxidises EtNH, yielding CII,5OOH, CH<sub>2</sub>CN, CH<sub>3</sub>CH NOH, nitroethane, and CH<sub>4</sub>C(OH)NOH (Bamberger, Ber 35, 4293) It forms a compound C<sub>2</sub>II<sub>5</sub>NHK (Titherley)

Salts (v Wurtz, Annalen, 76, 329)—(C.H.)NH, HCl, deliquescent plates, mp 76°-80°, bp 315°-320° (with decomposition), sp gr 1 2045 at 21°/4° (Schiff and Monsacchi), molecular refract 35 97 (calc 35 95) (Kanonnikow, J pr Chem [2] 31, 347), soluble m alcohol, soluble in 0 42 part of water at 17° (S and M Zeitsch physikal Chem 24, 513) Prepared by heating 1 volume of C.H.(1 with 3 volumes alcoholic ammonia to 100° (Groves, Chem Soc Trans 1861, 13, 331) The hydrochloride and hydroiodide exhibit isodimorphism, both are monoclinic at ordinary temperatures, changing at higher temperatures to uniaxial modifications C<sub>2</sub>H<sub>5</sub>NH<sub>2</sub>, HgCl<sub>2</sub>, by action of alcoholic HgCl<sub>2</sub> on alcoholic ('\_1H<sub>5</sub>NH<sub>2</sub>, a crystalline precipitate, soluble in hot HCl solution. With excess of HgCl<sub>2</sub> in aqueous solution a white precipitate

# $2\mathrm{C}_2\mathrm{H}_5\mathrm{NH}_2,\mathrm{HgCl}_2+2\mathrm{HgO}$

is thrown down; by heating  $C_2H_5NH_2$  with excess of  $HgCl_2$ , a yellow precipitate

#### ClHg·OHg·NH C2H,

separates; whilst a crystallisable compound  $ClHg\cdot NH\cdot C_2H_5$  remains in solution (Köhler, Ber.

12, 2308)  $2C_2H_5NH_2$ , Pt(12, yellow powder, combines with  $(C_2H_5)NH_2$ , and forms

4C<sub>2</sub>H<sub>5</sub>NH<sub>2</sub>,PtCl<sub>2</sub>,2H<sub>2</sub>O

colourless crystals, soluble in water

(C<sub>2</sub>H<sub>5</sub> NH<sub>2</sub>,HCl)<sub>2</sub>,PtCl<sub>4</sub>, orange-yellow flat rhombohedrons (Weltzien, Annalen, 93, 272), hexagonal rhombohedrons (Topsoe, J. 1883, 619), sp.gr. 2 255 at 19°/4° (Clarke, Bei 12, 1399). C<sub>2</sub>H<sub>5</sub>NH<sub>2</sub>,HCl,AuCl<sub>3</sub>, golden-yellow monoclinic prisms, soluble in water (T)

 $(C_2H_5NH_1)_2$ ,  $H_2SO_4$ , deliquescent body, soluble in alcohol, forms double salts with other sulphates, eg ethyl-ammonium alum

 $(C_2H_5NH_2)_2$ ,  $H_2SO_4$ ,  $AI_2(SO_4)_3$ ,  $24H_2O_4$ 

octahedral crystals, soluble at 25° in 689 parts of water.

Ethylchloramine C<sub>2</sub>H<sub>5</sub>NHCl. A very pungent-smelling oil; sp gr 1 067 at 0°, formed by action of NaClO upon C<sub>2</sub>H<sub>5</sub>NH<sub>2</sub>,HCl. Heated with HCl, yields ethylamine (Berg, Ann. Chim.

Phys [7] 3, 319)

Ethylduchloramine, ethylmitrogenchloride

C<sub>2</sub>H<sub>5</sub> NCl<sub>2</sub>; b p 88°-89° at 762 mm.,
sp gr 1 230 at 15°, by passing Cl through
aqueous C<sub>2</sub>H<sub>5</sub>NH<sub>2</sub> (Wurtz, Compt rend 11,
810), prepared by distilling a mixture of

C<sub>2</sub>H<sub>5</sub>NH<sub>2</sub>, HCl with 2! times its weight of bleaching powder and a little water (Tschermak, Ber.
9, 146), a yellow only liquid with a penetrating
smell, insoluble in water and acids, decomposes
on long standing into HCl, NH<sub>4</sub>Cl,C<sub>2</sub>H<sub>5</sub>NH<sub>3</sub>, HCl,
CHCl<sub>3</sub>, CH<sub>3</sub>CN, and CH<sub>3</sub>COCl (Kohler, Ber 12,
1870) The pure substance keeps unchanged
for long periods under water (Tschermak, ibid
12, 2129) Alkalis decompose it into acetic
acid and NH<sub>4</sub>, behaves towards many bothes as

12, 2129) Alkans decompose to mee accea and and NH<sub>1</sub>, behaves towards many bodies as free (1 Zn(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> forms (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>N and Zn(1<sub>2</sub> Ethyl di-iodoamine (2<sub>1</sub>H<sub>3</sub>NI<sub>2</sub>, and Ethyl dibromanine (2<sub>1</sub>H-NB<sub>12</sub>, are formed similarly; the former is a dark-blue liquid (Wurtz)

Ethyl nitramine C<sub>2</sub>H<sub>5</sub>NH NO<sub>2</sub>, m p + 6°, sp gr 1 1675 at 15° A colourless liquid, with an acid reaction, prepared by the action of NH<sub>3</sub> upon diethyl dimitro-oxamide. It gives two classes of alkyl derivatives (Umbgrove and Franchimont, Rec trav chim 16, 388). It is also formed from methyl ethylcarbamate and cone. HNO<sub>3</sub> (Franchimont and Klobbie, ibid. 7, 356).

Nitroethylisontramine ('H<sub>3</sub> ('HNO<sub>2</sub> N(OH)NO is obtained by the action of NO upon the Na derivative of introethane. It forms metallic salts, which are hydrolysed by mineral acids, giving NO and ethylintrolic acid (Traube, Annalen, 300, 106)

Annaich, 300, 100)

Diethylamine ( $({}^{\circ}_{2}\Pi_{5})_{2}NH$ , mp – 40° (Hofmann, Ber 22, 699); bp 57 5° (Hofmann, Annalen, 73, 91), 55 5° at 759 mm (Oudemans, Rec trav chim 1, 59); crit temp 223 3, crit press 36 6 atm (Berthoud), sp gi 0 7262 at 0°, 0 7107 at 15° (Hofmann, Ber. 22, 669), 0 7226 at 4°, 0 7116 at 15°, 0 7028 at 25°. From NH<sub>3</sub> and  $C_{2}H_{5}II$  (Hofmann), or NH<sub>3</sub> and  $C_{2}H_{5}NO_{3}$  (Lea, J 1861, 493, cf Gainei and Tyrer, lc) From  $C_{2}H_{5}Br$  (Werner, Chem Soc. Trans 1918, 113, 899) Prepared by the action of KOH upon the  $C_{2}O_{2}N(C_{2}H_{5})_{2}OC_{2}H_{5}$  obtained in manufacture of ethylamine (qv)

Also by action of very dilute NaOH solution upon  $[(C_2H_5)_2N(NO)]_2$ ,  $H_2SO_4$  (Kopp, Ber 8, 622). Also by action of EtOH upon phospham

at 225°-250° (Vidal, D R P 64346). By heating p-toluenesulphodiethylamide with chlorsulphonic acid at 130°-150° (Marckwald and v Droste-Hulshoff, Ber 31, 3263) By dissolving 50 grams diethylaniline in 148 grams HCl (sp gr 11), diluting with 75 cc H<sub>2</sub>O, adding 32 grams NaNO<sub>2</sub> in 50 cc H<sub>2</sub>O and pouring slowly through a reflux condenser into a boiling solution of 85 grams NaOH in 2 litres of H<sub>2</sub>O (Norms and Kimberley, Amer (hem J. 20, 60)

Price, Brazier, and Wood (J Soc Chem. Ind 1916, 35, 147) have described a convenient mode of preparing large quantities of diethylamine in the laboratory by a simple modification

of this method

NO C6H4 NEt2 + NaOH =NHEt2+NOC6H4 ONa

It a colourless, inflammable liquid with strong ammoniacal smell, very soluble in water, is a strong base, and acts like C<sub>2</sub>H<sub>5</sub>NH<sub>2</sub>, except that it does not dissolve Zn(OH), (Carey H<sub>2</sub>O<sub>2</sub> oxidises it to diethylhydroxylamine (Dunstan and Golding) The nitrate decomposes suddenly at 170°, and yields nitrosodiethylamine (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NNO (Franchimont, Rec trav chim. 2, 95); the hydrochloride (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NH,HCl forms non-deliquescent plates, mp 215°-217° (Wallach, Annalen, 214, 275), bp 320°-330° (W), sp.gr 1 0475 at 21°/4° (Schiff and Monster), and combines with many many and stately sacchi), and combines with many metallic chlorides,  $eg[(C_2H_6)_2NH,HC]_2PtCl_4$ , orangeyellow monoclinic crystals (Topose, J 1883, 619)

Diethylchlorumine (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NCl A pungent-smelling oil, bp 91°, sp gr. 0 943 at 0°, formed by action of NaClO upon (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NH It decomposes on keeping with formation of (('2Ho)2NH,HCl (Berg, Ann Chim Phys [7] 3,

320)

Diethylnitramine Et<sub>2</sub>N NO<sub>2</sub>, bp 206 5° at 757 mm, 93° at 16 mm, spgr 1 057  $15^{\circ}$ Formed by action of Eti upon EtNK·NO<sub>2</sub>; also by action of highest concentrated HNO<sub>3</sub> upon as-diethylurea It is decomposed by KOH at 150°-160° into EtNH<sub>2</sub>, HNO, and CH<sub>4</sub>CHO (Franchimont, Rec trav chim 6, 149, F and Umbgrove, *ibid* 16, 396)

Diethylisonitramine An oil, bp 46°-50° at 18~mm , sp gr  $1.000~at~15^{\circ}$  , formed by interaction of Etl and  $C_2H_5NAgNO_2$  KOH at 100° decomposes it into alcohol, N, and CH<sub>3</sub>CHO

(U and F. lc 399).

Nutrosodiethylamine  $(C_2H_5)_2$ NNO, bp 176.9° (corr); sp.gr. 0.951 at 17.5°, VD = 3.36 (calc = 3.53) (Knecht, Ber 10, 979) b p V D by distilling neutral solution of (C2H5)2NH,HCl with a concentrated solution of KNO<sub>2</sub> (Geuther, Annalen, 128, 251, J. 1871, 695), also from (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NH and NOCl in ether solution at -15° to -20° (Solonina, J. Russ. Phys. Chem. Soc 30, 431), a yellow oil with aromatic smell, decomposed by HCl into (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NH and HNO<sub>2</sub> Alcoholic KOH at 140° forms NH<sub>3</sub> HNO<sub>2</sub> Alcoholic KUII at 170 and (C<sub>2</sub>H<sub>5</sub>)NH<sub>2</sub>. Na amalgam forms N<sub>2</sub>O and  $(C_2H_5)_2NH$ . Triethylamine  $(C_2H_5)_3N$ ; b p 89°-89 5° at

736 5 mm. (Bruhl, Annalen, 200, 186), 89°-90 5° at 767 8 mm (Hofmann); spgr 0.735 at 15° (Hofmann, Ber. 22, 700), 0.7426 at 4°, 0.7331 at 15°, 0.7527 at 25° (Perkin), crit temp. 267 1° (Pawlewski, Ber 16, 2633), remains liquid at 75° or 15° or 15 -75° under 10 mm. pressure (H.) By the hours at 140°, β-ethyl-α-benzylhydroxylamine

action of NH<sub>3</sub> upon C<sub>2</sub>H<sub>5</sub>I (Hofmann, Annalen,

73, 91) or upon C<sub>2</sub>H<sub>5</sub>NO<sub>7</sub> (Carey Lea).

\*\*Preparation\*\*—(1) Crude ethylamine (from C<sub>2</sub>H<sub>5</sub>Cl and NH<sub>3</sub>) in alcoholic solution is treated with C, H, Cl (Duvillier and Buisine), (2) by dis-

tillation of (C<sub>2</sub>H<sub>5</sub>)<sub>4</sub>N OH.

Properties—An only liquid with strong ammoniacal smell, slightly soluble in water; strong base. On strongly heating its salts,  $(C_2H_5)_3N$  is destroyed, with formation of a little  $(C_2H_5)_2N$  NO (Geuther, Zeitsch Chem 1886, 513)

The hydrochloride forms feathery non-deliquescent scales, and combines with many metallic salts to form double compounds N(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>,HCl, sp gr 1 06885 at  $21^{\circ}/4^{\circ}$  1 part of water dissolves 15 parts salt (Schiff and Monsacchi) (C<sub>2</sub>H<sub>s</sub>)<sub>3</sub>N,HNO<sub>3</sub>, mp 98°-99° (Franchimont, Rec trav chim 2, 339).

Tetra-ethylammonium hydroxide

(C,H<sub>5</sub>)<sub>4</sub>N OH

formed from the iodide (C2H5)4NI by the action of Ag<sub>2</sub>O. It forms very deliquescent needles, is a strong base, which eagerly absorbs CO<sub>2</sub>, displaces NH3, precipitates metallic hydroxides, and gives a blue solution with sugar and CuSO, is decomposed by dry distillation, forming

tructhylamine, ethylene, and  $H_2O$ , when heated with  $C_2H_5I$ , gives  $(C_2H_5)_4I$  and alcohol Salts  $-(C_2H_5)_4NCI$ , forms deliquescent crystals, sp gr 1 0801 at 21°/4° (Schiff and Monsach), and yields many double salts,  $eg[(C_2H_5)_4NCl]_2HgCl_2$ , tetragonal crystals;  $(C_2H_5)_4NCl_1HgCl_2$ , triclimic crystals (Topsoc, J. 1883, 620),  $[(C_2H_5)_4NCl]_2PtCl_4$ , orange-yellow, crystalline (monoclinic (T)), difficultly soluble in water, almost insoluble in alcohol, (C2H5)4NBr, light-orange needles, mp. 78°, combines with Br to form an unstable pentablomide (Marquart, Ber 3, 284), gives with alcoholic I solution a precipitate of (('.2H<sub>5</sub>)<sub>4</sub>NI<sub>3</sub>, quadratic piisms (Weltzien, Annalen, 91, 33), which is also formed along with iodoform when the monoiodide is electrolysed between platinum electrodes (Goecke, Zeitsch Elektrochem 10, 249), the monoiodide (C2H5)4NI forms large crystals soluble in cold water and in alcohol, insoluble in ether, sp gi. 1 559 (Schroder, Ber 12, 562)

a-Ethyl hydroxylamine C  $_2$ H  $_5$ O NH  $_2$ . b p 68°, sp gr 0 8827 at 7 5° (Gurke, Annalen, 205, 277) , by the action of HCl upon benzoyl ethylhydroxylamine ethyl ether  $\dot{C}_6H_5CO$   $\dot{N}\dot{C}_2H_5$   $\dot{O}\dot{C}_2^{\prime}H_5$ , or upon the ethyl ether of benzaldoxime

C<sub>6</sub>H<sub>5</sub> CH NOC<sub>2</sub>H<sub>5</sub>

(Lossen and Zanni, ibid 182, 223)

A strongly smelling inflammable liquid, miscible with water, alcohol, or ether; gives with AgNO<sub>3</sub> a white precipitate, which, on heating, is changed to metallic silver, with acids, forms salts. eg C<sub>2</sub>H<sub>2</sub>ON,HCl, scaly plates, mp 128°, decomposed by heating with HCl to 150° into C<sub>2</sub>H<sub>5</sub>Cl, NH<sub>3</sub>O, HCl, and NH<sub>4</sub>Cl; unites with PtCl<sub>4</sub> to form (C<sub>2</sub>H<sub>7</sub>ON,HCl)<sub>2</sub>PtCl<sub>4</sub>; prismatic crystals, soluble in water and in absolute alcohol (Lossen and Zanni) The sulphate (C2H7ON), H2SO4 crystallises with difficulty, and is soluble in water and in alcohol.

 $\beta$ -Ethyl hydroxylamine  $C_2H_5NHOH$ ; m p. 59°-60°, with decomposition; sp gr 0 9079 at 63 9° (Bruhl). Formed by heating for 8

with conc HCl (Behrend and Leuchs, Annalen, 257, 239); from hydroxylamine and EtI (Lobry de Bruyn, Rec. trav. chim 13, 48; Hantzeh and Hilland, Ber. 31, 2065; Dunstan and Golding, Chem. Soc Trans. 75, 807); by heating 1 part m-nitrobenzylaldoxime-N-ethyl ether with 7 parts cone HCl (Kjellin, Ber 26, 2378); by electrolytic reduction of nitroethane in H<sub>2</sub>SO<sub>4</sub> solution at 15°-20° (Pierron, Bull. Soc. chim. [3] 21, 784).

It is very easily soluble in water or alcohol,

less so in ether, benzene, or cold ligroin reduces Barreswil's solution, and is reduced by

HI to  $C_2H_5NH_2$ .

\$\textit{\beta}\$B\$-Diethyl hydroxylamine (\$C\_2H\_5\$)\_N OH, bp 130°-134°. with decomposition (Dunstan and Golding), bp. at 15 mm 47°-49° (Lachman), \$\text{COMP}\$ (D. and G.), 0.8784 sp gr 0 8771 at 15°/15° (D. and G.), 0 8784 (L). An oil formed by action of Etl upon NH<sub>2</sub>OH, and also from  $(C_2H_5)_2$ NH and H<sub>2</sub>O<sub>2</sub> (D. and G. Chem. Soc. Trans. 75, 800). From addition product of diphenylnitrosamine and Zn(Et)<sub>2</sub> by decomposition with water, along with diphenylamine and Zn(OH), (Lachman, Ber 33, 1022)

Is a feeble base, soluble in water, alcohol, or ether. Reduces AgNO<sub>3</sub> and HgCl<sub>2</sub>, and, on heating, CuSO<sub>4</sub> Reduced with HI, yields heating,  $C_1$  ( $C_2H_5$ )<sub>2</sub>NH.

αβ-Diethyl hydroxylamine C<sub>2</sub>H<sub>5</sub>NH OC<sub>2</sub>H<sub>5</sub>; b.p. 83°; sp gr 0 829 at 0°; formed by interaction of a-ethylhydroxylamine and EtBr. It is easily soluble in water, alcohol, or ether Heated

with cone. HCl at 200°, yields  $HN_2(C_2H_5)$  and  $C_2H_5(l)$  (Lossen, Annalen, 252, 230).

The hydrochloride  $C_4H_{11}NOHCl$  of an isomeric compound is obtained by action of Sn and HCl upon C<sub>2</sub>H<sub>5</sub>NO<sub>3</sub> (Lossen, *ibid* Suppl 6, 238) The salts are more soluble in water than those of hydroxylamine. The free base is a syrup, easily soluble in water, and has strong basic properties. The platinum salt is in the form of orange-yellow plates, soluble in warm alcohol and in water

Triethyloxamine (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>NO is a colourless crystalline mass obtained from ββ-diethylhydroxylamine and EtI. Also from NEt, and

H<sub>2</sub>O<sub>2</sub> (Dunstan and Golding; Lachman)
It is very easily soluble in water, less so in CHCl<sub>3</sub> and insoluble in ether Decomposes on heating. Reduces Barreswil's solution on heating It gives a precipitate with CuSO<sub>4</sub> and AgNO<sub>3</sub> On reduction, yields triethylamine

Triethyl methyl ammonium iodide

# $N(C_2H_5)_3CH_3I$

obtained by action of  $N(C_2H_5)_3$  upon  $CH_3I$  (Hofmann, Annalen, 78, 277) (for other Salts, v Topsoe, J. 1883, 620) The picrate melts at v Topsoe, J. 1883, 620) The picrate 267°-268° (Lossen, Annalen, 181, 374)

Diethyl dimethyl ammonium iodide, obtained from N(CH<sub>3</sub>),H and C<sub>2</sub>H<sub>5</sub>I; or from N(C<sub>2</sub>H<sub>5</sub>),H and CH<sub>3</sub>I (V. Moyer and Lecco, Annalen, 180, 177) (for other Salts, v Topsoe, lc) The picrate melts at 285°-287° (Lossen, Annalen, 181, 374)

Ethyl trimethyl ammonium iodide is formed from  $(CH_3)_3N$  and  $C_2H_5I$  (Müller, *ibid*. 108, 1) (for other *Salts*, v. Topsoe). The picrate melts at 299°-300° (Lossen)

Triethyl propyl ammonium iodide  $N(C_2H_5)_3(C_3H_7)I$ 

crystallises in large needles (Mendius, Annalen, **M**1, 136).

Diethyl \*\*soamylamine  $N(U_1H_5)_2(C_5H_{11})$ ; b p 154°; from the distillation of  $N(U_2H_5)_3(C_5H_{11})OH$  (Hofmann),  $[N(U_2H_5)_2C_5H_{11},HCl]_2PtCl_4$ , yellow

### Triethyl isoamyl ammonium iodide

$$N(C_2H_5)_3(C_5H_{11})I$$

formed by the action of  $N(C_2H_5)$ , upon  $C_5H_{11}I$  (Hofmann, Chem. Soc. Trans. 1852, 4, 313, Annalen, 78, 279), the hydroxide decomposes on heating as follows -

C<sub>5</sub>H<sub>11</sub>(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>N OH

 $= N(C_5H_{11})(C_2H_5)_2 + C_2H_4 + H_2O$ 

# Diethyl methyl isoamyl ammonium iodide

 $N(C_2H_5)_2CH_3(C_5H_{11})I$ 

is formed from N(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>(C<sub>5</sub>H<sub>11</sub>) and CH<sub>3</sub>I (Hofmann)

### Ethyl-methyl-150amylamine

NC2H2(CH3)(C5H11)

b p  $135^{\circ}$ ; is obtained by distillation of the hydroxide of the radical of the preceding compound (Hofmann).

Acetethylamide CH<sub>3</sub> CONHC<sub>2</sub>H<sub>5</sub>; b p 205°, sp gr 0 942 at 4 5° (Wurtz); b p. 204°-205° (Titherley), from ethyl acetate and ethylamine (Wurtz, Ann Chim Phys [3] 30, 491, Compt. rend 36, 180; Annalen, 76, 334) or from C<sub>2</sub>H<sub>5</sub>NCO and HC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> (Wurtz, *ibid* 88, 315), from CH<sub>3</sub>CONHNa and Et1 at 150° The hydrochloride forms deliquescent needles, melting at 60° With NaNH, yields CH3CONNaC2H5, which, with KMeSO4, gives CH3CONMeEt, an oil boiling at 180°, and soluble in water (Titherley, Chem Soc Trans 1901, 393) By action of Cl yields ethyl acetyl nitrogen chloride NClEt(C2H3O) (Norton, Tehermak, Bull Soc chim. [ii ] 30, 106, Compt rend 86, 1409), an oily unstable liquid, slightly soluble in water

N(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>C<sub>2</sub>H<sub>3</sub>O; bp 0 9248 at 8 5° (Wallach, Acetdiethylamide 185°-186°; sp gr Annalen, 214, 235)

Ethyl hydrazines; Ethylamide.

1 Ethyl hydrazine C<sub>2</sub>H<sub>5</sub>HN NH<sub>2</sub>; b p 99 5° at 709 mm, is prepared by reducing nitrosodiethyl urea N(C<sub>2</sub>H<sub>5</sub>)H·CO N(NO)C<sub>2</sub>H<sub>5</sub> by means of zinc-dust and acetic acid; this yields ethyl hydrazine urea (semi-carbazide)  $N(C_2H_5)H$  CO  $N(NH_2)C_2H_5$ , and this, by action of HCl, forms  $C_2H_5HN$   $NH_2$ ,  $CO_2$ , and  $C_2H_5NH_2$ . by passing in HCl the chloride separates out, which is then decomposed by strong KOH solution and solid KOH, and the resulting oily liquid distilled over BaO (Fischer, Annalen, 199, 287); also by reducing ethylnitramine with Zn and HCl (Thiele and Meyer, Ber 29, 963)

Is a colourless liquid, with faintly ammoniacal odour; has great affinity for water, in which it is soluble, as also in alcohol, ether, chloroform, and benzene; fumes in air and destroys cork and caoutchoue; reduces Barreswil's solution in the cold. Br water liberates N. It precipitates metallic oxides, and gives the isonitrile reaction with KOH and CHCl<sub>3</sub>. Forms two chlorides: (1) C<sub>2</sub>H<sub>8</sub>N<sub>2</sub>,2HCl, white needles, very

soluble in water and alcohol; on heating to 110° yields (2) C<sub>2</sub>H<sub>8</sub>N<sub>2</sub>,HCl, an amorphous horn, deliquescent body. The sulphate crystallises from alcohol in thin plates, and is very soluble in water By heating C<sub>2</sub>H<sub>5</sub>NH NH<sub>2</sub> with K<sub>2</sub>S<sub>2</sub>O<sub>7</sub> at 80°-100°, potassium ethyl hydrazine sulphonate C<sub>2</sub>H<sub>5</sub>NH NHSO<sub>3</sub>K is obtained; this forms fine needles, very soluble in water, much less

soluble in alcohol or ether (Fischer)

2 as-Diethylhydrazine (C2H5)2N NH2; bp. 96°-99°; prepared by action of zinc-dust and acetic acid upon a solution of mitrosodiethylamine (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>(NO)N; 30 grams (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>(NO)N dissolved in 300 grams water are mixed with 150 grams Zn dust and 150 grams C2H4O (of 50 p c) kept at 20°-30°, and, towards the end, at 40°-50° Excess of Zn is then dissolved by HCl, an excess of NaOH added, and the mixture distilled, the distillate is neutralised with HCl and NH<sub>4</sub>Cl separated by crystallisation the mother liquor  $(C_2H_5)_2N_2H_2$  mixed with  $(C_1H_5)_2HN$  is freed by solid KOH. By the action of HCNO diethylhydrazine urea (semicarbazide) NH<sub>2</sub>CO NH N(C<sub>2</sub>H<sub>5</sub>), is formed 4 grams of this compound are heated with 15 grams of HCl in a sealed tube at 100°, diluted and the NH4Cl separated; on treatment with KOH, pure  $(C_2\Pi_5)_2N_2H_2$  is obtained (Fischer, Annalen, 199, 308).

Is a colourless liquid with a faintly ammoniacal smell, very hygroscopic and soluble in water, alcohol, ether, chloroform, and benzene; reduces Barreswil's solution only on warming; is monobasic; the salts are soluble in water and alcohol, and difficult to crystallise  $[(C_2H_5)_2N_2H_2$   $HCl]PtCl_4$  forms fine yellow needles, soluble in water With SOCl<sub>2</sub> in icecold ether, yields (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>N NSO, an aromatic oil, b p 73° at 20 mm It is slowly hydrolysed by water (Michaelis and Storbeck, Ber 26, 310)

3 sym-Diethylhydrazine C<sub>2</sub>H<sub>5</sub> HN NH C<sub>2</sub>H<sub>5</sub>, b p at 758 mm 84°-86°. Formed by heating at 100° for 3 hours 1 part sym-diethyl-diformylhydrazide and 2 parts fuming HCl, an oil; heated with cone HCl, at 155°, yields NH<sub>4</sub>Cl and  $\rm C_2H_5Cl$  With yellow HgO forms HgEt<sub>2</sub>. With HNO, yields ethyl nitrite The hydrochloride melts at 160° with decomposition (Harries, Ber 27, 2279)

Triethyl-azonium iodide (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>NNH<sub>2</sub>I 18 formed by action of diethylhydrazine upon 11 times its weight of C2H5I (Fischer, Annalen, 199, 316). It forms needles very soluble in water and in hot alcohol; insoluble in ether and strong alkalis By action of Ag<sub>2</sub>O, gives the strongly alkaline free base, which, on heating, yields  $(C_2H_5)_2N$   $NH_2$  and  $C_2H_4$ . By the action of nascent H (Zn and  $H_2SO_4$ ), the iodide yields HI, NH<sub>3</sub>, and  $(C_2H_5)_3N$ 

Tetra-ethyl tetrazone  $(C_2H_5)_2N$  N.N  $N(C_2H_5)_2$ ; by the action of yellow HgO upon a cold aqueous solution of (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>N NH<sub>2</sub> (Fischer, Annalen, 199, . 319), is an only liquid with a disagreeable smell, not volatile without decomposition, and which does not freeze at  $-20^{\circ}$ . When decomposed by heat, yields N and  $(C_2H_5)H_2N$ . Forms an explosive oily compound with I. Is a strong base, though its salts are very unstable. It reduces silver solutions with formation of a mirror The solution decomposes on heating, yielding N,  $N(C_2H,)_2H$ , and aldehyde The Pt doubl salt [(C2H5)4N4,2HCl]2PtCl4 forms yellow prisms soluble in water.

Ethylene C<sub>2</sub>H<sub>4</sub>, Olefiant gas, Heavy car-etted hydrogen, Bicarburetted hydrogen, buretted hydrogen, Elayl, Ethene, Etherin, discovered by Deiman, Van Trootswyk, Bondt, and Lauwerenburgh (Crell's Ann. 1795, [2] 195, 310, 430) Obtained by action of H2SO4 upon alcohol; the addition of Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> increases the rate of production (Senderens, Compt rend 1910, 151, 392). The sulphuric acid can be replaced by syrupy phosphoric acid, sp gr 1.75 (Newth, Chem Soc. Trans 1901, 915); or alcohol vapour may be passed over heated phosphoric acid, or over thin layers of aluminium sulphate at 350°-400°; by the dry distillation of many organic bodies (hence occurs to the extent of 4 or 5 pc in coal gas). Also formed when CS<sub>2</sub> and H<sub>2</sub>S (or PH<sub>3</sub>) are led over heated copper (Perthelot, Annalen, 108, 194) To prepare the gas, a mixture of 25 parts (by weight) of alcohol and 150 parts sulphuric acid is heated to 170°, and a mixture of 1 part of alcohol and 2 of H2SO4 is allowed to drop slowly into the vessel by means of a funnel. The gas is passed through H2SO4, NaOH solution, and then again through H2SO4. For the preparation of small quantities of pure gas, an alcoholic solution of C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> is warmed with granulated Zn (Sabanejeff, J. Russ. Phys. Chem. Soc 9, 33) Equal volumes of CO and H led over coke impregnated with reduced Ni and Pd heated at  $95^{\circ}-100^{\circ}$ , yield  $8.3~{\rm p.c.}$  C<sub>2</sub>H<sub>4</sub> (Orloff, 1bid. 40, 1588)

Ethylene is produced on an industrial scale by the method of Maihle by passing the vapour of alcohol over amorphous alumina heated to 360°. For details, see Sprent, J. Soc. Chem.

Ind 1913, 171

Properties —A colourless gas, liquefied by a pressure of 42½ atmospheres at -11°, b p -105° (Calletet, Compt rend 94, 1224), -102°-103° (Wroblewsky, Olszewsky, Monatsh 4, 338), -103 9° (Burrell and Robertson); mp -169°, bp at 757 mm. -104 3°, sp gr 0 6095 at -102 7° (Ladenburg and Krugel, Ber 32, 49, 1821); -102 5°, sp gr 0 565 (Maass and McIntosh, J. Amer Chem. Soc 1014 36 737). crit. temp. 9 5° becomes 1914, 36, 737); crit. temp. 95°; becomes liquid at 1° and 45 atmospheres, at 4° and 50 atmospheres, at 8° and 56 atmospheres, and at  $10^{\circ}$  and 60 atmospheres (C);  $L_{\rm D} = 1.26031$ (Batuecas, Helv Chim Acta, 1918, 1, 136) I volume of water absorbs at  $t^{\circ}$ ,

#### $0.25629 - 0.009136t + 0.0001881t^{2}$

volumes C<sub>2</sub>H<sub>4</sub> (Bunsen) Alcohol (of sp gr 0 792 at 20°) absorbs  $3.59498 - 0.05772t + 0.000681t^2$ volumes (Carius, Annalen, 94, 133); H.C.p. =341.4 Cals; H.F. (from amorphous C) = -9.4 Cals. (Berthelot, Ann. Chim. Phys. [5] 23, 180).

Ethylene forms an explosive mixture with oxygen, and explodes, even in the cold, in contact with ozonised oxygen (Houzeau and Renard, J 1873, 319) Led through a hot tube, it splits up into C, H, CH<sub>4</sub>, C<sub>2</sub>H<sub>6</sub>, and C<sub>2</sub>H<sub>2</sub> (Berthelot, Annalen, 139, 277; Bone and Coward, Chem. Soc. Trans. 1908, 1197). When heated in an iron tube under a pressure of about 70 atmospheres it undergoes rapid polymerisation at 380°-400°. The liquid polymerisation products consist of mixtures of saturated, e-hylenic, and polymethylene hydrocarbons; viz.

iso-pentane, hexane, heptane, octane, nonane, amylene, hexylene, nonanaphthene, and  $\alpha\beta$  decanaphthene, hen-, deca-, dodeca-, tetradeca-, and pentadeca-naphthenes At atmospheric pressure ethylene does not polymerise, even at 600° (Ipatieff, Ber. 1911, 44, 2978) Decomposed 600° (Ipatieff, Ber. 1911, 44, 2978) Decomposed by leading over reduced Ni at 300° into C, C<sub>2</sub>H<sub>6</sub>, CH<sub>4</sub>, and H (Sabatier and Senderens, Compt rend. 124, 616, 1358). By the action of the electric spark it forms C<sub>2</sub>H<sub>2</sub> and H, and then C and H (Wilde, Zeitsch. Chem 1866, 735) It combines with H to form C<sub>2</sub>H<sub>6</sub>, when the mixture is passed through a hot tube (Ann. Chim. Phys [4] 3, 431; Bull Soc chim [ii.] 39, 145) or when in contact with Pt black in the Chim. Phys [4] 9, 431; Bull Soc chim [ii.] 39, 145), or when in contact with Pt black in the cold (Wilde, Ber 7, 354) By heating a mixture of C<sub>2</sub>H<sub>4</sub> and CO<sub>2</sub> at 400°, aldehydo is formed (Schutzenberger, Bull. Soc. chim. [ii.] 31, 482) CrO<sub>3</sub> converts it into aldehydo at 120° (Annalen, 150, 373). Fuming sulphuric acid absorbs readily large quantities of C<sub>2</sub>H<sub>4</sub> at ordinary temperatures, as does also common H SO<sub>2</sub> at 160°-170° (Butlerow Ber 6, 193) H<sub>2</sub>SO<sub>4</sub> at 160°-170° (Butlerow, Ber. 6, 193), forming C<sub>2</sub>H<sub>5</sub>HSO<sub>4</sub> (Faraday). C<sub>2</sub>H<sub>4</sub> combines at 100° with strong HI or HBr solution, but not with HCl (Berthelot, Annalen, 104, 184; 115, With bromine water forms a mixture of othylene bromohydrin and ethylene dibromide (Read and Williams, Chem Soc Trans 1917, 111, 240). N<sub>2</sub>O<sub>4</sub> reacts with ethylene to form cthylene nitrosite, and  $N_2O_5$  to form ethylene nitrate (Demjanow, Chem. Zentr. 1899, 1–1064) In presence of AlBr<sub>3</sub>, HBr unites at 0° with C<sub>2</sub>H<sub>4</sub>, forming C<sub>2</sub>H<sub>5</sub>Br With Cl<sub>2</sub>O, chlorethyl chloracetate CH<sub>2</sub>Cl CO<sub>2</sub>H<sub>4</sub>Cl is formed, whilst ClO<sub>2</sub> yields CH<sub>2</sub>Cl CO<sub>2</sub>H. C<sub>2</sub>H<sub>4</sub> combines with BF<sub>3</sub> ir sunlight to form C<sub>2</sub>H<sub>3</sub>BF<sub>2</sub> (Landolph, Ber. 12, 1586), a liquid, b p. 124°-125°, sp gr 1 0478 at 23°. Ethylene acts as a divalent radical, and forms salts with most of the acids.

radical, and forms salts with most of the acids.

Ethylene acetates (Wurtz, Compt rend. 43, 199; Atkinson, Phil. Mag [4] 16, 433).

1 Ethylene monoacetate C<sub>2</sub>H<sub>4</sub>(C<sub>2</sub>H<sub>3</sub>O<sub>2</sub>)OH, monoacetate glycol; bp. 190°-190 5° (corr) (Perkin, Chem Soc Trans. 45, 505); sp gr. 1·1108 at 15°/15°, 1 1018 at 25°/25° (P.); produced by action of KC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> upon C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> in presence of alcohol (Atkinson, 1c; cf. Seelig, D. R. P. 41507). A liquid not misciple with water: yields

41507) A liquid not miscible with water; yields glycol C<sub>2</sub>H<sub>4</sub>(OH), by heating with C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> and alcohol (Demole, Annalen, 177, 45); decomposed by heating with C2H3OCl into acetochlorhydrin

by neating with  $C_2H_3OC1$  into accoording the and ethylene diacetate (Lourenço, thid 114, 127) 2 Ethylene diacetate  $C_2H_4(C_2H_3O_2)_2$ ; b p  $186^\circ-187^\circ$ ; sp gr  $1^\circ-128$  at  $0^\circ$ ; prepared from  $C_2H_4Br_2$  or  $C_2H_4I_2$  and  $AgC_2H_3O_2$  (Wurtz, Ann Chim. Phys. [3] 55, 433), or from  $C_2H_4Br_2$  and anhydrous  $KC_2H_3O_2$  at  $150^\circ-200^\circ$  (Denoted in the second of th mole).

A liquid soluble in 7 parts of water, isomeric with ethylidene diacetate CH<sub>3</sub> CH(C<sub>2</sub>H<sub>3</sub>O<sub>2</sub>)<sub>2</sub>; b p 108 8°; sp gr. 1 061 at 12°; prepared from aldohyde and (C<sub>2</sub>H<sub>3</sub>O)<sub>2</sub>O. Dichlorethylene diacetate C<sub>2</sub>H<sub>2</sub>Cl<sub>2</sub>(C<sub>2</sub>H<sub>3</sub>O)<sub>2</sub>C; b.p. 120° at 20 mm; is produced by action of chloracetic acid upon C<sub>2</sub>H<sub>2</sub> (Prudhomme, Zeitsch. Chem. 1870, 397).

Ethylene acetochlorhydrin

# CICH<sub>2</sub>·CH<sub>2</sub>·O·C<sub>2</sub>H<sub>3</sub>O

b p. 145°; sp gr. 1 1783 at 0°; by heating a mixture of glycol and acetic acid at 100° with HCl (Simpson, Annalen, 112, 147); from C<sub>2</sub>H<sub>4</sub>

and CH2Cl CO2H (Schutzenberger and Lippman, i id. 138, 325); insoluble in water; yields ethylene oxide by action of KOH.

Ethylene acetoiodohydrin ICH, CH, O C, H<sub>3</sub>O,

heavy oil; and

Ethylene acetobromohydrin

BrCH, CH, O C, H,O

b p. 161°-163°; are prepared from

C2H4(C2H4O2)OH

by action of HI and HBr respectively, the former in the cold in presence of  $C_2H_4(OH)_2$  and  $CH_3$   $CO_2H$  (Simpson, Annalen, 113, 123), the latter at 100' (Demole, ibid 173, 120)

Ethylene glycols.

Ethylene glycols.

1 Ethylene glycol CH\_OH CH\_OH, glycol, mp —17.4°, bp 197.37° (Ladenburg and Krugel, Ber 32, 1821); bp 197°-197.5° at 764.5 mm (Wurtz), 196°-199° (corr) (Perkin, Chem Soc Trans. 45, 504), 195° at 751.3 mm (Pribram and Handl, Monatsh 2, 673); sp.gr. 1 125 at 0° (W), 1·1279 at 0° (P and H.), 1 1168 at 15°/15°, 1 112 at 25°/25° (Perkin).

Discovered by Wurtz (Corput, 1974.43, 190.

Discovered by Wurtz (Compt 1end 43, 199; Ann Chim Phys [3] 55, 400). Formed by action of ethylene diacetate upon KOH (W), from  $C_2H_4\mathrm{CH}$  and moist silver oxide at  $160^\circ-200^\circ$ (Simpson, Annalen, Suppl 6, 253); by heating ethylene monacetate with Ba(OH), or with water in sealed tubes (Debus, Annalen, 110, 316); by heating a strong aqueous solution of neurine, when glycol and N(CH<sub>3</sub>)<sub>3</sub> are formed (Wurtz, *ibid* Suppl. 6, 200); by heating ethylene chloride or bromide with PbO and 15-20 times its volume of water at 140°-170° (Eltekow, Ber. 6, 558); or with ferric oxide, or with an alkali formate and an alcohol under pressure; from ethylene bromide and water at 140°-150° (Niederist, Annalen, 186, 393), together with polyethylene glycol, by action of C<sub>2</sub>H<sub>4</sub>O (oxide of ethylene) upon water in scaled tubes (Wurtz, 1bid. 113, 255)

A mixture of glycols, in which ethylene glycol predominates, may be prepared by decomposing petroleum vapours in an iron tube heated at about 650°, converting the product into dichlorethane, &c., purifying this compound by distillation and treating the distillates with alkali carbonates in a closed vessel (Hibbert,

Met & Chem Eng. 1918, 19, 571)

Preparation -1 600 grams ethylene bromide, 700 grams fused potassium acetate, and 1500 grams alcohol (sp gr 0 83) are heated in a flask with reflux condenser until all action ceases, cooled, filtered from KBr and filtrate distilled, the portion distilled above 140° is decomposed by slight excess of Ba(OH)<sub>2</sub> and heated for 12 hours on water-bath The excess of baryta is removed by CO<sub>2</sub>, the liquid evaporated to onethird its volume, the residue treated with a mixture of alcohol and ether, the liquid removed from the crystals and distilled, first on water-bath, to separate alcohol and ether, and then over the flame; the portion distilling above 185° is then redistilled (Erlenmeyer, Annalen, 192, 244).

2. A mixture of 188 grams ethylene bromide, 138 grams potassium carbonate and 1 litre of water [or 32 parts C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub>, 25 parts K<sub>2</sub>CO<sub>3</sub>, 350 parts H<sub>2</sub>O (Groscheintz, Bull Soc. chim. [ii] 31, 293)], is heated with reflux condenser for

10 hours, is then evaporated to small volume on water-bath, the liquid portion poured off th crystals of KBr, the latter are washed with absolute alcohol. The filtrate and alcoholic washings are then distilled as in previous method; a loss owing to formation of C2H3Br is experienced by this process (Zeller and Huffner, J pr. Chem [2] 11, 229) Haworth and Perkin (Chem. Soc Trans. 1896, 175) obtained a 60 p c yield by digesting 138 grams K<sub>2</sub>CO<sub>3</sub> in 1000 c c. H<sub>2</sub>O with 188 grams C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> under a reflux condenser. The solution is evaporated very slowly to a syrup, and then extracted with a mixture of alcohol and ether.

3 1 part of ethylene bromide and 26 parts water are heated to 100° in a sealed vessel for 130 hours. This method gives a yield of over 60 p.c. of the theoretical amount (Niederist,

Annalen, 196, 354)

4. Glycol diacetate is decomposed with powdered Ca(OH)2, and the mixture distilled under reduced pressure. The yield of glycol is 93 p.c. of theory (Henry, Rec. trav. chim. 18. 221).

5 It may also be prepared by heating ethylene diacetate with methyl alcohol and hydrochloric acid (Henry, Bull. Acad. Roy

Belg. 1896, 732).

1 mol of ethylene dichloride, 5 vols. of methyl alcohol and 3 mols, of sodium formate are heated together at 165°-170° in an autoclave for 7 hours After cooling, the methyl alcohol is separated and distilled at ordinary prossure, the glycol under reduced pressure (Brooks and Humphrey, J. Ind. Eng Chem 1917, 9, 750)

Glycol is a colourless, odourless, syrupy liquid with sweet taste, miscible with alcohol and water, but almost insoluble in ether parts ether dissolve 1 1 part of glycol (Knorr, Ber. 30, 912). It dissolves NaCl, ZnCl<sub>2</sub>, and many other chlorides; also K<sub>2</sub>CO<sub>3</sub>, KOH, and

Ca(OH),

By action of oxidising agents, e.g. platinum black, it forms glycollic acid. Nitric acid converts it into glycollic acid, glyoxylic acid, and oxalic acid (Debus, Annalen, 110, 316) Heated with solid KOH to 250°, glycol yields potassium oxalate and hydrogen (Wurtz) Heated with large quantity of water at 200°-210° yields aldehyde (Nevole, Bull Soc. chim. [11 ] 25, 289); ZnCl, at 250° decomposes glycol into aldehyde, crotonaldehyde, and water. By electrolysis of an acid (H2SO1) solution of glycol, formic acid, formaldehyde, CO,, traces of a sugar and a non-volatile acid, not glycollic, are (Lob and Pulvermacher, Zeitsch. formed Elektrochem 1910, 16, 1) Chlorine forms a crystallisable halogen compound, m.p. 39°, b.p. 200°; and an only body,  $C_8H_{12}O_4$ , b.p. 240° (Mitscheilich, J. 1863, 485)  $H_2O_2$  in presence of ferrous compounds yields glycollic aldehyde (Fenton and Jackson, Chem. Soc. Trans. 1899, 75). Heated with aldehydes, glycol yields ethylene oxide derivatives, e.g glycol and crianthaldehyde, heated at 125°-130° for some days yield ethylene cenanthylidene oxide

C<sub>6</sub>H<sub>13</sub> CH CCH<sub>2</sub>

b p 180°; similarly, valeraldehyde and propaldehyde yield C<sub>4</sub>H<sub>9</sub> CH COCH<sub>2</sub>, b p 142°;

and C<sub>2</sub>H<sub>5</sub> CH OCH<sub>2</sub>, b p. 105°-107°, respectively (Lochert, Bull. Soc. chim. [ii.] 48, 337, 716). With Na and EtI, yields glycol monoethyl ether, a liquid boiling under 748 mm at 134 8°, and having a density of 0 93535

at 15°/15° (Palomaa, Ber 42, 3873).

Glycol is converted into glycollic acid by the action of Bacterium accti, provided the acid be neutralised (e.g. by CaCO<sub>3</sub>) as fast as formed, otherwise after a short time the glycollic acid formed stops the further action (A. J. Brown, Chem. Soc Trans, 51, 638). NH<sub>4</sub>Cl and glycol at 300°-400° form collidine C<sub>8</sub>II<sub>11</sub>N HCl (Hofmann, Ber. 17, 1905). Phosgene gas at ordinary temperatures converts glycol into glycol carbonate CO(OCH<sub>2</sub>)<sub>2</sub> (with liberation of HCl), a stable compound, soluble in water, alcohol, and ether, and crystallising in colourless needles (Nemirowsky, J pr Chem [2] 28, 439) Heated with strong formic acid for some time (Henninger, Ber 7, 263), or with ovalic acid (Lorin, Bull. Soc chim. [n ] 22, 104), gives glycol diformin  $({}^{\circ}_{2}H_{4}(\mathrm{CH}_{2}\mathrm{O})_{2}, \mathrm{\ b\ p.\ 174}^{\circ}; \mathrm{\ m\ the\ latter\ case}$  formic acid is also produced. With mineral acid or dehydrating agents yields acetaldehyde, ethylidene ethylene ether and chiefly diethyno other  $O < \begin{array}{c} CH_2 CH_2 \\ CH_2 \end{array} = \begin{array}{c} CH_2 \\ CH_2 \end{array} = \begin{array}{c} O \\ O \end{array}$  (Faworsky, Russ Phys. Chem Soc 1906, 38, 741), By action of sodium on glycol, we get sodium ethylenate C<sub>2</sub>H<sub>4</sub>(OH)ONa, a white crystalline deliquescent body, which, on heating to 190° with more sodium yields disodium ethylenate, a deliquescent mass The former,

with C<sub>2</sub>H<sub>2</sub>Br in a sealed tube, yields ethylene, glycol, NaBr, and probably NaCHO<sub>2</sub> (Wurtz).

De Coninck (Bull Acad Roy Belg. 1905, 360) distinguishes between glycol and glycerol as follows Uranyl sulphate is dissolved in a small quantity of water, excess of ethylene glycol added, the whole placed in a flask and exposed to sunlight In 2 hours the hquid is quite green, and in 2½ hours uranous sulphate is precipitated With glycerol no such colouration or precipitation takes place

Glycol forms a number of cyclic esters and cyclic compounds analogous to the metallic saccharates (Bischoff, Ber. 40, 2803; Grun and Bockisch, ibid 41, 3465).

### 2. Diethylene glycol

# HO CH, CH, O CH, CH, OH

b p. 250°, sp gr. 1 132 at 0°; V.D. = 3 78 at 311° (calc. 3.67) (Lourenço, Ann. Chim. Phys. [3] 67, 275), from ethylene oxide and water, or better, ethylene oxide and glycol at 100° (Wurtz); from glycol and ethylene bromide or bromhydrin at 115°-120° (Lourenço); by action of glycol monoacetate upon sodium glycol at 130°-140° (Mohs, Zeitsch. Chem. 1866,

An only liquid, soluble in water, alcohol, and ether; concentrated HI at 100° forms C2H4I2; oxidised by HNO<sub>3</sub> to glycollic acid, oxalic acid, and diglycollic acid C<sub>4</sub>H<sub>6</sub>O<sub>5</sub>. The chlorhydrin C<sub>4</sub>H<sub>9</sub>O<sub>2</sub>Cl, b p. 180°–185° (L.), 190°–200° (W.), is formed by leading HCl into ethylene oxide, or from ethylene oxide and ethylene chlorhydrin at 140° (Wurtz, Ann. Chim. Phys [3] 69, 338). I molecule ethylene chlorhydrin and 2 molecules glycol are heated at 140° saturated with HCl

and again heated at 400° (Lourenço, ibid. [3] 67, 290); a liquid soluble in water.

The bromhydrin, b p. 205°, is prepared from glycol and ethylene bromide at 160° (L)

#### 3. Tri-ethylene glycol

# C2H4(OH) O C2H4 O C2H4OH

b p  $290^{\circ}$ , sp gr 1.138; a liquid miscible with alcohol and water, and oxidised by HNO3 to diglycol-ethylenic acid CaH10O6 (Louienco, Wutrz).

The chlorhydrin  $C_6H_{13}O_3C1$ , bp  $222^{\circ}-232^{\circ}$ ;

is a liquid soluble in water (L)

The bromhydrin C6H13O3Br; bp. (with decomposition) 250° (L)

4 Tetra-ethylene glycol C<sub>8</sub>H<sub>18</sub>O<sub>5</sub>; b p. 230°,

at 25 mm (L. ; W ) The chlorhydrin  $C_8H_{17}O_4CI$  , b p. 262°–272° , is soluble in water (L)

5. Penta-ethylene glycol  $C_{10}H_{22}O_6$ ; b p 281° at 25 mm.; a viscid liquid soluble in water, alcohol, and ether (L).

6 Hexa-ethylene glycol  $C_{12}H_{26}O_7$ , b p 325° at 25 mm; a very viscid liquid (L).

Ethylene bromide C2H4Br2 or CH2Br CH2Br, m p 9 975° (Moles, Anal Fis Quim 1912, 10, 131), 10 0.2° (Biron, Zeitsch physikal Chem 1913, 81, 590), b p 131 6° (R), 129 5° at 745 mm (Anschutz, Annalen, 221, 137), 130 39° (corr.) (Thorpe and Rodger); sp gr 2 1804 at 20° (Bron, 1c), 2 2132 at 0°/4°, 2 1901 at 10 9°/4° (Thorpe Chem Soc Trans 37, 177); by action of C<sub>2</sub>H<sub>4</sub> and Br (Balard, Ann Chim Phys. [2] 32, 375); formed together with ethyldene bromide CH<sub>4</sub>CHBr, by heating CL H Br, with Br to 180° (Chandlaron, Appellar C<sub>2</sub>H<sub>5</sub>Br with Br to 180° (Tawildarow, Annalen, 176, 14) From C<sub>2</sub>H<sub>5</sub>Cl, Br, and iron wire at 176, 14) From C<sub>1</sub>H<sub>5</sub>Cl, Br, and iron wire at 100° (V. Meyer and Petienko, Ber 25, 3307), also from C<sub>2</sub>H<sub>2</sub>Br, Br, and AlBr<sub>3</sub> at 65°-70° (Mouneyrat, Bull. Soc chim. [m] 19, 497)

Preparation.—1 Ethylene, purified by passing through H.SO4 and NaOH solution, is led into bromine covered with water, contained in a wide tube, until the colour of the Br disappears; the product is washed with NaOH and water, dried by CaCl, and distilled (Erlenmeyer and Bunte, Annalen, 168, 64; Erlenmeyer, ibid 192, 244; Prideaux, Chem News, 1916, 113, 277) 2 By heating together at 150° in glacial acetic acid glycol diacetate and HBr, a quantitative yield of C2H4Br, is obtained (Perkin and Simonsen,

Chem. Soc. Trans. 1905, 856).

Is a colourless mobile liquid with a pleasant smell and sweet taste; VD 6.485 (Regnault). When heated with water to 150°-160°, it yields, first glycol, and, on longer heating, HBr and aldehyde (Carius, Annalen, 131, 173) Zn acts upon an alcoholic solution of C2H4Br2 with formation of C<sub>2</sub>H<sub>4</sub> and ZnBr<sub>2</sub> (Gladstone, Ber. 7, 364), by heating with KI and water, ethane is produced. Alcoholic KOH yields C,H<sub>3</sub>Br, and in excess C<sub>2</sub>H<sub>2</sub>. Heated with AlBr<sub>3</sub> at 100°-110°, yields C,H, and C<sub>2</sub>H<sub>2</sub>Br<sub>4</sub>; with Cl and AlCl<sub>3</sub>, yields C<sub>2</sub>Cl<sub>6</sub> (Mouneyrat)

Aqueous KOH produces, after long contact, C<sub>2</sub>H<sub>3</sub>Br (Stempnovsky, Annalen, 192, 240) By heating with strong NaOH and KOH solution, glycol and C<sub>2</sub>H<sub>3</sub>Br are produced. If C<sub>2</sub>H<sub>3</sub>Br be heated with excess of H2O and PbO to 220° aldehyde is formed (due to decomposition of C<sub>2</sub>H<sub>4</sub>(OH)<sub>2</sub>, first formed, into C<sub>2</sub>H<sub>4</sub>O and H<sub>2</sub>O) (Eltekow, Ber. 6, 558, and Nevole, *ibid* 9, 447)

Heated with strong HI solution, yields C2H4I2 (Sororkin, Zeitsch. Chem 1870, 519) Heated with Ag<sub>2</sub>O and water, aldehyde is produced, and when heated with Ag<sub>2</sub>CO<sub>3</sub> and water, yields glycol (Beilstein and Wiegand, Bei 15, 1368). Treated with Ag<sub>2</sub>SO<sub>4</sub> and benzene, yields dibromethyl sulphate (C<sub>2</sub>H<sub>4</sub>Br)<sub>2</sub>SO<sub>4</sub>; with Ag SO<sub>4</sub> and water, bromethyl sulphune acid (C<sub>2</sub>H<sub>4</sub>Br)HSO<sub>4</sub> (B and W)

Bromethylene bromide ('H\_Br ('HBr\_, bp. 186 5° (Wurtz, Annalen, 104, 243), 187°-188° at 721 mm (Denzel, ibid. 195, 202), 191° (Tawiklarow, ibid. 176, 22), 73° at 11 5 mm, 83° at 18 mm, 187°-188° at 751 5 mm (Anschutz, ibid. 221, 138), spgr 2 624 at 16° (T), 2 620 at 23° (W), 2 6189 at 17 5°/4°, 2 6107

at 21 5°/4° (A ).

Prepared from monobromethylene and Br (Wuttz), from C<sub>2</sub>H<sub>3</sub>I and Br (Simpson, J. 1857, 461), from C<sub>2</sub>H<sub>3</sub>Br and Br at 170° (Hofmann, J. 1860, 364), or from C2H4B1, and Br at 200° (Tawildarow), decomposed by KC2H3O2 at 150° or by H<sub>2</sub>O and PbO into dibromethylene and HBr C<sub>2</sub>H<sub>5</sub>NaO yields ethylidene dibromide (Gray, Chem Soc Trans 1897, 1021) Alcoholic KOH gives C<sub>2</sub>H<sub>2</sub>Br<sub>2</sub>, C<sub>2</sub>H<sub>3</sub>, and bromacetyleno C<sub>2</sub>HBr When heated with excess of absolute alcohol, C<sub>2</sub>H<sub>5</sub>Br and probably C<sub>2</sub>H<sub>3</sub>BrO bromaldehyde, are formed (Glockner, Annalen, Suppl. 7, 110)

The isomeric body CH<sub>3</sub>CBr<sub>3</sub> is not known. Dibromethylene dibromide ('.H.Br. isomerides are known

1 Acetylidine tetrabromide; CH,Br CBr, bols with decomposition at 200°; bp 103 5° at 13 5 mm; sp gi. 2 9292 at 17 5°/4°, 2 9216 at 21 5°/4° (Anschutz, Annalen, 221, 140) Formed from as-dibromethylene CH<sub>2</sub> CBr, and bromine (Lennox, *ibid* 122, 124; Chem Soc Trans 1862, 206, Reboul, Annalen, 124, 270) From C<sub>2</sub>H<sub>5</sub>Br and Br at 180° a compound C<sub>2</sub>H<sub>2</sub>B<sub>14</sub> is produced, which boils with decomposition at 208°-211° (Tawildarow) By heating a mixture of pyrotaitanc acid and biomine with water at 150° (Bourgoin, Ann Chim. Phys. [5] 12, 427)

2 Acctylene tetrabromide CHBr, CHB12, b p 137°-137 2° at 36 mm, 114° at 12 mm, at 15 mm 124°-126°, at 54 mm 151°, sp gr. 2 9710 at 17·5°/4°, 2 9629 at 21 5°/4° (Anschütz, Ber. 12, 2974, and Annalen, 221, 139); decomposes at 190° into HBr, Br, and C, HBr,

By leading C.H. into bromine covered with water (Reboul, Annalen, 124, 269, Berthelot, Bull Soc chim [11] 5, 97); the crude C<sub>2</sub>H<sub>2</sub>Bi<sub>4</sub> is then reduced by means of alcohol and Zn dust to C<sub>2</sub>H<sub>2</sub>Br<sub>2</sub>, when the admixed C<sub>2</sub>H<sub>3</sub>Br Br<sub>2</sub> is converted into C2H3Br, the C2H2Br2 is then purified by distillation and treated with bromine (Anschutz, Annalen, 221, 139), by action of Br and AlBr<sub>3</sub> at 105°-110° upon C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> (Mouneyrat, Bull Soc chim [III] 19, 498) A liquid smelling of camphor and chloroform, A liquid smelling of campnor and chlorotorm, decomposed by heating or by action of Na, by heating with alcoholic KOH, C<sub>2</sub>H<sub>2</sub> and C<sub>2</sub>HBr are produced—Cl produces C<sub>2</sub>Cl<sub>4</sub>Br, (Bourgoin, Bull Soc chim [n] 23, 4); when heated with Br and water to 180°, yields C<sub>2</sub>Br<sub>4</sub> and C<sub>2</sub>Br<sub>6</sub> (Anschutz); with C<sub>4</sub>H<sub>6</sub> and AlCl<sub>3</sub>, produces anthracene; heated with annline, dimethylanline, or alcoholic NH<sub>3</sub>, yields CHBr. CBr<sub>2</sub>.

Pentabromethane CHBr<sub>2</sub> CBr<sub>3</sub>, m.p. 56°-57°

(Bourgoin), 54° (Denzel, Ber 12, 2208), 48°-50° (Reboul); bolls with decomposition at 210° (at 300 mm.) (Denzel). From C<sub>2</sub>HBr<sub>3</sub> (Elbs and Newmann, J. pr. Chem [2] 58, 254; Lennox, Annalen, 122, 125) or C<sub>2</sub>HBr (Reboul, *ibid.* 124, 268) and bromme By slow oxidation (by exposure to air) of C<sub>2</sub>HBr<sub>3</sub> (Demole, Bull. Soc chim. [ii] 34, 204); from C<sub>2</sub>H<sub>2</sub>Br<sub>4</sub> and Br at 165° (Bourgoin, *ibid.* 23, 173). Forms prismatic needles soluble in alcohol and other.

Partmether (\* Br. \* (APRON WEIRROMER\*)

Perbromethane C<sub>2</sub>Br<sub>6</sub>v Carbon Tribromide. Ethylene bromoiodide; mp 28°; bp 163°; sp gr 2 516 at 29°. From C<sub>2</sub>H<sub>3</sub>Br and cone H1 at 100° (Reboul, Annalen, 155, 213) From C<sub>2</sub>H<sub>4</sub> and IBr (Simpson, J 1874, 326) Needles, with clocker KOH and Large 1975. with alcoholic KOH yields, in the cold, C<sub>2</sub>H<sub>3</sub>I and IIBr, and on warming HBr, HI, and C<sub>2</sub>H<sub>2</sub>. Forms iodoform with alcoholic CH<sub>2</sub>COOK at 100°

Ethylene bromhydrin C<sub>2</sub>H<sub>4</sub>Br·OH, Glycol bromhydrin, b p. 150°-152°, at 18 mm 63°-64° (Henry, J. 1889, 1321), 155° (Lourenço, Ann Chim Phys [3] 67, 287); sp gr 1·66 at 8° (H); sp gr 1·7195 at 18 6° (H.) From glycol and C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> at 115°-120° (Lourenço); from glycol and HBr at 100°, and from CH<sub>2</sub>I CH<sub>2</sub>OH and browner (Hapry); also from 3 mate shoots bromme (Henry); also from 3 mols. glycol and 1 mol PBr<sub>5</sub> (Demole, Ber 9, 48), from cthylene and HBiO (60 p.c.) (Mohiewsky, J Russ Phys. Chem Soc 30, 900); with zincolar the state of the dust and alcohol is reduced to C2H4, together with ethylene dibromide by the action of ethylene on bromine water (Read and Williams,

Chem. Soc Trans. 1917, 111, 240)

Ethylene dichloride, Elwyl chloride, Dutch liquid CH2ClCH2Cl; bp 84 9° (Pierre, J 1847-48, 63), 83 5° (corr ) (Thorpe, Chem Soc. Trans 37, 182), 84 5°-85° at 750°9 mm (Bruhl, Annalen, 203, 10), 83 3° at 749 mm (R Schiff, bbid. 220, 96), 84 1° at 760 mm (Stidel, Ber. 15, 2563); sp gr. 1 2808 at 0°/4° (Thorpe), 1 2803 at 0° (Pierre), 1 2562 at 20° (Haagen, Bull Soc. chum. 10, 355), 1 2566 at 9.8°44° Bull Soc. chim. 110, 355), 1 2656 at 98 /4°, 1 1576 at 83 3°/4° (R. Schiff), 1 2606 at 14 4°, 1.204 at 62 5° (Landolt and John), bp 83 93° (corr ) (Thorpe and Rodger) refractive index; at  $t^{\circ}$   $\mu_{A} = 1 \ 441466 - 0 \ 000446t$ , mol refract = 34 06 (Kanonnikow); capill constant at b p  $a^2 = 4$  198 (R. Schiff, Annalen, 223, 72) By action of  $C_2H_4$  upon Cl (Deiman, Trootswyk, Bondt, and Lauwerenburgh, Crell's Ann 1795, 2000) 2, 200), by leading C<sub>2</sub>H<sub>4</sub> into SbCl<sub>5</sub> or into molten CuCl<sub>2</sub> (Wohler, Pogg Ann. 13, 297), from C<sub>2</sub>H<sub>5</sub>Cl and SbCl<sub>5</sub> at 100° (V Meyer and Muller, J pr Chem [n | 46, 173); also by action of glycol upon PCl<sub>3</sub> (Wutz) or upon HCl at 100° (Schorlemmer, Chem. Soc Trans. 1881, 1); from ethylene diamine and NOCI in carefully cooled m-xylene solution (Solonina, J Russ Phys Chem. Soc 30, 606) Prepared best accord-ing to Limpricht's method (Annalen, 94, 245) Ethylene is passed into a gently heated mixture of 2 parts manganese dioxide, 3 parts common salt, 4 parts water, and 5 parts sulphuric acid, and when the mass turns yellow it is distilled It can be prepared in good yield from ethylene and chlorine if the temperature is kept at 0°; at higher temperatures considerable quantities of trichloroethane are formed It forms an

(Liebig, Annalen, 14, 37). Heated with AlCl<sub>3</sub> to 80°-85° is decomposed into HCl and C<sub>2</sub>H<sub>2</sub> (Mouneyrat, Bull. Soc. chim. [ii.] 19, 446). With NH<sub>3</sub> it forms bases, N<sub>2</sub>H<sub>4</sub>C<sub>2</sub>H<sub>4</sub>, N<sub>2</sub>H<sub>2</sub>(C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>, &c. With ethylamine, it yields collidize (trimethylpyruline C<sub>5</sub>H<sub>2</sub>(CH<sub>3</sub>)<sub>3</sub>N), C<sub>2</sub>H<sub>5</sub>Cl, and also NH<sub>3</sub> and N(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub> (Hofmann, Ber 17, 1907).

Chlorethylene CH<sub>2</sub>: CHCl, Vinyl chloride; at ordinary temp a gas; bp -18° to -15°; by action of alcoholic KOH upon ethylene chloride (Regnault, Annalen, 14, 28), or ethylidene chloride (Wurtz and Frapolli, ibid. 108, 224). To prepare it the ethylere dichloride and alcoholic potash are left in contact for 3 or 4 days in the cold, and the mixture is then warmed Combines with Cl to form C2H3Cl3 Polymerises in sunlight, and forms a solid insoluble mass of sp gr. I 406 (Baumann, Annalen, 163, 317)

(Regnault, J pr Chem [n ] 18, 80) Also by action of Zn shavings in alcoholic solution upon the trichlorethyl ester of acetic acia (Jocitsch and Faworsky, J Russ Phys Chem Soc 30, 998) Polymerises easily into a solid amorphous msoluble body

2 Sym-Dichlorethylene (Acetylene dichloride) CHCl. CHCl, bp 55°, by distillation of the compound of C<sub>2</sub>H<sub>2</sub> with SbCl<sub>5</sub> (Berthelot and Jungfleisch, Annalen, Suppl. 7, 253); also by action of Zn upon an alcoholic solution of CHClBr CHClBr, or by leading C<sub>2</sub>H<sub>2</sub> into aqueous solution of ICl (Sabanejeff, Annalen, 216, 263).

216, 262)

Trichlorethylene CHCl CCl<sub>2</sub>; bp 87 4°–
87 55°; sp gr. 1 4904 at 4°/4°, 1 4598 at 25 5°/25 5° (Veley, Proc Roy Soc. 1910, B 82, 217), 85°8′–86 0°/741 6 mm, m.p. —83°, D<sub>40</sub> 1·4649; D<sub>45</sub> 1 4695 (Erdmann, J pr. Chem. 1912, 11 85, 78) From isomeric compounds C<sub>2</sub>H<sub>2</sub>Cl<sub>4</sub>, and alcoholic KOH (Berthelot and Jungfleisch), also by action of nascent H (Zn and H<sub>2</sub>SO<sub>4</sub>) upon C<sub>2</sub>Cl<sub>8</sub> (Fischer, J. 1864, 481): from anhydrous chloral and P<sub>2</sub>S<sub>5</sub> at 160°-170° (Paternò and Oglaloro, Ber 7, 81); combines with Cl to form C<sub>2</sub>HCl<sub>5</sub> By action of ammonia in aqueous solution on tetrachloroethane (Comp. prod. chem d'Alais; Eng. Pat, 132755)

For observations on its autoxidation, see

Erdmann (l c)

Tetra-chlorethylene C<sub>2</sub>Cl<sub>4</sub> v Carbon dichloride, art Carbon Cf Weiser and Wightman, J. Phys Chem. 1919, 23, 415.

Hexachlorethane C2Cl6 v Carbon trichlor-

ide, ait Carbon.

Ethylene chlorhydrin HO CH2 CH2Cl Chlorethyle alcohol, allycol chlorhydrin; b p. 128° (Wurtz, Annalen, 110, 125), 132°, 51°-52° at 22 mm.; sp gr. 1 2005 at 18 6° (Henry, J. 1889, 1321), 1 24 at 8°. From glycol and HCl (gas) at 100° (W.) If excess of HCl be used, C<sub>2</sub>H<sub>4</sub>Cl<sub>2</sub> is produced (Schorlemmer, Chem. Soc. Trans. 39, 143); from glycol and Cl<sub>2</sub>S<sub>2</sub> (Carius, Annalen, 124, 257); from C<sub>2</sub>H<sub>4</sub> and ClOH (Carius, thid. 126, 197. Butlerow, thid. ClOH (Carius, ibid. 126, 197; Butlerow, ibid. oily liquid, insoluble in water When heated 144, 40) Dry HCl is led into glycol kept at with alcoholic KOH, it yields KCl and C<sub>2</sub>H<sub>3</sub>Cl, 148°; the C<sub>2</sub>H<sub>4</sub>Cl(OH) distils off (Ladenburg, and with K it forms H, KCl, and C<sub>2</sub>H<sub>3</sub>Cl Ber. 16, 1408) A liquid miscible with water;

yields alcohol with Na amalgam and H<sub>2</sub>O Chourenço, Annalen, 120, 92). Oxidised by CrO<sub>3</sub> to chloracetic acid (Kriwaxin, Zeitsch. Chem. 1871, 265); with KOH, yields ethylene oxide Cf Gomberg, J. Amer Chem. Soc. 1919, 41, 1414.

Ethylene chlorobromide CH<sub>2</sub>Cl CH<sub>2</sub>Br; bp 107-108° (Lesceur, Bull Soc. chim [ii ] 29, 484), sp gr. 1 79 at 0° (L), 1 705 at 11° (Montgolfier and Giraud, ibid 33, 12), 1 689 at 19°. By action of Br upon CH<sub>2</sub>Cl CH<sub>2</sub>I (Henry, Annalen, 156, 14); from C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> and SbCl<sub>5</sub> (Lossner, J. pr. Chem. [2] 13, 421) or  $C_2H_4Br_2$  and  $HgCl_2$  at  $150^\circ-180^\circ$  (M and G.); by action of Br upon  $C_2H_4Cl(OH)$  at  $130^\circ$  (Demole, Ber 9, 556). To prepare it, first chlorine and then ethylene is passed into Br, kept under a mixture of equal vols of strong HCl and water (James, J pr. Chem [2] 26, 380, also Simpson, Proc Roy Soc 27, 118), decomposed by alcoholic KOH, with formation of C<sub>2</sub>H<sub>3</sub>Cl

Ethylene chloroiodide CH,Cl CH,I; m.p. -15 6° (Schneider, Zeitsch physikal Chem 19, -15 6° (Schneider, Zeitsch physikal Chem 19, 157), bp. 140° (Sorokin, Zeitsch Chem 1870, 519), 140 1° (corr) (Thorpe, Chem Soc Trans 31, 189), 137°-138° (Meyer and Wurster, Ber. 6, 964); srgr 2 151 at 0° (S), 2 16439 at 0°, 2·13363° at 15·3°/0° (T) From CH<sub>2</sub>l CH<sub>2</sub>l and ICl; from C<sub>2</sub>H<sub>4</sub> and an aqueous solution of ICl (Simpson, Proc Roy. Soc 12, 278) Decomposed by alcoholic KOH and HI and Cl; H (1), pascent H wedle H(1) HI and (1) H C<sub>2</sub>H<sub>3</sub>Cl; nascent H yields HCl, HI, and C<sub>2</sub>H<sub>4</sub>, moist Ag<sub>2</sub>O at 160° produces glycol (Simpson) Finely divided silver at 160° yields C<sub>2</sub>H<sub>4</sub> and C<sub>2</sub>HCl CH<sub>2</sub>Cl (Friedel and Silva, Bull Soc. chim. [n.] 17, 242) Heated with HI solution, yields C<sub>2</sub>H<sub>4</sub> and C<sub>2</sub>H<sub>4</sub> [Sorokin]

Ethylene evaphydrin HO CH, CH CN: h.p.

Ethylene cyanhydrin HO CH<sub>2</sub> CH<sub>2</sub>CN; b p 220°-222° at 723.5 mm; sp gr 1 0588 at 0°. By long digestion of C<sub>2</sub>H<sub>4</sub>O (ethylene oxide) with anhydrous HCN at 50°-60° (Etlenmeyer, Annalen, 191, 273); miscible with alcohol and water; 100 parts ether dissolve 2.3 parts  $C_2H_4(OH)CN$  at 15°; insoluble in Cs. Forms a chloride with PCl<sub>5</sub>, which boils at 174°–176° under 752 mm, and has sp gr 1 443 at 18 5° (Henry, Bull Acad. Roy Belg. in. 35,

360)

Ethylene cyanide C<sub>2</sub>H<sub>4</sub>(CN)<sub>2</sub>, Succinonitrile; m.p. 54 5° (Nevole and Tscherniak, Bull Soc. chim. [n.] 30, 101), 51°-52° (Henry, ibid. 43, 618); bp 158°-160° at 20 mm (Pinner, Ber 16, 360), 265°-267° (H); sp gr 1 023 at 45° By heating on a water-bath CH<sub>2</sub>Br CH<sub>2</sub>Br with KCN and sleebel (sp. gr. 0.84) (Suprep. Proc. KCN and alcohol (sp gr. 0 84) (Simpson, Proc. Roy. Soc. 10, 574), the liquid is filtered from the KBr, and distilled, when the alcohol is first removed, then the distillation is conducted under diminished pressure; also is produced by electrolysis of potassium cyanacetate (Moore, Ber. 4, 520); is a white amorphous mass soluble in water, chloroform, and alcohol; slightly in carbon disulphide and ether; decomposed when distilled at ordinary pressure Decomposed by heating with KOH or HCl into NH<sub>3</sub> and succinic acid; with AgNO<sub>3</sub> forms plates of C<sub>2</sub>H<sub>4</sub>(CN)<sub>2</sub>,4AgNO<sub>3</sub>, which is soluble in water and alcohol, and explodes when heated (Simpson).

Ethylene diamine NH<sub>2</sub>  $C_2H_4$ NH<sub>2</sub>; m.p. 85° (Kraut, Annalen, 212, 251); b.p. 116·5°; sp.gr. 0·902 at 15° (Kraut). By heating  $C_2H_4CI_2$  or  $C_2H_4Rr_2$  with alcoholic NH<sub>3</sub> to

100° (Cloez, J. 1853, 468); by distillation of 18-diaminopropionic acid (Neuberg and Neimann, Zeitsch. physikal Chem 45, 110), by treatment of C<sub>2</sub>H<sub>4</sub>(CN), with Sn and HCl (Fairley, Annalen, Suppl 3, 372). 42 grams of CH<sub>2</sub>Cl CH<sub>2</sub>Cl and 510 cc aqueous NH<sub>3</sub> are heated for 5 hours to 115°-120° in a sealed tube; the product is then evaporated until it begins to crystallise, and is then precipitated with 3 times its volume of absolute alcohol, the precipitated (',H<sub>4</sub>(NH<sub>2</sub>),,2HCl is then washed with alcohol and the base set free by distillation with powdered NaOH (Kraut, lc., also Hofmann, Ber 4, 666) The by-product from the manufacture of chloral, consisting of CH2Cl CH2Cl, CH3 CHCl2, &c, can be used. A thick oily liquid, with faint ammoniaeal smell, soluble in water, not miscible with other or benzene, the aqueous liquid, which contains  $C_2H_4(NH_2)_2,H_2O$ , cannot be freed from water by BaO, but only by distillation over Na Caro's acid oxidises it to glyoxime (Bamberger and Seligman, Ber 36, 3831) With HClO and HBiO, yields tetrachloro and tetrabromo derivatives, eg Bi N C.H4 NBr. (Chattaway, Chem Soc Trans 1905, 381) Decomposed by HNO, into ethylene oxide and oxalic acid (Hofmann, J 1859, 386), is a strong base and forms salts, combines with ('S, to form crystals of

soluble in water, insoluble in alcohol and ether C2H4(NH2)2,2HCl, long silvery needles insoluble ın alcohol C2H4(NH2)2HCl, PtCl4, yellow leaflets, slightly soluble in water (Greiss and Martius, Annalen, 120, 327); C<sub>2</sub>H<sub>4</sub>(NH<sub>2</sub>)<sub>2</sub>(HCNS)<sub>2</sub>, large prisms, very soluble in water, in p 145° (Hofmann, Ber 5, 245) Forms many compounds with metallic salts and a periodido C<sub>2</sub>H<sub>4</sub>(NH<sub>2</sub>)HI I<sub>4</sub>, which melts at 218°.

Diethylene diamine, Preparatine

$$(C_2H_4)_2(NH)_2$$
 or  $C_2H_4 < NH > C_2H_4$ 

m p  $104^{\circ}$  (Berthelot) , b.p  $170^{\circ}$  (Hofmann, J. 1858, 343),  $145^{\circ}$ – $146^{\circ}$  (Berthelot),  $140^{\circ}$ (Rosdalsky) From ethylene chloride and (Rosalsky) From ethylene thiolide and alcoholic NH<sub>3</sub> (Cloez, Hofmann, Natanson, Annalen, 98, 291), from sodium ethylene glycollate and acid derivatives of ethylene diamine by heating at 250°-350° (D R P 67811), by heating the sodium compound of sym-diacyl ethylene diamine with anhydrous glycol or ethylene bromide at 200° (D. R. P. 73354); by reduction of ethylene oxamide with zinc-dust and KOH (D. R. P. 66461) (For other methods of preparation, see D R. P 70055, 70056, 73125, 74628, 79121, 98031, 100232)

Forms a hydrate C<sub>4</sub>H<sub>10</sub>N<sub>2</sub>,6H<sub>2</sub>O, mp 44° (Berthelot) Piperazine is not changed by heating with HCl or H<sub>2</sub>SO<sub>4</sub> at 200°. With carbonyl chloride it forms tricarbonyl piperazine It forms a periodide  $C_4H_{10}N_2$  2H11<sub>4</sub>3H<sub>2</sub>O, m.p 283° The anhydrous periodide melts at 280° (Herz, Ber. 30, 1585). Piperazine reacts with 2 molecules HB<sub>1</sub>O to form an additive compound, which, on treatment with dilute alkalı or piperazine solution, yields n-dibromq-piperazine. This latter can form an additive compound with 2 molecules of HBrO (Chattaway, Chem. Soc. Trans. 1905, 951). Piperazine reacts

with an excess of EtI at temperature of waterbath to form triethyl piperazonium iodide, mp 240°. Colourless needles, insoluble in cold water, ligroin, C<sub>2</sub>Cl<sub>3</sub>, ('<sub>6</sub>H<sub>6</sub>, and CS<sub>2</sub>; soluble in waim alcohol (Van Rijn, Chem Zenti 1898, 1, 727) (v Priperazine)

sym-Diethylene diethyldiamine

 $(C_2H_4)_2(NH\cdot C_2H_5)_2, H_2O$ 

b p 165° (Schmidt and Wichmann, Ber 24, 3247); from (C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>(NH<sub>2</sub>)<sub>2</sub> and C<sub>2</sub>H<sub>5</sub>I, or from C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> and NH<sub>2</sub>C<sub>2</sub>H<sub>5</sub> (Hofmann, J 1859, 389); from piperazine and an excess of KEtSO<sub>1</sub> in aqueous solution (Van Rijn, Chem Zentr 1898, i 727) It combines with salts of Cd, Cr, Zn, and Ni

# as-Diethylene diethyldiamine

 $NH_2 \cdot C_2H_4 \cdot N(C_2H_5)_2$ 

mobile liquid; bp 145°, sp gr. 0827 at 185°/185°; from bromethylphthalimide and diethylamine with subsequent hydrolysis, yields a platinochloride, mp 230°; an airochloride, mp 161°-163°, and a picaute, mp 211° (Ristenpart, Ber 1896, 29. 2526)

Triethylene diamine (C<sub>2</sub>H<sub>4</sub>)<sub>3</sub>N<sub>2</sub>; b p 210°; soluble in water (Hofmann, J 1858, 343; Harries, Annalen, 294, 350)

Diethylene triamine

# NH<sub>2</sub>·C<sub>2</sub>H<sub>4</sub> NH C,H<sub>4</sub>·NH<sub>2</sub>

b p. (with slight decomposition) 208°; formed with other products by action of NH<sub>3</sub> upon C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub>; the double salt with PtCl<sub>4</sub> being less soluble than that of triethylene triamine, it can be separated from that body (Hofmann, J 1861, 514)

A strongly alkaline liquid miscible with water and alcohol. Its salts are soluble in water, less so in alcohol, 2[(C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>N<sub>3</sub>H<sub>5</sub>,3HCl]3PtCl<sub>4</sub> forms golden-yellow needles.

Triethylene triamine

, 
$$C_2H_4 < NH C_2H_4 > NH$$

b p.  $216^{\circ}$  (Hofmann, J. 1861, 514); forms salts;  $[(C_2H_4)_3H_3N_3,3HCl]_2PtCl_4$ , long golden-yellow needles moderately soluble in water; with hydrobromic acid gives  $(C_2H_4)_3N_3H_3,3HBr$  from acid solutions: from weaker acid solution  $(C_2H_4)_3N_3H_3,2HBr$  Tetraethylene triamine  $(C_2H_4)_4N_3H_3$ ; by

Tetraethylene triamine  $(C_2H_4)_4N_3H_3$ ; by action of alcoholic NH<sub>3</sub> upon  $C_2H_4Br_3$  (Hofmann, Ber 3, 762); forms 3 series of salts with 1, 2, or 3 molecules of monobasic acid; the hydrobromides are amorphous bodies, almost insoluble in water, alcohol, and ether.

Triethylene tetramine

m p.  $+12^{\circ}$ , b p  $266^{\circ}$ - $267^{\circ}$ ; sp gr. 0 9817 at 15°; a strongly alkaline syrup from  $C_2H_4(1_2)$  and  $C_2H_4(NH_2)_2$ , or from  $C_2H_4Br_2$  and alcoholic  $NH_3$  (Hofmann, J. 1861, 519); yields

a yellow amorphous powder almost insoluble in water

Ethylene diformin C<sub>2</sub>H<sub>4</sub>(CHO<sub>2</sub>)<sub>2</sub>; bp 174°; by heating glycol with pure formic acid (Heninger, Ber. 7, 263); also by heating oxalic acid with glycol (Lorin, Bull. Soc. chim [ii.] 22, 104) Decomposed when heated at 200° in sealed tube into CO<sub>2</sub>, CO, H<sub>2</sub>O, and C<sub>2</sub>H<sub>4</sub>.

Ethylene ferrous chloride C<sub>2</sub>H<sub>4</sub>FeCl<sub>2,2</sub>H<sub>2</sub>O; by heating FeCl<sub>3</sub> and other to 150° (Kachler, Ber. 2, 510); forms prisms fairly soluble in water. The corresponding compound

is prepared by leading C<sub>2</sub>H<sub>4</sub> into a strong aqueous solution of FeBr<sub>2</sub> in sunlight (Chojnacki, Zeitsch. Chem. 1870, 420); forms light-green deliquescent crystals

Ethylene iodide CH<sub>2</sub>I CH<sub>2</sub>I; mp.  $81^{\circ}-82^{\circ}$  (Anonstein and Kramps, Ber. 13, 489); sp gr. 207; from C<sub>2</sub>H<sub>4</sub> and I in sunlight (Faraday, Gm. 4, 682), also in the shade, especially if warmed (Regnault, Annalen, 15, 67); a mixture of I and alcohol (absolute) is saturated with C<sub>2</sub>H<sub>4</sub> with repeated agitation (Semenow, J. 1864, 483)

Crystalline plates or prism3 decomposed by heating; when warmed with alcohol to 70°, IC<sub>2</sub>H<sub>4</sub> OC<sub>2</sub>H<sub>5</sub> is produced, HgCl<sub>2</sub> gives in the cold C<sub>2</sub>H<sub>4</sub>ICl, and on heating C<sub>2</sub>H<sub>4</sub>Cl<sub>2</sub> (Maumené, J. 1860, 345); alcoholic KOH converts it into C<sub>2</sub>H<sub>3</sub>I (Regnault, Annalen, 15, 63).

Ethylene iodohydrin CH<sub>2</sub>I CH<sub>2</sub>OH; from C<sub>2</sub>H<sub>4</sub>(OH)<sub>2</sub> and gaseous HI (Simpson, *ibid*. 11., 121); also by heating C<sub>2</sub>H<sub>4</sub>(OH)Cl with KI (Butlerow and Ossokin, *ibid*. 144, 42).

An oil, b p. 85°/25 mm.; sp.gr. 2:1649 at

18 6° (Henry, Ber 24 Ref 75).

Ethylene nitrate NO<sub>3</sub>CH<sub>2</sub>CH<sub>2</sub>NO<sub>3</sub>; b p. 114°-116° with explosion (Demjanow, Chem Zentr 1899, 1 1064); sp gr. 1 5099 at 4°, 1 4960 at 15°, 1 4860 at 25° (Perkin). Is formed when glycol is treated with HNO<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub>, also by interaction of C<sub>2</sub>H<sub>4</sub> and N<sub>2</sub>O<sub>5</sub> in the cold (Demjanow); an oily liquid which is inflammable, explodes on percussion, and is poisonous; KOH converts it into alcohol (Henry, Ber. 3, 529, also Champion, Compt. rend. 73, 571) On reduction yields CH<sub>3</sub>CHO, C<sub>2</sub>H<sub>4</sub>(NH<sub>2</sub>)<sub>2</sub>, and H<sub>2</sub>N CH<sub>2</sub>CH<sub>2</sub>OH

Ethylene nitrite

# C<sub>2</sub>H<sub>4</sub>(NO)<sub>2</sub> or NO<sub>2</sub> CH<sub>2</sub>CH<sub>2</sub>·NO

m.p below  $-15^{\circ}$ ; bp.  $96^{\circ}8^{\circ}$ ; sp gr  $1^{\circ}2156$  at  $0^{\circ}$  (Berton) Is prepared by distilling glycerol trinitrite with more than an equivalent amount of glycol Soluble in alcohol to form  $C_2H_5ONO$  (Bertoni, Gazz. chim ital 15, 353), insoluble in and slowly decomposed by water.

Nitroethylene can be prepared in 50 p.c. yield by the dehydration of β-nitroethyl alcohol by phosphoric oxide or sodium hydrogen sulphate; an almost colourless mobile liquid, b.p. 98·5°; D<sup>13</sup> 8·1 073. Vapour violently attacks the eyes and throat Readily undergoes polymerisation; with alkali the change occurs with explosive violence. Combines with bromine in ethereal solution, yielding nitroethylene dibromide, colourless liquid, b.p. 97°/21 mm. With aniline gives N-β-nitroethyl aniline NHPh-CH<sub>2</sub>-CH<sub>2</sub>-NO<sub>2</sub>, colourless leaflets, m.p. 37° (Wieland and Sakellarios, Ber. 1919, 52, B, 898).

Ethylene passed into an ice-cold mixture of nitric acid (D 1 4) and concentrated sulphuric acid containing 20 p.c. of sulphur trioxide yields on steam-distillation and fractionation under diminished pressure ethylene dimitrate, colourless oil, b.p. 105 5°/19 mm. D<sup>17</sup> 1·433, and B-n troethyl nitrate, colourless poisonous oil, b.p.

d20-122°/17 mm. D<sup>18</sup> 1 468. The latter is converted by phosphoric oxide into nitroethylene

β-Nitroethyl alcohol is a colourless odourless liquid, b p. 103°/11 5 mm. D13 3 1 309, miscible with water, alcohol, and ether obtained by the action of silver nitrite on ethylene iodohydiin (Wieland and Sakellarios, Ber. 1920, [B] 201.

CH<sub>2</sub> 0, b p. 125°, sp gr. Ethylene oxide

0.8909 at  $4^{\circ}/4^{\circ}$ ; 0 8824 at 10°/10° (Perkin, Chem. Soc. Trans. 1893, 488). From C<sub>2</sub>H<sub>4</sub>(OH)Cl and KOH (Wurtz, Annalen, 110, 125, Chim. Phys [3] 69, 317), also from  $C_2H_4(OH)Cl$ and C<sub>2</sub>H<sub>4</sub>(OH)ONa (Scheitz, Zeitsch. Chem. 1868, 379), also from  $C_2H_4I_2$  and  $Ag_2O$  at 150°, from  $C_2H_4Br_2$  and  $Ag_2O$  at 250°, or from  $C_2H_4Br_2$  and  $Na_2O$  at 180° (Greene, J. 1877, 522); also by treatment of  $C_2H_4CI(OC_2H_3O)$ with KOH (Demole, Annalen, 173, 125); by dropping chlorethylacetate on to a cooled mixture of powdered KOH and sand (Roithner, Monatsh. 15, 666).

A pleasant-smelling liquid miscible with water; when heated with water in a closed tube, yields glycol, and polyethylene glycol. Has str ng basic properties, although not an alkaline reaction. It combines with acids, and precipitates metallic hydroxides from solutions of Mg, Al, Fe, and Cu salts. With Na amalgam forms C2H6O. Pt black oxidises it to glycollic acid; PCl<sub>5</sub> produces CH<sub>2</sub>Cl CH<sub>2</sub>Cl

(Wurtz, Ann. Chim. Phys. [3] 69, 317, and 355). Equal molecules of  $C_2H_4O$  and Br at  $0^\circ$  form C<sub>2</sub>H<sub>4</sub>(OH)Br, C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> and other bodies (Demole, Ber 9, 47), but 2 molecules C2H4O and 1 molecule Br, on standing, yield large red or small yellow prisms of (C<sub>2</sub>H<sub>4</sub>())<sub>2</sub>Br<sub>2</sub>; m.p. 65°; b p with decomposition at 95°, they are insoluble in water, but soluble in alcohol or contact with Hg separates the Br and leaves dioxyethylene (Wurtz, Ann Chim Phys [3] 69, 321). By long contact with Zn(12 or KHO, a polymeride which melts at 56° and is insoluble in ether, is produced (Wurtz, Bull Soc. chim. [11.] 29, 530).

CH2O CH2 Dioxyethylene, Diethylene dioxide

mp 9°, bp 102°, sp.gr. 1 0482 at 0°. From (C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>O<sub>2</sub>Br<sub>2</sub>, and Hg by contact at ordinary temperature. The mixture is then distilled, and distillate rectified over KOH (Wurtz, Ann. Chim. Phys. [3] 69, 323), has no marked basic properties, but combines slightly with acetic acid on heating to 120°. Lourenço cold. [3] 67, 288) obtained it by heating C<sub>2</sub>H<sub>4</sub>(OH)<sub>2</sub> and C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> to 160°, but the product boiled at 95°. Forms an iodide with 2 atoms of I, m p 84°, which is decomposed by water and air, but soluble in benzene; also a sulphate and a picrate melting respectively at 100° and 66°. It also forms a compound with HgCl<sub>2</sub>, soluble in, but slowly decomposed by, water (Faworsky, J. Russ. Phys. Chem. Soc. 38, 741; Paternò and Spallino, Atti. R. Acad Lincei, [v.] 16, i. 87)

Chlorethylene oxide  $C_2H_3ClO$ ; b.p.  $70^{\circ}-80^{\circ}$ . long contact of acetylene chloriodide CHCl: CHI with 40-50 vols. of water at 200°-220° (Sabanejeff, Annalen, 216, 268); difficultly

soluble in water.

Bromethylene oxide  $C_2H_3B_1$  O, bp  $89^{\circ}-92^{\circ}$ . From biomoglycol bromhydim CHBi, CH2OH and KOH (Demole, Ber 9, 51); soluble in water.

Ethylene phosphides 1. Phosphorus, Organio

COMPOUNDS OF.

Ethylene selenocyanate  $C_2H_4(SeCN)_2$ ; m p. 128° (Proskauer), 138° (Hagelberg, Ber. 23, From CH<sub>2</sub>Br CH<sub>2</sub>Br and 1092). alcoholic KCNSe (Proskauer, ibid 7, 1281) Colourless needles, insoluble in cold water or ether, difficultly soluble in hot water or cold alcohol, dissolves unchanged in strong HNO3, but on heating gives ethylene selemous acid  $C_2H_4(SeO_3H)_2$  With alcoholic alkali, yields

othylene disclende (Hagelberg).

Diethylene disulphide  $S < {\rm CH_2\ CH_2\ CH_2\ S}$ ; m.p.  $111^\circ-112^\circ$ ; b p  $199^\circ-200^\circ$ ; V D = 4 28 (Huselberg). mann, Annalen, 126, 280). From  $C_2H_4B_{12}$  and  $K_2S$  (Crafts, *ibid.* 124, 110; 128, 220); also by heating  $C_2H_4CS_3$  or  $C_2H_4S_2Hg$  with  $C_2H_4Br_2$  at 150° (H).

Crystallises from alcohol in needles or leaflets, from ether in thick prisms which are volatile at ordinary temperatures, combines with Br and certain salts, but not with NH3; oxidised by  $\mathrm{HNO_3}$  to  $(\mathrm{C_2H_4})_2\mathrm{S_2O_2}$  The bromide

$$(C_2H_4)_2S_2Br_4$$

is a lemon-yellow amorphous body, in p 96°, very unstable, the nodide (C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>S<sub>2</sub>I<sub>4</sub>, mp. 132°-133°, forms non-black monochnic needles, insoluble in water The oxide (C2H4)2S2O2 can also be obtained by decomposition of the chloride or bromide; with water, forms crystals which decompose without fusion on heating, and are soluble in water, almost insoluble in alcohol. The peroxide  $(C_2H_4)_2S_2O_4$ , obtained by heating  $(C_2H_4)_2S_2$  with fuming HNO<sub>3</sub> to 150° (Crafts, Annalen, 125, 124), crystallises from strong HNO, in small crystals which are insoluble in

Ethylene ethylidene disulphide is obtained by heating ethylene sulphide almost to dull redness in absence of air and in a current of hydrogen sulphide. After being shaken with aqueous alkalı is obtained as an almost colourless liquid, b p 172-173° (O Matter, D R P 313650)

Ethylene hydroxysulphide C<sub>2</sub>H<sub>4</sub>(OH)SH (Throethylene glycol), from HO CH<sub>2</sub>CH<sub>2</sub>Cl and alcoholic KHS, the KCl is filtered off and the filtrate acidified with dilute HCl and evaporated at 30°-40° (Carius, Annalen, 124, 258). Is a heavy liquid, almost insoluble in water, soluble in alcohol, the salts are fairly soluble in alcohol; the mercury compound Hg(C2H5OS)2 crystallises from alcohol in needles.

Throdiethylene glycol (C2H4OH)2S is formed when the above compound is heated, H2S being evolved. It is a crystalline solid; in p. under 60°, soluble in alcohol, insoluble in water, forms salts and double compounds with metallic salts.

Ethylene mercaptan C<sub>2</sub>H<sub>4</sub>(HS)<sub>2</sub>: b.p. 146°; sp gr. 1-123 at 23 5°. From CH<sub>2</sub>Cl CH<sub>2</sub>Cl (or bromide, Werner, J. 1862, 424) and alcoholic KHS (Lowig and Weidmann, Annalen, 36, A colourless liquid, soluble in alcohol and alkalis, forms insoluble mercaptides with heavy metals;  $Pb(C_2H_4)S_2$  yellow,  $Cu(C_2H_4)S_2$ chreme green. Ethylene dimethyl sulphid. C<sub>2</sub>H<sub>4</sub>(SCH<sub>3</sub>)<sub>2</sub>, b p. 183°, from C<sub>2</sub>H<sub>4</sub>Br<sub>2</sub> and CH<sub>3</sub>SNa (Ewerlof, Ber. 4, 716) Ethylene

diethyl sulphide  $C_2H_4(SC_2H_5)_2$ , b.p.  $210^{\circ}-213^{\circ}$ (E.) gives on oxidation first  $(C_2H_5SO)_2C_2H_4$ , m.p. 170°; and next  $(C_2H_5SO)_2C_2H_4$ , m.p. 136·5° (Beckmann, J. pr. Chem. [2] 17, 469).

Ethylene thiocarbonates.

dithiocarbonateC<sub>2</sub>H<sub>4</sub>COS<sub>2</sub>, 1. Ethylene ethylene oxythrocarbonate; m p. 31°; by action of HNO<sub>3</sub> upon C<sub>2</sub>H<sub>4</sub>CS<sub>3</sub> in the cold (Husemann, Annalen, 126, 269); forms long thin tables, insoluble in water, soluble in alcohol, ether, and

Ethylene trithiocarbonate C2H4CS3; mp 39 5° (Husemann), 33 4° (Konowalow), 39° (Frasetti); sp gr. 1 4768. From  $C_2H_4Br_2$  and Na<sub>2</sub>CS<sub>3</sub> in presence of absolute alcohol (Husemann, Annalen, 123, 83), by action of water upon AlBr, C2H4Br, CS2 (Konowalow); by action of alcoholic KOH upon ethylene xanthate  $\begin{array}{l} \mathrm{C_2H_4(S\ CS\cdot OEt)_2} + \mathrm{KOH} \\ = \mathrm{KS\cdot CO\ OEt} + \mathrm{C_2H_4CS_3} + \mathrm{EtOH} \end{array}$ 

a theoretical yield; it reacts with dil KOH thus:  $C_2H_4CS_3 + EtOH + 3KOH$ 

$$-KSCOOEt+C_2H_4S_2K_2+2H_2O$$

(Frasetti, Ber. 38, 488). Forms golden-yellow, rhombic prisms, slowly soluble in alcohol. easily soluble in ether, very soluble in CS2,

CHCl<sub>3</sub>, and C<sub>6</sub>H<sub>6</sub>.

ββ'-Dichloroethyl sulphide (CH<sub>2</sub>Cl CH<sub>2</sub>)<sub>2</sub>S. so-called 'mustard gas,' was apparently obtained by Guthrie (Chem. Soc. Trans 1860, 12, 116, 1861, 13, 35) and by A Niemann (Ann 1860, 113, 288) by passing ethylene into cooled sulphur dichloride:

$$\cdot 2CH_2 \cdot CH_2 + SCl_2 = (CH_2Cl CH_2)_2S$$

The conditions for its formation by this reaction have been studied by Myers and Stephen (J Soc Chem. Ind 1920, 39, 65, T), and by Gibson and Pope (Chem. Soc Trans 1920, 117, 272) May also be prepared by converting ethylene into ethylene chlorohydrin, thence into thiodiglycol by treatment with sodium sulphide, and thiodiglycol into  $\beta\beta'$ -dichloroethyl sulphide by the action of hydrogen chloride

(1) CH<sub>2</sub> · CH<sub>2</sub>+HClO=CH<sub>2</sub>Cl·CH<sub>2</sub> OH

(2) 2CH<sub>2</sub>Cl CH<sub>2</sub>·OH+Na<sub>2</sub>S

$$=$$
(HO CH<sub>2</sub> CH<sub>2</sub>)<sub>2</sub>S+NaCl

(3)  $(\mathrm{HO}\cdot\mathrm{CH_2}\cdot\mathrm{CH_2})_2\mathrm{S} + 2\mathrm{HCl}$ 

$$=(CH_2CICH_2)_2S+2H_2O$$

(V. Meyer, Ber. 1886, 19, 3260, Clarke, Chem. Soc Trans. 1912, 101, 1583). For the conversion of ethylene chlorohydrin into dichloroethyl sulphide, see Gomberg, J Amer. Chem Soc. 1919, 41, 1414.

 $\beta\beta'$ -Dichloroethyl sulphide is more readily procured by the action of ethylene on sulphur monochloride at about 60°

$$2CH_2: CH_2+S_2Cl_2=(CH_2Cl\cdot CH_2)_2S+S$$

The product has either the constitution

or is a colloidal solution of S in (C2H4Cl)2S. According to Gibson and Pope, Guthrie's compound is a disulphide of the constitution

(Guthrie, lc; Gibson and Pope, l.c., cf. Josephson and 1919, 38, 348, T, et seq.).

technical scale by this reaction were worked out by A. G. Green.

A continuous vacuum still for its manufacture is described by Streeter (J. Ind. Eng. Chem 1919, 11, 292)

 $\beta\beta'$ -Dichloroethyl sulphide, when pure, boils at 120°/34 mm, 122 5°/37 mm., and 217°/760 mm. and readily solidifies in cold weather, forming long, colourless needles or prisms, which melt at 135° to a liquid of sp gr. 15°/4°=1.285. It is almost insoluble in water, and is readily hydrolysed by boiling with an alcoholic solution For other physical properties, see Gibson and Pope; for a number of synthetic reactions, see Davies (Chem. Soc. Trans. 1920, 117, 297). It causes intense inflammation and suppuration when in contact with the skin or when breathed First used on account of its physiological and toxic action as an offensive

agent by the Germans during an attack on Ypres in June, 1917 For a method of quantitative estimation of the substance in air, see J. Amer. Chem. Soc.

1920, 42, 266.

The existence of the so-called chloroethylene dithiodichloride (C<sub>2</sub>H<sub>3</sub>Cl)<sub>2</sub>S<sub>2</sub>Cl<sub>2</sub> (?), said to be obtained by the action of C<sub>2</sub>H<sub>4</sub> upon boiling S<sub>2</sub>Cl<sub>2</sub>, and described as a light yellow liquid with a pleasant smell, is doubtful.

On treating  $\beta\beta'$ -dichloroethyl sulphide with concentrated intric acid it is converted into ββ'-dichloroethyl sulphoxide (CH<sub>2</sub>Cl CH<sub>2</sub>)<sub>2</sub>SO, colourless plates, m.p. 51°, and afterwards the sulphone (CH<sub>2</sub>Cl CH<sub>2</sub>)<sub>2</sub>SO<sub>2</sub>, m.p. 110° (Spica, Gazz. chim. ital. 1919, 49, ii. 299) Treated with bromine the dichloroethyl sulphide yields (CH<sub>2</sub>Cl CH<sub>2</sub>)<sub>2</sub>S,2Br<sub>2</sub>, an orange-coloured substance which rapidly loses bromine, and is converted into a bright-yellow solid

(CH2Cl·CH2)2S,Br2

m.p 43°-44° (Gibson and Pope)
Ethylenethiccyanate C<sub>2</sub>H<sub>4</sub>(SCN)<sub>2</sub>; m p. 90°.
From CH<sub>2</sub>Cl-CH<sub>2</sub>Cl and alcoholic KCNS (Sonnenschem, J. 1855, 609, Buff, Annalen, 100, 229); CH<sub>2</sub>B<sub>1</sub> CH<sub>2</sub>Br may be used with advantage (Glutz, *ibid.* 153, 313); forms rhombic plates slightly soluble in cold water, more so in hot, and in alcohol, decomposed by heat, volatile in steam; its vapour excites tears.

Ethylidene acetamide CH<sub>3</sub>CH(NHC<sub>2</sub>H<sub>3</sub>O)<sub>2</sub>; m p. 169°; formed by acting on acetamide with aldehyde; forms large prisms decomposed by

acids (Tawildarow, Ber. 5, 477).

Ethylidene acetate CH<sub>3</sub>·CH(C<sub>2</sub>H<sub>3</sub>O<sub>2</sub>)<sub>2</sub>; p.p. 169°; sp gr. 1061 at 12°. From aldehyde and  $(C_2H_3O)_2O$  at 180° (Geuther, Annalen, 106, 249), from alcoholic C<sub>2</sub>H<sub>3</sub>O<sub>2</sub>K and CH<sub>3</sub>CHCl·C<sub>2</sub>H<sub>3</sub>O<sub>2</sub> (Schiff, Ber 9, 304); by passing acetylene into a solution of mercuric oxide in glacial acetic acid to which an alkyl sulphate, particularly methylene sulphate, has also been added (Eng Pat. 112766, 1918); or \(\beta\)-naphthalene sulphonic acid dissolved in glacial acetic acid may be used instead (Eng. Pat. 112765); has a smell like that of onions, and is decomposed by water into aldehyde and acetic acid.

Ethylidene azine  $CH_3CH:N\cdot N:CHCH_3$ ; b p.  $95^\circ-96^\circ$  at 760 mm.; sp gr. 0.832 at  $17^\circ$ . Prepared by shaking an ethereal solution of aldehyde with an aqueous solution of hydrazine hydrate. The conditions for its preparation on a At '80° it is unchanged, but at a higher tempera-

ture gives off nearly all its N as gas It is fairly stable to alkalis, but is hydrolysed by acids into aldehyde and hydrazine (Curtius and Linkeisen, J. pr. Chem. 1898, [ii.] 58, 310).

Ethylidene biuret  $NH < {\rm CO \ NH} > {\rm CH \cdot CH_3}$ ,

Trigenic acid, by leading HCNO into well-cooled aldehyde (Liebig and Wohler, Annalen, 59, 296), crystallises in small prisms, slightly soluble in water, nearly insoluble in alcohol, has a slightly When heated, liberates CO2, NH3, acid taste. and traces of collidine C<sub>8</sub>H<sub>11</sub>N (Herzig, Monatsh. 2, 398). Is hardly decomposed by NaBrO. HNO3 decomposes it and liberates cyanuric acid The silver compound AgC4H6N3O2 forms amorphous precipitate, soluble in boiling water.

Ethylidene bromide CH, CHBr, b p. 114°-115° (Tawildarow, *ibid.* 176, 12), 109°-110° at 751 mm. (Anschutz, *ibid.* 195, 202), 110 5° at 760 mm. (Anschutz, *ibid.* 221, 137), 108°-110° (corr.) (Perkin, Chem. Soc. Trans 45, 523), b p. 107°-108° (V. Meyer and Muller, J. pr Chem. [2] 46, 168), sp gr 2 129 at 10° (T). 2 1001 at 17 5°/4°, 2 0891 at 20 5°/4° (Anschutz) 2 0822 at 21 5°/1°, 2 1029 at 15°, 2 0854 at 25° (P) From C2H5Br and Br at 170° (Hofmann, Proc Roy. Soc. 10, 619; Caventou, Compt rend 52, 1330) Is produced by action of PCl<sub>3</sub>Br<sub>2</sub> but not of PBl<sub>5</sub> upon aldehyde (Paterno and Pisati, Ber 5, 289), also by heating CH<sub>2</sub>: CHBr with HBr to 100° (Reboul, Compt. rend. 70, 398). A heavy liquid; alcoholic KHS has no action upon it On heating with water and PbO to 130°, aldehyde and HBr are produced (T) With SbCl<sub>5</sub> gives CH<sub>3</sub> CHCl<sub>2</sub> (Henry, Bull. Soc chim [n ] 42, 262)

Ethylidene bromiodide CH3CHB1I, below -20°; b p 142°-143°, sp g1 250 at 1°, 2 452 at 16°. From C<sub>2</sub>H<sub>3</sub>Br and HI in the cold (Pfaundler, J. 1865, 483; Reboul, Annalen, 155, 212); by shaking CH<sub>3</sub>CHI<sub>2</sub> with IBr solution (Simpson, Bull Soc chim [ii ] 31, 412); decomposed by alcoholic KOH or Ag<sub>2</sub>O into HI and C<sub>2</sub>H<sub>3</sub>Br, Br yields CH<sub>4</sub>CHBr,

Ethylidene chlorobromide CH CHClBr; m p. 16 6° (corr ) (Schneider, Zeitsch. physikal Chem. 19, 157); b p. 81°-84·5° at 750 mm, 82 7° at 760 mm. (Stadel, Ber. 15, 2563); sp gr. 1 667 From C2H, Br and concentrated H(1 at 100° (Reboul, Annalen, 155, 215); from C<sub>2</sub>H<sub>5</sub>Cl and Br in sunlight (Denzel, ibid. 195, 193). By action of Cl upon C<sub>2</sub>H<sub>5</sub>Br (Lescœur, Bull. Soc chim [11] 29, 483) Is decomposed at ordinary temperature by alcoholic KOH on long standing; with Ag<sub>2</sub>O gives aldehyde; and with

AgC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> forms CH<sub>3</sub>CH(C<sub>2</sub>H<sub>3</sub>O<sub>2</sub>)<sub>2</sub> (L.)

Ethylidene chloriodide CH<sub>3</sub>CHCH , b p

117°-119°; sp gr 2 054 at 19° By agitating a

mixture of CH<sub>3</sub>CHI<sub>2</sub> and ICl, formed also from CH3CHCl2 and Al2I6 (Simpson, Bull. Soc chim

[1i.] 31, 411)

Ethylidene or Ethidene chloride CH<sub>3</sub>CH(1<sub>2</sub>, m.p. -101 5° (Schneider, Zeitsch. physikal Chem. 22, 233), b.p. 57·4°-57 6° at 750·9 mm, sp gr. 1·1743 at 20°/4° (Bruhl, Annalen, 203, 11), 1·2124 at 0°, 1·1805 at 22°/0°; respectively. fractive index  $\mu_{\Lambda}$  (at  $24.7^{\circ}$ ) = 1 405724.  $R_{\alpha}$ = 34·1 (Kanonnikow); bp 57°-57 7° at 738 7 mm., sp gr. 1.2013 at 0° (Pribram and Handl, Monatsh 2, 650), b p. 56.7°-56.9° at 749.1 mm., sp gr. 1.1895 at 9.8°/4°, 1.11425 at 56.7°/4° (R. Schiff Annalen, 220, 96), 57.32° (corr.) (Thouge

and Rodger), crit. temp. 254 5° (Pawlewsky, Ber. 16, 2633); H.C.p. = 267 1 cals. (Berthelot and Ogier, Bull. Soc chim. [11] 36, 68). From C<sub>2</sub>H<sub>5</sub>Cl and Cl (Regnault, Annalen, 33, 312); from C<sub>2</sub>H<sub>4</sub>O and PCl<sub>5</sub> (Beilstein). By action from C<sub>2</sub>H<sub>4</sub>O and PCl<sub>5</sub> (Beilstein). By action of HCl upon copper acetylene (Sabanejeff,  $\imath b \imath d$ . 178, 111). Is prepared by passing a mixture of chlorine and  $C_2H_5Cl$  over animal charcoal heated to  $250^\circ{-}400^\circ$  (Damoiseau, Bull. Soc chim. [n ] 27, 113) Is obtained as a by-product in the manufacture of chlora! Is decomposed by alcoholic KOH into HCl and C2H3Cl. Sodium produces at 180°-200° hydrogen, acetylene, cthylene, ethane, and C₄Ĥ₃Cl (Tollens, Annalen, 137, 311) By action of Cl, CH, CCl3 and CH2Cl CHCl2 are produced.

Ethylidene di-150-nitramine is formed by the interaction of  $CO(Et)_2$ , or COEtMe, and NO, in  $C_2H_5ONa$  The lead salt is anhydrous and crystallises in cubes. The dimethyl ether torms rhombic (rystals, and melts at 75°. The 180-nitramine itself is hydrolysed by mmeral acids into acetaldehyde NH<sub>2</sub>OH and oxides of N. With Na amalgam, is reduced to hydrazine (Traube, Annalen, 300, 120).

Ethylidene diethyl ether

CH<sub>3</sub> CH(OC<sub>2</sub>H<sub>5</sub>)<sub>2</sub> (v Acetal)

Ethylidene dimethyl ether CH3CH(OCH3)2, Dimethyl acetal, b.p 64 4° (Dancer, Annalon, 132, 240), 62 7°-63 3° at 757 6 mm (R Schifl, ibid 220, 104), sp gr 0 8787 at 0°, 0 8590 at 14°, 0 8476 at 25° (D), 0 8013 at 62 7°/4° (S); capillarity constant at bp  $a^2 = 4.092$  (Schiff, Annalen, 223, 74), occurs in clude wood spirit (D.). 2 volumes of wood spirit, I volume aldehyde, and I volume of glacial acetic acid are heated to  $100^{\circ}$  (Alsberg, J. 1864, 485), also by oxidation of CH<sub>3</sub>OH and C<sub>2</sub>H<sub>5</sub>OH by MnO<sub>2</sub> and H2SO4 (Wurtz)

Ethylidene methyl propyl ether

 $CH_3$   $CH(OCH_3)(OC_3H_7)$ 

b p $~103^{\circ}\text{--}105^{\circ}$  (Bachmann, Annalen, 218, 46).

Ethylidene ethyl propyl ether

CH<sub>3</sub> CH(OC<sub>2</sub>H<sub>5</sub>)(OC<sub>3</sub>H<sub>7</sub>)

b p 124°-126° (Bachmann, lc).

Ethylidene dipropyl ether CH<sub>3</sub> CH(OC<sub>3</sub>H<sub>2</sub>)<sub>2</sub>, b p 146°-148°, sp gi. 0 825 at 22° (Girard, J. 1880, 695).

Ethylidene methyl isobutyl ether

 $CH_3 CH(OCH_3)(OC_4H_9)$ 

bp 125°-127° (Claus and Tramer, Ber 19, 3005; Bachmann, l.c.).

Ethylidene ethyl isobutyl ether

 $CH_3 \cdot CH(OC_2H_5)(OC_4H_9)$ 

b p  $155^{\circ}$  (Claus and Trainer, lc).

Ethylidene di isobutyl ether CH<sub>3</sub> CH(OC<sub>4</sub>H<sub>9</sub>)<sub>2</sub>, b.p.  $168^{\circ}$ -170°, sp.gr. 0.816 at 22° (Claus and Trainer,  $l\epsilon$ ; Guard,  $l\epsilon$ ).

Ethylidene methyl 180amyl ether

 $CH_3 CH(OCH_3)(OC_5H_{11})$ 

b p 141°-144° (Bachmann, l.c.)

Ethylidene ethyl isoamyl ether  $CH_3 \cdot CH(OC_2H_5)(OC_5H_{11})$ 

b p. 165°-167° (Claus and Trainer, lc.).

Ethylidene di isoamyl ether

 $\mathrm{CH_3CH}(\mathrm{OC_5H_{11}})_2$ 

b p 210.8° (corr.), sp.gr. 0 8347 at 15° (Claus and Trainer, lc).

Ethylidene hydramine CH<sub>3</sub>·CH(OH)NH<sub>2</sub> v. | Aldehyde-ammonia, art. Aldehyde.

Ethylidene imine CH<sub>3</sub>CH: NH; m.p. about 85°; b.p. 123°-124°. If aldehyde ammonia be kept in vacuó over H<sub>2</sub>SO<sub>4</sub> for several days, the imine is formed. It crystallises in brilliant colourless crystals, which have an odour like It is soluble in water, EtOH, acetamide CH<sub>3</sub>COOH, CHCl<sub>3</sub>, C<sub>6</sub>H<sub>6</sub>, and toluene. The vapour density at 260° agrees with the simple formula, but at lower temperatures the V.D is higher. It forms a picrate, and combines with HCN to form ('H<sub>3</sub>·CH(NH<sub>2</sub>)CN. It polymerises to form trimeric ethylidine imine

which forms a trinitroso- derivative, with N<sub>2</sub>O<sub>3</sub> in CHCl<sub>3</sub>; opaque yellow-white needles, melting at 161° (Delépine, Compt. rend. 1897, 125, 951, and 1907, 114, 853).

Ethylidene iodide CH<sub>3</sub>CHI<sub>2</sub>; b p. 177°-179° sp.gr. 284 at 0°. By combination of C2H2 and HI (Berthelot, Annalen, 132, 122, Semenow, Zeitsch. Chem. 1865, 725); from CH<sub>3</sub>CHCl<sub>2</sub> and Al<sub>2</sub>I<sub>6</sub> (Gustavson, J. Russ. Phys. Chem. Soc. 6, 164); from C<sub>2</sub>H<sub>3</sub>Br and HI (Friedel, Ber 7, 823). Decomposed by alcoholic KOH into HI and C.H.I.

Ethylidene malonic acid CH<sub>3</sub>·CH C(COOH)<sub>2</sub>; only known in combination, the ethyl ester CH<sub>3</sub>CH:  $C(COOC_2H_5)_2$ , bp. 220°, 115°-118° at 17 mm.; sp.gr. 1.0435 at 15°. From CH<sub>2</sub>(CO<sub>2</sub>Et)<sub>2</sub> (1 mol.) aldehyde (2 mols), and  $(C_2H_3O)_2O$  ( $(1\frac{1}{2})_2O$ ) and  $((1\frac{1}{2})_2O$ ) and ((Annalen, 218, 157). An ethereal oil smelling of camphor; by long contact with Ba(OH) in the cold yields ethoxy malonic acid C5H8O5, malonic acid C<sub>3</sub>H<sub>4</sub>O<sub>4</sub>, and aldehyde.

Ethylidene oxide CH<sub>3</sub> CHO v. ALDEHYDE.

Ethylidene ethylene oxide

$$CH_3 \cdot CH < \frac{OCH_2}{O\dot{C}H_2}$$

b p. 82° (Verley, Bull. Soc. chim [iii.] 21, 276). 82 5° at 765 8 mm.; sp gr. 1 002 at 0°. aldehyde and excess of glycol at 100° (Wurtz, Compt. rend. 53, 378; Annalen, 120, 328); a hquid with irritating smell, soluble in 1½ vols water, from which CaCl<sub>2</sub> separates it; with acetic acid gives glycol diacetate.

Ethylidene ethoxyacetate CH<sub>3</sub>CH(OEt)OAc; bp. 125°-130°; sp gr 0 941. By heating together acetal and acetic anhydride for 3 hours at 150°. A pleasant-smelling oil, slowly decomposed by cold water into alcohol, aldehyde, and acetic acid, rapidly on boiling.

Ethylidene sulphonic acids.

1. Ethylidene hydroxysulphonic acid

### CH<sub>3</sub>CH(OH)(HSO<sub>3</sub>)

Salts of this acid are formed by action of aldehyde upon alkaline hydrogen sulphites; they are crystalline bodies, soluble in water, and decomposed on heating into water, aldehyde, and sulphites.

2. Ethylidene chlorsulphonic acid

obtained by action of CH3CHCl2 upon neutral alkaline sulphites at 140°; the salts are crystalline, and the acid is fairly stable.

3. Ethylidene disulphonic acid

By oxidation of trithioaldehyde (C<sub>2</sub>H<sub>4</sub>S<sub>3</sub>) or thialdin by KMnO<sub>4</sub> solution (Guareschi, Gazz. chim. ital. 9, 75; Annalen, 222, 302). 10 grams thialdin are treated with 30-35 grams ZnMn<sub>2</sub>O<sub>8</sub> and 300 grams water; after filtering, BaH<sub>2</sub>O<sub>2</sub> is added and excess of Ba precipitated by CO<sub>2</sub>; the Ba salt is then precipitated by alcohol. forms a strongly acid only liquid, very soluble in water and alcohol, and is very stable; forms stable salts Na<sub>2</sub>C<sub>2</sub>H<sub>4</sub>S<sub>2</sub>O<sub>6</sub>,H<sub>2</sub>O, small silky crystals soluble in 6071 parts of alcohol (90 p.c.) at  $24.5^{\circ}$ ;  $K_2C_2H_4S_2O_6, 2H_2O$  forms large transparent crystals soluble in 1.56 parts of water at 17°

ETHYL ACETATE v. Alkyl aretates, art.

# ETHYL-m-AMINOPHENOL

$$\langle \frac{OH}{} \rangle NH \cdot C_2H_5$$

(1) Prepared by adding monoethyl aniline to fuming sulphuric acid, converting the ethyl and and and into the sodium salt, melting this with potassium hydroxide at 220° dissolving the product in water, and acidifying with hydrochloric acid. The filtered solution is neutralised with sodium carbonate, and the mono ethyl-m-amino phenol extracted with benzene (Bad. Anil. und Soda Fabrik, D. R. P. 48151).

# (2) Sodium-m-phenylene oxamato

is mixed with sodium ethyl sulphate, alcohol, and sodium carbonate, and heated in an autoclave fitted with a stirrer to 180°. After distilling off the alcohol, and extracting the mass with water, the residue is boiled with dilute sulphuric acid, and the cooled solution of ethyl-m-phenylenediamine sulphate is mixed with sodium nitrite, warmed, and neutralised with sodium carbonate (idem D R P. 76419).

(3) Aniline-2 · 5-disulphonic acid is neutralised with alkali, and the solution diluted, mixed with sodium ethyl sulphate, and heated in an autoclave to 170°-180°. Sodium carbonate is added to the cooled solution which precipitates ethyl-m-ammophenol (Farberfabrik, vorm F. Bayer & Co, D R. P. 82765); m.p. 62°; b.p 176°/12 mm

### ETHYLANILINE

Is manufactured by heating aniline hydrochloride with alcohol in an autoclave at 180°. The hydrochloride separates out on cooling. Or aniline hydrochloride may be boiled with diethylaniline under a reflux condenser, hydrochloric acid added, and the hydrochloride separated by crystallisation. The base boils at 206°/760 mm.; sp gr. 0.954 at 18°. Yields methyl ethyl aniline on methylation, and benzyl ethyl aniline on benzylation.

ETHYLBUTYLACETIC ACID v. OCTOIC ACIDS. ETHYL-iso-BUTYLACETIC ACID v. OCTOIC ACIDS.

ETHYL BUTYRATE v. BUT'RIC ACID.

MINE

ETHYLKETENE v. KETENES.

ETHYLKETENECARBOXYLATEv. KETENES. ETHYLMALONIC ACID v. GLUTARIC ACID and MALONIC ACID

ETHYLMORPHINE v. OPIUM.

ETHYLPROPYLACETIC ACID v. HEPTOIC ACTOS

#### ETHYL-o-TOLUIDINE

$$\begin{array}{c} \mathrm{CH_3} \\ \end{array}$$

May be prepared by heating a mixture of otoluidine, ethyl alcohol, and hydrochloric acid, or a mixture of o-toluidine, ethyl alcohol, and a small quantity of iodine. Boils at 213°-214°;

sp.gr. 0 9534.

EUBORNYL. Trade name for bornyl-a-bromo-isovalerate, obtained by brominating chloro-isovaleric acid and esterifying borneol with the product. A syrupy aromatic liquid, b.p. 175°-178°. Used as a sedative (v. Syn-THETIC DRUGS).

α-EUCAINÉ. Methyl ester of N-methylbenzoyl-triacetone-alkamine carboxylic acid. First obtained by Merling (Ber Deut pharm Ges. 1897, 173) by acting on acctone with ammonia to form triacetoneamine, treating this with hydrocyanic acid to form the cyanhydrin, of \(\beta\)-eucaine.

ETHYL DIPHENYLAMINE v. DIPHENYLA- | which by hydrolysis yields triacetone-alkaminecarboxylic acid. On benzoylation and methylation it forms a-eucaine. Formerly employed as a substitute for cocaine. Its use is now superseded by  $\beta$ -eucaine, which is less painful and not so toxic

> B-EUCAINE (benzoyl-vinyl-diacetone-alkamine)

$$\begin{array}{c} \text{CH} \\ \text{O\cdot CO C}_{6}\text{H}_{5} \\ \text{CH}_{2} \\ \text{(CH}_{3})_{2}\text{C} \\ \text{NH} \end{array}$$

A local anæsthetic, used chiefly as the lactate or hydrochloride, in 2-3 p.c. solution. Is prepared by condensing acetone with oxalic acid and ammonia to form the hydrogen oxalate of diacetoneamine, condensing this with paraldehyde to produce the cyclic vinyl-diacetoneamine (Harries, Annalen, 1897, 328; 1898, 346), reducing by means of sodium amalgam to a mixture of the cis and trans forms of the trimethyl hydroxy piperidine (D. R. P. 95622), treating with sodium amylate to produce the cis form only of this compound (D. R. P. 95621), and treating with benzoyl chloride (D R P 97672), and finally with hydrochloric or lactic acid to obtain the corresponding salt

EUDOXIN v. SYNTHETIC DRUGS.

**EUCAIRITE.** Selenide of silver and copper (Ag,Cu)2Se, crystallising in the cubic system. It is lead-grey, but usually tarnished and dull; sp gr. 75. It is found massive and granular embedded in calcite in the Skrikerum copper mine in Småland, Sweden, and in the Cacheuta mine in the province of Mendoza, Argentina.

L. J. S. EUCALYPTOL. The volatile oil of the leaves of Eucalyptus globulus, consists mainly of a body C<sub>10</sub>H<sub>18</sub>O, b p. 176°-177°; sp gr. 0 923 at 16°. It is optically mactive, has a camphorlike smell, and is probably identical with cincol and cajeputol (v. OILS, ESSENTIAL).

EUCÂLYPTUS GUM v. Kino.

EUCALYPTUS MACRORHYNCHA. Eucalyplus macrorhyncha (F. v. M.), a fair-sized tree, is the 'red stringy bark' of New South V'ales,

EUCAINE, EUCHININ, EUCODIN, EUCOL, and the ordinary stringy bark tree of Victoria (Smith, Chem. Soc. Trans. 1898, 73, 697).

The leaves yield under favourable conditions a very large amount (10 pc.) of a crystalline glucoside termed by Smith myrticolorin, which can be isolated in the crude condition by mere extraction with boiling water. The solution on cooling became semi-solid owing to the separa-tion of crystals, and these can be purified by extraction with ether to remove chlorophyll and crystallisation first from alcohol and subsequently from water. It formed pale-yellow needles, gave on hydrolysis quercetin and glucose, and at first appeared to be a new glucoside of quercetin. Though very similar to rutin its identity with this glucoside was unsuspected in that rutin by hydrolysis was presumed at that time to give quercetin and 2 molecules of rhamnose (Schunck, *ibid.* 1888, 53, 264). Schmidt in 1908 (Arch. Pharm 246, 214), however, pointed out that rutin in this manner yields not only rhamnose but glucose, and the probability that myrticolorin—as also viola quercitrin and osyritrin—were identical with rutin was subsequently confirmed by Perkin (*ibid.* 1910, 97, 1776)

A. G. P

EUCALYPTUS OIL v OILS, ESSENTIAL EUCALPYTUS RESIN v. RESINS

EUCLASE. Basic silicate of aluminium and glueinum (GlO, 17·3 pc.) HGlAlSiO<sub>5</sub>, crystallising in the monoclinic system. The welldeveloped crystals have a very perfect cleavage parallel to the plane of symmetry, hence the name, from εθ, well, and κλάσις, fracture They are colourless, yellow, green, or blue; sp gr 3.1 (higher than that of beryl), H 71/2 The mineral is not attacked by acids, and the water is expelled only at a high temperature It is found as single isolated crystals in gold washings at Ouro Preto in Brazil, and on the River Sanarka in the southern Urals. Minute crystals have also been found in mica-schist in the Grossglockner district of the Austrian Alps, and in granite in the Fichtelgebirge, Bavaria The mineral is occasionally cut as a gem-stone, but it has the drawback that it readily splits along the perfect cleavage. L J. S.

EUCODAL. Trade name for the hydrochloride of dihydrohydroxycodemone Used as a nageotic

**EUCODEINE.** Syn. for codeine methyl bromide.

EUCOL. Trade name for guarcol acetate

EUCOLITE v EUDIALYTE

EUCRYPTITE. Orthosilicate of aluminium and lithium (Li<sub>2</sub>O, 11 9 pc) Li<sub>2</sub>AlSiO<sub>4</sub>, crystallising in the hexagonal system and belonging to the nephelite group of minerals. It occurs intimately intergrown with albite as an alteration product of spodumene at Branchville, Connecticut. An artificial orthorhombic form of Li<sub>2</sub>AlSiO<sub>4</sub>, dimorphous with eneryptite, has been called pseudo- or β-eucryptite (F. M. Jager and A. Simek, 1914).

L. J. S.

EUCUPIN. Trade name for iso-amylhydro-

cuprein.

EUDESMIN C22H26O6 occurs in the kinos of eucalyptus species, the oils of which contain cincole and pinene, but not phellandiene It may be obtained by extracting a concentrated aqueous solution of the kino with ether, purifying by treatment with chloroform, and crystallising from methyl alcohol Colourless prismatic needles, m p 107°,  $[a]_{\rm D}^{21}$  -64 4° (m chloroform). Contains 4 methoxy- groups, and is unacted upon by hydroxyl or ketone reagents. Red solution with sulphuric acid. Nitric acid converts it into dinitroeudesmin, colourless needles, m p. 214°. Boiling cone. nitric acid forms 4:5-dinitroveratrole (2 mols). Chlorine in acetic acid solution gives dichloroeudesmin; colourless rectangular plates, mp. 163°. Dibromoeudesmin, prepared in like manner, colourless needles, m.p. 172°,  $[a]_{\rm p}^{22}+69.4$ ° (in chloro form); this, on oxidation with permanganate, gives 6-bromoveratric acid, m.p. 184°. Diiodocudesmin, needles, m p. 175° (Robinson and S.nith, J. Roy. Soc. New South Wales, 1914, 48, 449)

**EUDIALYTE.** Silicate and zirconate (ZrO<sub>2</sub>,

14-16 p.c.) of sodium, calcium, and ferrous iron, occurring as large well-developed rhombohedral crystals. These are brownish-red or rose-red in colour; sp.gr. 29-3·1. The mineral occurs in nepheline- and sodalite syemites in the Juliane-haab district in south Greenland, at Magnet Cove in Arkansas, on Sedlovatoi Island in the White Sea, and on the Kola peninsula in Russian Lapland The name cudialyte, from εδ, well, and διαλύειν, to dissolve, refers to the fact that the mineral is readily decomposed by acids.

Eucolite, a closely related variety, differs in being optically negative, instead of positive This is from the nepheline-syemites of the Langesundsfjord in Norway L J S

EUDRENINE. A solution containing cucaine

and adrenaline.

EUFORMOL. Dextrm formaldehyde

**EUGENOL** (HO)(CH<sub>3</sub>O)C<sub>6</sub>H<sub>3</sub>·CH<sub>2</sub>·CH : CH<sub>2</sub> (C<sub>3</sub>H<sub>5</sub>: CH<sub>3</sub>O: HO=1 3.4) occurs in oil of cloves from the leaves of Eugenia caryophyllala (Thunb) (Bonastre and Ettling, Annalen, 9, 68), in the oil from the leaves of the Ceylon cinnamon tree (Stenhouse, Annalen, 95, 103, Schimmel & Co, Chem. Zentr 1902, 11 1486), from Cinnamomum pedatinervium (Meissn.) (Goulding, Chem Soc. Trans 1903, 1101), C Tamala (Nees et Eberm.) (Schimmel & Co., Chem. Zentr. 1910, 1 1720), C cassia (Plume), and C zeylanicum (Nees) (Duyk, Chem. Zentr. 1896, ii. 358, Weber, Arch Pharm. 230, 232); from the fruit of Pimenta officinalis (Lindl.) (Bonastre, lc., Oeser, Annalen, 131, 277); from the sap of Acacia Farnesiana (Willd) (Walbaum, J. pr Chem. 68, [2] 235), in the oil from Ocimum Basilicum (Linn) (Schimmel & Co, Chem Zentr. 1900, 1 906); in calamus oil (Thoms and Beckstroem, Ber. 1902, 3187); in Ylang Ylang oil (Schimmel & Co, Chem. Zentr 1903, 1 1087; n. 272); in olive oil from Pugli (Canzoneri, Gazz chim. ital. 1897, 27, 11. 1); in oil of nutmeg (Power and Salway, Chem. Soc. Trans. 1907, 2041); in sassafras leaves and bark (Pomeranz, Monatsh. 11, 101; Power and Kleber, Chem. Zentr. 1897, u. 42); in the oil from the leaves of the bay tree (Mittmann, Arch. Pharm. 27, [3] 539); in oil from Maltese oranges (Gildemeister and Stephan, Arch. Pharm 235, 583), and in other ethereal The methyl ether of eugenol

# $(CH_3O)_2C_6H_3CH_2\cdot CH:CH_2$

occurs in the oil of Asarum canadense (Linn.) (Power and Lees, Chem Soc. Trans. 1902, 67), of A. arifolium (Michx.) (Miller, Arch. Pharm. 240, 371); in oil from Paracoto bark (Jobst and Hosse, Annalen, 199, 75; Wallach and Rheindorff, ibid. 271, 300), in Ylang Ylang oil; in oil from the bark of Cinnamomum pedatinervium, in oil from Maltese oranges (v. supra); and in oil of citron (Schimmel & Co, Chem Zentr 1899, ii. 879).

Oil of cloves, which contains eugenol and a terpene as the chief constituents, is treated with potash; the potassium salt of eugenol separates, is pressed out, washed with alcohol, and the eugenol set free by the addition of a mineral acid (Wasserman, Annalen, 179, 369). It is obtained by a similar process from oil of cinnamon leaves or from that of Primenta officinalis (Lindl.). Another method consists in separating eugenol from oil of cloves by means of the compound it forms with sodium accetate (Chem.

EUGENOL 687

Werke Byk D. R. P. 100418; Chem. Zentr. 1899, i. 764). In the former process, a residue is left after treating the oil of cloves with potash, and by distilling this under reduced pressure, acetyl eugenol, m p. 29°, is obtained (Erdmann, J. pr Chem. 1897, [2] 56, 146). By reducing coniferin in alkaline solution with sodium amalgam, eugenol is formed (Chiozza, Chem Zentr. 1888, 443). Methyl eugenol (allyl guaiacol) has been prepared synthetically by treating veratrol (dimethylcatechol) with allyl iodide and zinc-dust (Moureau, Compt. rend. 121, 721).

Pure eugenol is a colourless oil; b p. 244 5° (Frankforter and Lando, J. Amer. Chem Soc 27, 641), 247 5° (Wassermann, Annalen, 179, 366), 253'5° (corr ) (Perkin, Chom Soc Trans 1896, 1247); sp.gr. 1 0785 at 4°/4°, 1 0734 at 10°/10°, 1 0663 at 20°/20°; specific magnetic rotation, 2·1974; molecular magnetic rotation at 15°, 18.727 (Perkin, l.c.); dielectric constant, 60 (Mathews, J. Phys. Chem. 9, 641),  $\mu_{\rm D}$  1.54437, sp. heat, 0 5024; mol. heat of combustion, 1304 cals. (F. & L. lc) Eugenol reddens litmus, smells strongly of cloves, and has a burning taste It does not reduce Barreswil's solution but reduces ammoniacal silver solutions on long standing Eugenol may be detected by the following reactions (i) ferric chloride imparts a blue colour to its alcoholic solution; (ii) zinc chloride yields a transitory pale-yellow colour; (iii) sulphuric acid gives first a brown colour, changing quickly to purple and finally to wine-red; (iv) Burgess (Analyst, 1900, 25, 265) makes use of a reagent prepared by dissolving 10 grams of mercuric salt in 25 n c. sulphuric acid, and making the solution up to 100 cc. with the latter. By shaking 2 c.c of eugenol with 5 c.c of the reagent, and allowing the solution to stand, a pale violet colour is developed (For estimation of eugenol in oil of cloves, v. Verley and Bosling, Ber 1901, 3359; Thoms, Chem. Zeit. 1903, 27, 954; Arch. Pharm. 241, 592; Spurge, Pharm J. 1903, [4] 16, 701, 757; Schimmel & Co., Chem. Zentr. 1903, n. 1124; Reich, Zeitsch Nahr. Genussm 1909, 18, 401.)

Eugenol and its derivatives are readily converted into the corresponding derivatives of the isomeric isoeugenol (v. infra), which on oxidation yields vanillin and its derivatives Chromic acid oxidises eugenol to acetic acid, carbon dioxide, and water (Wassermann, lc.); chromyl chloride, however, combines with eugenol, and on decomposing the product with water, vanillin can be extracted (Novarine, US. Pats. 365918, 365919; Ber. Ref. 1896, 812). Nitric acid oxidises eugenol to oxalic acid and a resin, but in ethereal solution, 5-nitro-eugenol is formed (v. infra). Ferric chloride oxidises it to dehydroeugenol, mp. 105°-106° (Cousin and Hérissey, Compt. rend. 1908, 146, 1413). Oxidised with potassium permanganate, eugenol yields homovanillin, vanillin, and vanillic acid (Erlenmeyer, Ber. 1876, 273) Hydrogenisation of either eugenol or isoeugenol in the presence of platinum black, yields dihydroeugenol (propylguaiacol), b.p. 246°-248° (Fournier, Bull. Soc. chim. [4] 7, 23).

5-Nitroeugenol is prepared by acting on eugenol in ethereal solution with nitric acid. It forms large triclinic crystals, m.p. 43°-44°

(Weselsky and Benedikt, Monatsh. 3, 388). With tin and hydrochloric acid, it produces aminochlorhydroeugenol hydrochloride; aminochlorhydroeugenol melts at 97°. Nitroeugenol, heated with acetic anhydride and sodium acetate, forms intro-aceto-eugenol, mp. 61°, which, oxidised by potassium permanganate at 70° (Tiemann, Ber 1876, 418), yields nitrovanilic acid. C<sub>4</sub>H<sub>2</sub>(COOH)(OCH<sub>3</sub>)(OH)NO<sub>2</sub>, decom-

posing at 210° without melting.

Acyl and aryl derivatives of eugenol are obtained by treating eugenol with acyl or aryl anhydrides in the cold, in presence of some condensing agent such as sulphuric acid, zinc chloride, pyridine, &c. The chlorides may be substituted for the anhydrides (Merck, D. R. PP. 103581, 109445, Chem Zenti 1899, 11 927, 1900, 11 407; Riedel, D. R. P 189333; Chem. Zentr 1908, 1. 185, Pond & Beers, J. Amer. Chem. Soc. 19, 825). Acetyl eugenol, which occurs in oil of cloves (Erdmann, J. pr Chem. 1897, [2] 56, 146), melts at 29°, and boils at 281°–282° (752 mm.) (Freyss, Chem Zentr. 1899, 1 835), benzyl eugenol has b p. 235°, and on heating with potash and subsequently with potassium dichromate and sulphuric acid, the benzyl ether of vanillin is obtained (Boehringer and Sons, D. R. P. 65937; Ber Ref. 1893, 211) Eugenol carbonate, m.p. 93°-94°, is obtained by passing phosgene gas into an alkaline solution of eugenol, on treatment with ammonia, the carbamate is formed (F. von Heyden Nachf D. R P 58129, Ber Ref 1892, 186), the car-bonate can also be obtained from eugenol and the diphenyl ester of carbonic acid (D. R. P. 99057, Chem Zentr. 1898, n. 1190) adding eugenol to a cooled mixture of pyridine and chlorsulphonic acid in carbon disulphide, potassium eugenyl sulphate, m.p. 203°, is obtained, the latter is transformed by heating with excess of potash into potassium isoeugenylozone, yields potassium vanillin sulphate (Verley, Bull. Soc. chim. 1901, [3] 25, 46).

### Eugenyl acetic acid

$$C_6H_3(CH_2 CH : CH_2)(OCH_3)(OCH_2 CO_2H)$$

is obtained by heating eugenol with chloracetic acid in the presence of sodium hydroxide for 20 hours, and decomposing the sodium salt thus formed with hydrochloric acid, m.p. 75°. By heating the acid with potash and amyl alcohol at 150°, isoeugenyl acetic acid, m.p. 92°-94°, is produced; and oxidation of the latter with potassium permanganate yields vanillin acetic acid (Gassmann and Krafft, Ber. 1895, 1870).

Eigenyl phosphoric acid is obtained by treating eugenol with phosphorus oxychloride and decomposing the resulting chloride with water; in p. of anhydrous acid, 105° (Boehringer & Sons, D. R. P. 98522; Chem. Zentr. 1898, ii. 950; Oeser, Annalen, 131, 277). On heating with alcoholic potash, isocugenyl phosphoric acid is obtained, and by heating the acid sodium salt of the latter to 150°, isocugenol is obtained quantitatively.

Eugenyl alcohol is prepared by heating eugenol in 20 p c. sodium hydroxide solution with formaldehyde at 60°; m.p. 37°-38° (Monasse, Ber 1902, 3894).

Eugenol glucoside, m.p. 132°, is produced by the action of acetochlorhydrose on the potassium 688 EUGENOL.

salt of eugenol (Michael, Amer. Chem. J. 6,

Eugenol and isoeugenol form compounds with proteins which are stated to be used in the treatment of tuberculosis (Belart, Eng. Pat. 9246, 26075; Fr. Pat. 389889; J. Soc. Chem. Ind. 1908, 998; 1909, 1325).

For compounds with iodine, v F. v. Heyden Nachf. D. R P. 70058; Ber Ref. 1893, 915; Ingle, J. Soc. Chem. Ind. 1904, 422) The Nsubstituted aminoethyl compounds of eugenoland isoeugenol- acetamide are stated to be used as local anæsthetics (Einhorn, D. R. P. 208255; J. Soc. Chem Ind 1909, 491).

Bromine in excess forms with eugenol, dibromeugenol dibromide, m p 118°-119°, which, treated with zinc-dust in alcoholic solution, yields dibromeugenol, m.p. 59° (Chasanowitz and Hell, Ber. 1885, 823, Auwers, ibid 1901, By treating eugenol with bromine in chlorotorm at 0°, bromeugenol is formed (Lando, J. Amer Chem. Soc. 1905, 27, 641) Tubromeugenol and other brom- derivatives (v. Lando, l c., Auwers and Muller, Ber. 1902, 35, 114;Hell and Anwandter, ibid. 1895, 2085)

Eugenol methyl ether occurs in several ethereal oils, and can be obtained from veratrol (v. supra). It is also obtained by the action of methyl iodide and caustic potash on eugenol (Ciamician and Silber, Ber. 1890, 1164); b p 247°-248°. It is readily converted into isoeugenol methyl ether, b p 263°, which yields methyl vanillin and veratric acid on oxidation with potassium dichromate and sulphuric acid

iso Eugenol

 $(HO)(CH_2O) C_6H_3 \cdot CH CH \cdot CH_3(C_3H_5 CH_3O HO = 1 3.4)$ occurs in small quantities in oil of nutmeg (Power and Salway, Chem Soc Trans 1907, 2041), and as the methyl ether in the oil from Asarum arifolium (Michx) (Miller, Arch Pharm. 240, 371). It is prepared by adding 5 parts of eugenol or an equivalent quantity of oil of cloves to 12.5 parts of potash, dissolved in 18 parts of amyl alcohol, and heating for 16-20 hours at 140°. The product is steam distilled, and the residue acidified with sulphuric acid. The isoeugenol separates out, is washed with sodium carbonate solution, and purified by distillation (Tiemann, Ber. 1891, 2870; 1894, 2580, Lairi, Eng Pat 17547, J. Soc. Chem Ind. 1891, 854, Haarmann and Reimer, D. R. P. 57808, Ber. Ref 1892, 94). The amyl alcohol may be replaced by methyl, ethyl, or butyl alcohols (Gassmann, Compt. rend. 124, 38; F. von Heyden Nachf. D. R. P. 70274; J. Soc Chem Ind 1892, 633). Other methods are to heat eugenol with 4 parts of caustie potash and some water at 220° (Einhorn and Frey, D. R P 76982; Frdl m 863; Ber 1894, 2455); to heat the alkalı derivative of eugenol to 200° in the absence of air (Fritzsche, D. R P. 179948; J. Soc. Chem. Ind. 1907, 1216); and to heat the acid sodium salt of isoeugenylphosphoric acid to 150° (v. Eugenylphosphoric acid).

iso Eugenol forms colourless crystals, m p. 33°; b.p. 264°-265° (J. Soc. Chem. Ind. 1892, 633), 193 5° (100 mm.), and 266 5°-268.5° (760 mm ); sp gr. 1.0994 at 4°/4°, 1.0944 at 10°/10°, 1.0872 at 20°/20°; specific magnetic rotation 2.5778; molecular magnetic rotation at 15°, 21·469 (Perkin, Chem Soc Trans. 1896, 1247). On

oxidation, isoeugenol and its derivatives yield the corresponding derivatives of vanillin. isoeugenol, when treated with sodium peroxide, yields vanillin itself (Haarmann and Reimer. Eng. Pat. 11952, 14928; J. Soc. Chem. Ind. 1895, 506; 1897, 633; cf. Majert, D. R. P. 82924; Ber. Ref. 1895, 878). Ozone oxidises isoeugenol in the same way, and vanillin is also produced by the electrolysis of the sodium salt of isoeugenol and subsequent addition of acid (Otto and Varley, U.S. Pat. 553039, 553593, Ber. Ref 1896, 249; cf. Otto, Ann. Chim Phys. 1898, [viii.] 13, 120). Ferric chloride oxidises isoeugenol to dehydroisoeugenol, m.p. 133° (Cousin and Hérrisey, Compt. rend. 1908, 147, 247).

sso Eugenol is readily polymerised by small quantities of mineral acids, acid chlorides, or metallic haloids, forming discougenol, which crystallises in colourless needles, mp. 178° (F. von Heyden Nachf. D. R. P. 70274; J. Soc Chem. Ind 1892, 633), 180° (Puxeddu, Gazz. chim. ital. 39, i. 131) Similarly, the ethyl ether of isoeugenol, when dissolved in alcohol hours, polymerises into diethyldissoeugenos, m.p. 130° (Puxeddu, l.c.; Wassermann, Annalen, 179, 375).

The acyl and aryl derivatives are obtained by methods similar to those employed for the eugenol compounds, but the solutions must be kept cool to prevent polymerisation taking place, acetyl isoeugenol, mp. 79°-80°; benzoyl isoeugenol, mp. 103°-104°; benzyl isoeugenol, mp. 48° (Pond and Beers, J. Amer. Chem. Soc. 19, 825; Merck, D. R. PP. 103581, 109145; Chem. Zentr. 1899, 11. 927; 1900, 11. 407; Haarmann and Reimer, D. R. P. 57568; Ber. Ref 1892, 93) If acetyl chloride is added to isocugenol at 54°, and the temperature is finally raised to 80°, diacetyldisseugenol is obtained, and by hydrolysis with acids, disoeugenol is formed (Tiemann, Ber. 1891, 2870; 1894, 2580). Methylene chloride reacts with an alkaline solution of eugenol forming methylenedissoeugenol, m p. 50°-52°, which on oxidation yields methylenedivanillin (Lesault & Co., D. R. PP. 75264, 76061; Ber Ref. 1894, 812, 928).

5-Nitrossoeugenol is formed by the action of nitric acid on isoeugenol in acetic acid solution, on recrystallisation from isobutyl or amyl alcohols it forms a reddish-vellow mass, which decomposes at about 150° (Puxeddu and Comella, Gazz chim. ital. 1906, 36, ii. 450).

isoEugenol carbonate is prepared in the same way as eugenol carbonate (q.v.) (F. von Heyden Nachf D R P. 61848; Ber. Ref. 1892, 486).

By adding excess of bromine to isoeugenol, bromisoeugenol dibromide, m.p. 138°-139°, 19 formed. If only 1 molecule of bromine is added, an unstable isoeugenol dibromide, m.p. 95°, is produced Di- and tri-soeugenol dibromides have been prepared (Hell and Portman, Ber. 1895, 2088; Hell and Bauer, Ber. 1904, 1128; Zincke and Hahn, Annalen, 329, 1).

iso Eugenol methyl ether occurs in the oil of Asarum arifolium (v. supra). It can be prepared by warming eugenol methyl ether with alcoholic potash (Ciamician and Silber, Ber. 1890, 1165) or by treating isoeugenol with dimethyl sulphate and aqueous potash (Mannich, Aich. Pharm. 248, 127); bp. 263°.

isoEugenol is distinguished from eugenol by the following reactions. (1) ferric chloride gives an olive-green colouration with its alcoholic solution, (11) zinc chloride, a bright rose-pink colour; (m.) sulphune acid, a rose-pink colour changing to light-brown

EUGUFORM, EUMYRDIN, EUPHTHAL-MIN, EUPORPHIN v SYNTHETIC DRUGS.

EUKODAL. Oxydihydrocodemone hydrochloride Used as a narcotic (Freund and Speyer, Munch med Woch 1917, 64, 380).

EULATIN. Trade name for a mixture of p-bromobenzoic acid, o-aminobenzoic acid, and antipyrine

**ÉŬONYMUS** (Euonymi Cortex, B.P.) (deleted from U.S. P. 1916) is the root bank of E. atropurpureus (Jaquin), a shrub indigenous to the United States, and known there as 'wahoo' or burning bush.' It is said to contain an amorphous bitter principle and a glucoside euonymin; the latter, according to Hans Meyer (cf. Schmiedeberg, Aich exp Path. Pharm. 1883, 16, 163), possesses a digitalis-like action, causing systolic arrest of the flog's heart in very small doses Nothing is known about it chemically. For a. account of earlier investigations, v Rogerson (Chem Soc. Trans. 1912, 101, 1040), who isolated dulcitol (2 1 p c of the bark) and other substances, but could not find any glucoside The latter negative result may have been due to hydrolysis by the steam distillation employed The name euonymin is also applied to dried extracts of varying composition, brown euonymm being from the root bark, and green (containing chlorophyll) from the stem back

EUPAD. An antiseptic consisting of equal weights of chloride of lime and bone acid.

**EUPHORBIC** EUPHORBIUM, ACID, EUPHORBONE v Gum resins.

EUPHORINE v SYNTHETIC DRUGS.

**EUPHRASIA TANNIN** v TANNINS.

EUPHYLLIN. Trade name for a compound of theophyllme with ethylene-diamine white crystalline soluble powder, used as a diuretic (v. SYNTHETIC DRUGS).

**EUPITTONIC ACID, Eupittone, Pittacal,** Hexamethoxyaurin C25H26O9

$$O \ \, \underbrace{\begin{array}{c} \mathrm{OMe} \\ \mathrm{OMe} \end{array}} \ \, \mathrm{C[C_6H_2(\mathrm{OMe})_2\mathrm{OH}]_2}$$

Pittacal is a blue colouring matter obtained by Reichenbach in 1835 from the highboiling portions of beechwood tar. Gratzel also from the same products obtained a brown substance which gave the same blue colour reaction with baryta as the pittacal of Reichenbach. The colouring matter, which only exists in small quantity in this brown substance, was extracted and examined by Liebermann (Ber. 9, 334). It is an orange-red crystalline powder, soluble in alcohol and acetic acid, forming brown solutions. It forms with alkalis purple. and with ammonia blue solutions, from which carbon dioxide precipitates blue salts, soluble in pure water. Calcium, magnesium, barium, and tin salts also give blue precipitates with the alkaline solutions. The calcium and magnesium salts are soluble ın water, Hydrochloric and sulphuric acids form red Vol. II.-T.

solutions, and the latter turns pure blue on warming. In acid solutions, it dyes animal fibres orange, in ammoniacal solution especially with tin mordant, blue-violet Liebermann called this colouring matter eupittone, and regarded it as at least closely allied to pittacal (Bei 11, 1145) Hofmann (Ber. 12, 1371, 2216), by the action of hexachlorethane C<sub>2</sub>Cl<sub>6</sub> on dimethyl pyrogallate mixed with alcoholic potash or soda, obtained a substance identical in composition with the cupittone of Liebermann, and strongly resembling it in properties. It is an orangeyellow substance, soluble in acetic acid, and precipitated therefrom by alcohol. It melts at 200° and decomposes partly into a blue sublimate. It forms the same alkali salts and gives the same sulphuric acid reaction as cupittone. This body is hexamethoxy-rosolic acid C<sub>19</sub>H<sub>8</sub>(OCH<sub>3</sub>)<sub>6</sub>O<sub>3</sub> Heated with alcoholic ammonia, it yields hexamethoxy-rosandine

which crystallises in broad colourless needles, and has no tractorial properties. When 2 grams cupittone are heated with 20 cc alcoholic methylamine (10 pc) at 150°-160° for 21/2 hours, it yields hexamethoxydimethylformylparaleucamline

 $CH[C_6H_2(OMe)_2NHCH_3]_2C_6H_2(OMe)_2NHCHO$ m p 187° (Liebermann, Bei 34, 1034) gallol is produced in attempting to replace the methoxyl groups by hydrogen. Its formation is analogous to that of iosolic acid

$$3C_8H_{10}O_3+CO_2=C_{25}H_{26}O_9+2H_2O$$

Hofmann terms this body eupittonic acid, and uses the name as synonymous with pittacal and Eupittonic acid cannot be obtained eupittone by heating the sodium derivative of dimethyl pyrogallate or of dimethyl-methyl-pyrogallate separately, in air, a mixture of the two, how-ever, with excess of soda gives sometimes as much as 10 pc of its own weight of the acid. The action is comparable with that in which rosamline is produced from aniline and toluidine.

$$-2C_8H_{10}O_3 + C_9H_{12}O_4 = C_{25}H_{26}O_9 + 3H_2$$

The oxygen necessary to remove the hydrogen is obtained from the atmosphere, as in a closed vessel no such change as the above takes place. Eupittonic acid appears to be dibasic, the sodium and barium salts,  $C_{25}H_{24}Na_2O_9$  and  $C_{25}H_{24}BaO_9$ , have been prepared. Paper steeped m a solution of the acid, and dried, is a most sensitive test for free alkalis on account of the blue colour of the alkaline salts of cupittonic Hydrochloric acid, however, produces With acetic anhydride, the same blue colour a diacetyl derivative,  $C_{25}H_{24}O_9(C_2H_3O)_2$ , mp. 265°, is produced, which, curiously, is insoluble in alkalis, although its molecule ought to contain four hydroxyl groups

The dibenzoyl derivative  $C_{25}H_{24}O_9(C_7H_7O)_2$  forms golden needles, mp  $232^\circ$ , the dimethyl ether  $C_{25}H_{24}Me_2O_9$  has mp  $242^\circ$ , the diethylother  $C_{25}H_{24}Et_2O_9$  has mp.  $201^\circ-202^\circ$ ; and the 10do compound C25H26O9I4 forms brown shining

Eupittone black, noreupittone, hexaoxyaurin  $C_{19}H_{14}O_7$  or  $[C_6H_2(OH)_3]_2C: C_6H_2(OH)_2: O$ is formed by adding eupittone to sulphuric acid at 140° and keeping the temperature at 125° until the mass is pure blue; it is a dark shining black powder, and dyes mordanted fibres through a dirty violet to a deep black, the hydrochloride  $C_{19}H_{14}O_{7}, HCl, C_{2}H_{6}O$  is deep blue (Liebermann and Widermann, Ber. 34, 1033)

EUPNINE. Trade name for a preparation

of caffeme and rodine

**EUPORPHINE.** Trade name for apomorphine methyl bromide.

EUPYRIN v SYNTHETIC DRUGS.

**EUROPIUM.** Eu = 152 (cf Urbain and Lacombe, Compt rend 1904, 138, 637, and Jantsch, ibid 1908, 146, 173)

Source --The oxide of this extremely late element is present in very small amounts in monazite sand, and is extracted from this mineral in the fraction containing the yttrum earths

Exhaction.—In separating europium from its associates, advantage has been taken of the isomorphism existing between the double intrates of bismuth and those of the metals of the rare earths.

Bismuth nitrate gives rise to a series of double salts having the general formula

$$3M^{II}(NO_3)_2, 2B_1(NO_3)_3, 24H_2O$$

where the bivalent metal may be magnesium, zinc, nickel, cobalt, or manganese (Urbain and Lacombe, Compt. rend. 1903, 137, 568). Magnesium bismuth nitrate

$$3 {\rm Mg} ({\rm NO_3})_2, 2 {\rm Bi} ({\rm NO_3})_3 24 {\rm H}_2 {\rm O}$$

is isomorphous with the corresponding double magnesium nitrates

$$3 {\rm Mg}({
m NO_3})_2, 2 {
m M^{IM}}({
m NO_3})_3, 24 {
m HI}_2 {
m O}$$

where MIII Ce, La, Nd, Pr, Sm, Eu, Gd, and Tb

To a mixture of these metals in the form of then double magnesium intrates is added a large excess of magnesium bismuth intrate When the product is crystallised methodically from nitric acid solution, the double magnesium nitrates of cerium, lanthanum, praseodymium, neodymium, and samanium first separate, followed by the double salt of bismuth, leaving curopium and gadolinium in the mother liquors As the fractional crystallisation proceeds, the rare earths yielding double nitrates less soluble than the bismuth double salt, are gradually climinated until at a certain point the middle fractions contain no other tervalent metal than When this point is reached, all the samarum has been crystallised out, and thus separated from the europium and gadolinium The bismuth still in solution is removed from the mother liquor by hydrogen sulphide, and the europium and gadolinium separated by further fractionation of the filtrate, the europium double nitrate being the first to crystallise from this solution (Demarçay, Compt. rend. 1900, 130 1019, 1469, Urbain and Lacombe, *ibid.* 1904, 138, 627). This crystallisation process is a satisfactory method for obtaining pure europium, samarium, and gadolinium, and affords a means of separating quantitatively europium and samarium (cf. Eberhard, Zeitsch. anorg. Chem. 1905, 45, 374, James and Robinson, J. Amer. Chem. Soc. 1911, 33, 1363).

J. Amer Chem Soc. 1911, 33, 1363).

Europia (Europrum oxide) Eu<sub>2</sub>O<sub>3</sub>, obtained from the purified double salt, shows no samarium spectrum, and only the strongest lines of gadolimum (Demarçay, Compt. 1end 1901, 132, 1482), it has a pale pink tint, but when produced by heating the sulphate at 1600°, the colour is somewhat deeper

Europous chloride EuCl, is a colourless amorphous substance, forming a neutral solution

in water, which oxidises at 100°.

$$12EuCl_2 + 3O_2 = 8EuCl_3 + 2Eu_2O_3$$

Europium sulphate  $\rm Eu_2(SO_4)_3.8H_2O$  forms pale-pink crystals, stable in air and dehydrated completely at 375° (Compt\_rend\_1904, 138, 627)

The europium salts yield pale-pink solutions and in strong nitric acid they exhibit an absorption spectrum consisting of eight somewhat faint bands

The spark spectrum is characteristic, and was first observed by Lecoq de Boisbaudian in that given by crude samaria, three very intense line in the blue being ascribed by him to a new earth  $Z_t$ . The reversion spectrum shows the band  $\lambda 615$  referred by de Boisbaudian to the earth  $Z_\zeta$  (Compt. rend. 1893, 116, 674., 117, 199)

The most intense lines of the arc spectrum are very characteristic, and constitute a delicate test for europium, which can be thus identified in the crude oxides from monazite after icmoving the ceium (Eberhard, Zeitsch anorg Chem 1905, 45, 374). The cathode phos-The cathode phosphorescence spectrum exhibits the anomalous iay referred by ('rookes to the 'meta-element' S<sub>δ</sub> Pure europia, however, give no phosphorescence spectrum unless diluted with some other earth. With lime in the proportion Eu<sub>2</sub>O<sub>3</sub> 99CaO, a red phosphorescence is observed, and similar effects are obtained on mixing europia with alumina or gadolima Mixtures with excess of the latter give a white. and with excess of europia a red, phosphorescence (Urbain, Compt rend 1906, 142, 205, and Seventh Congress of Applied Chemistry, 1909, section 10, 94)

(Ultra-violet and arc spectra, v Exner and Haschek, Sitzungsber Wien Akad 1902, Ha, 3, 42, and Die Wellenlangen der Bogenspektra, 1904)

Europium has been detected spectroscopically in the sun's chromosphere, in α-Bootis and in β-Geninorum (Lunt, Proc Roy Soc 1907, Λ, 79, 118)

EUROSAMARIUM. An element detected by Eder, and occurring associated with europium and gadolimium in monazite (Sitzungsber K K. Akad Wiss Wien 1917, 11a, 126, 473)

**EUSCOPOL.** Syn for mactive scopolamine hydrobromide

EUSOL. An antiseptic, used in surgery, consisting of a solution prepared by shaking up in a litre of water 25 grams of a mixture of equal weights of chloride of lime and boric acid, and filtering off the sed-ment; the solution

contains about 0.54 p.c. of hypochlorous acid, | the maximum pressure which corresponds with and 1.28 p.c. of calcium biborate. Although evaporation occurs

EUSTENIN. Trade name for an addition product of theobromine-sodium and sodium todide

EUSYNCHITE v. VANADIUM.

EUXANTHIC ACID, EUXANTHONE, and EUXANTHONIC ACID v. Indian Yellow

EUXENITE. A rare-earth mineral consisting essentially of columbate and titanate of yttium and erbium, with smaller amounts of uranium, thorium, cerium earths, iron, &c Crystals are orthorhombic, but are very rare and indistinctly developed; the mineral is more often massive, with a blackish-brown colour and a brilliant pitchy lustro; sp gr. 46-51, H 61 In appearance and character, it closely resembles several other rare-earth minerals, particularly polycrase, from which it differs in containing a lower ratio of (Cb,Ta)2O5 TiO, It is occasionally found in the felspar quarries at several places in the neighbourhood of Atendal in Norway (v W C Biogger, Die Mineralien der Sudnorwegischen Gramt-Pegmatitgange, 1906) Also in the pegmatite veins of Madagascar, Cooglegong in Western Australia, South Sherbrooke in Ontario, &c Named from εὔξενος, friendly to strangers, in allusion to the several rare-earths it contains

EVAPORATION. The term 'evaporation' is used in connection with technical or manufacturing operations when a liquid is converted into vapour, but in chemical manufactures it is generally limited to those processes where the object is to separate a liquid from a solid which is dissolved in it, or to separate a more volatile from a less volatile liquid. In cases where the liquid to be evaporated is one of the products of the process, and is collected by condensation, the process is known as Distillation  $(q \ v)$ a solid substance contains water, not as water of crystallisation, and without presenting visible moisture or wetness, the process of removing this moisture under suitable circumstances is known as Desiccation of Drying  $(q \ v)$ . The operation of evaporation, however, is conducted on the greatest scale in the generation of steam for steam engines, and in the production of steam generally for manufacturing purposes. Although more water is evaporated in connection with the steam engine than for any manufacturing processes, yet great quantities of steam are used as a convenient means of applying and distributing heat, especially when regulated and moderate temperatures are required. In such cases the heat is applied to the vessel to be heated by jacket spaces or through coils of pipes immersed in the liquid to be raised in tempera-Such applications are made in sugar and confectionery manufacture, and in distillenes, breweries, and dyeing, &c.

Water and many other liquids evaporate without the application of heat. A vessel of water freely exposed at the ordinary temperature of the atmosphere soon evaporates and disappears. This is due to the fact that water vapour has a sensible pressure at ordinary temperatures, and as gases and vapours freely diffuse throughout each other, any water placed with a free surface in a confined space continues to evolve and diffuse its vapour until the water vapour present in the whole space is . 5

the temperature Although evaporation occurs in this way without any application of increased temperature, yet heat is absorbed by the vapour formed from the liquid, and if the evaporation be rapid and be conducted under such circumstances that heat from surrounding objects is prevented from reaching the liquid, then its temperature will be greatly reduced. This fact temperature will be greatly reduced is illustrated by the well-known lecture experiment of placing a shallow copper cup filled with ether upon a block of wood, and under it a drop of water When an is blown upon the ether it rapidly evaporates and carries off so much heat from the copper that the water drop under it is trozen and the copper adheres to the wood A liquid is said to be volatile when its vapour has a considerable pressure at ordinary atmospheric temperatures At 20°, for example, the pressure of water vapour (or tension as it is somewhat mappropriately called) is 1739 mm mercury, whilst the pressure of ether vapour at the same temperature is 433 3 mm and that of alcohol 44.5 mm If the liquids be placed in atmospheres whose pressures could be kept at these points by artificial means, then these liquids would boil As the evaporation under these circumstances is very rapid, relatively to the flow of heat to the liquid from surrounding bodies, if only atmospheric temperature be available, the heat is abstracted so quickly that many liquids freeze

Advantage is taken of these properties for many purposes in the use of an currents passed over the surfaces of liquids to evaporate them without the application of other than natural heat. Reduced pressures are also applied to evaporate without heating or to reduce the temperature necessary in order to avoid chemical decomposition and also to produce cold mechanically

Evaporation in steam boilers. The evaporative efficiency of the steam boiler has been more closely studied than that of any other type of evaporating apparatus, and the principles of the economical application of heat for evaporating are more completely known in this connection than in any other

The leading types of steam boilers now in use for the purposes of motive power are as follows Lancashire, Cornish, Locomotive multitubular, Marine multitubular, and Water-tube or tubu-

lous types

Obviously in an article of this character detailed description of the various types of boiler is uncalled for, the reader is therefore referred to the numerous text-books existing on the subject, such, for example, as "Steam-Boiler Construction," by W.S. Hutton; "Steam-Boilers, Their History and Development," by H. H. P. Powles, "Steam-Boilers," by C. H. Peabody and E. F. Miller

Evaporation in open vessels. In many chemical manufactures it is necessary to evaporate off water in which the substance, the object of the process, is dissolved, and in such cases, when heat is to be applied, it is desirable to economise fuel to the greatest possible extent. The heat of waste gases is therefore used as much as possible. The method of applying heat varies considerably with the chemical nature of the substance dealt with, and choice of economical apparatus is often limited by the corresive nature.

of concentrating oil of vitriol from the dilute acid, a series of shallow open lead pans receives the diluted acid and heat is applied below hot furnace gases are allowed to impinge upon the bottom of the vessel containing the weakest acid, and therefore requiring the greatest quantity of heat for evaporation, and as the gases cool they impinge upon the succeeding vessels of stronger and stronger acid, requiring less quantity of heat until the acid has become as concentrated as it is safe to trust to leaden Instead of this plan, in some cases vessels the furnace gases are passed over the surface of the acid in order to heat it from above, and the volume of gases in motion removes the vapour as fast as it is formed The advantage of surface evaporation arises not from the fact of its being economical, because liquids are heated with difficulty from above. The hot liquid in contact with the gases expands and has no tendency to cause convection currents, but rather remains stationary above the colder portions, and accordingly it is always advisable to heat from below when possible In many processes, however, during evaporation, a deposit comes down and this, coating the bottom of the vessel, prevents the free contact of the metal with the liquid The resistance to the passage of heat from the metal to the liquid is thereby much mereased, and the bottom suffers rapid destruction from over-heating In boilers using very hard water this is a fruitful source of trouble and danger

When surface evaporation is resorted to, large surfaces are exposed in shallow tanks over which the flame and hot gases from a furnace are allowed to pass The pans are covered in so that the radiant heat from the brickwork assists the action of the flame and hot gases. Arrangements of this kind are used in evaporating weak alum liquors, and the tanks are built up of bricks bound together with a cement composed of lime and alum shale. Sometimes an open pan is placed above the gases to contain the feed liquid and heat it in its progress to the evaporating

Evaporation of brine. Brine is sometimes evaporated by allowing the liquor from the springs to flow over masses of twigs in such a manner as to expose very extensive surfaces to the action of air currents, by pumping over a succession of these surfaces it is gradually con-When artificial heat is applied to the evaporation of brine, large shallow salt pans are used They consist of flat quadrangular vessels of plate non supported upon suitable brick walls, forming flues which distribute the heat from furnaces placed in the centre part under the vessel The flames strike directly upon the bottom of the vessel, and the hot products of combustion are conducted outwards by flues leading to the stack or chimney. In this way they traverse the whole bottom surface of the evaporating pans. The pans are of great area, often 60 feet long by 30 feet wide. The water vapour is collected by a large conical hood and carried off by a separate chimney. The sides of the lower part of the cone are so constructed that they can be opened to admit air from the direction in which the wind is blowing. This assists the evaporation by carrying off the water

of the liquid to be evaporated. In the process | vapour generated and exposing the surface to a continual air current.

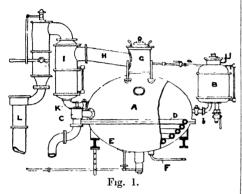

If heat enough to cause a liquid to boil be applied, an an current will not increase the evaporation, but will tend to diminish it by cooling the vessel containing the hquid; but when the liquid does not reach the boiling-point, the continuous removal of the atmosphere in contact with the liquid is necessary. If this be not done, then, so soon as the atmosphere has become saturated with the vapour, that is, so soon as the water vapour is present in quantity sufficient to produce the pressure which corresponds with the temperature of the liquid, the evaporation ceases.

It is a necessary condition of evaporation at temperatures less than the boiling-point, that the atmosphere into which the evaporation takes place should be continuously ranewed, and it is advisable that the air into which the water evaporates should not be of lower temperature than the liquid. When the temperature of the air is lower than that of the liquid, the volume of vapour carried off is much reduced, as the air must be heated by the vapour before it is capable of carrying off the volume equivalent '> the vapour pressure. Producer gas is used for evaporating the brine at Ischl salt works, and the operation is conducted in deep rectangular plate-iron vessels grouped together, and fed continuously by a system of distributing pipes.

Steam is much used to supply the heat iequired for evaporation, especially when the substances to be dealt with are of an easily decomposable nature if overheated. The heat is often applied to the vessel by means of a steam jacket, that is, the vessel is made double walled, and the interspace is utilised to receive the hot steam. When the temperature requires to be higher than 100°C, the jacket space is constructed to withstand pressure, and steam under boiler pressure is supplied, but steam is most commonly used at atmospheric pressure and applied to the liquid by passing through rows or coils of pipes namersed in it The arrangement of these pipes varies, and in some cases they are so connected as to be capable of hingeing out of the vessels for ready access and cleaning purposes.

Milk is now rapidly evaporated by spraying into heated air without raising the milk temperature to such a point as would cause chemical change

Evaporation under reduced pressures. In the older processes of sugar manufacture, the sugar liquois were concentrated by the direct application of heat from a fire upon the vessels containing them, but the greatest difficulty was experienced in preventing decomposition when the solution became concentrated. To avoid this difficulty, the vacuum pan was introduced by Howard, and in various modified forms it is still used. The boiling-point of a liquid depends upon the pressure to which it is subjected, and by reducing the pressure the boiling-point is greatly reduced. The vacuum pan consists essentially of a globular copper vessel containing the sugar liquor, and having the lower portion steam jacketed, while steam also passes through a coil of pipe immersed in the liquid. The upper part of the vacuum 1 an carries a circular steam dome or cylinder from which a pipe passes to a vessel intended to collect any liquor which may have primed over From this vessel it is run back into the pan again An air pump exhausts the apparatus and passes the steam to a condenser of usual construction. Fig 1 shows a vacuum pan made by Messrs. Manlove, Alliot, & Co. The vacuum pan A is formed in two por-tions bolted together. It is fed with liquor from the vessel B by suitable cocks, the pipe connections a, b being arranged to equalise the pressure within the vessel, so that the flow may be towards A. The live steam is admitted at the valve c, and passes through coil p into the jacket E, from whence it discharges and drains by the pipe F. The cylindrical dome or cylinder a prevents any great priming, but any liquid which may find its way by the pipe H is caught in the cylinder I and returned to A by the pipe K The pipe L leads to the air pump and condenser

A thermometer placed in the upper part of the pan indicates the temperature of the operation, whilst a vacuum gauge or barometer column is used to show the pressure within. The boilingpoint of the liquid at atmospheric pressure is about 250°F, and this is reduced to 150°F by using the vacuum pan

Fig. 2 shows a vacuum pan of modern construction, made by the Murlees Watson Co., Ltd., of Glasgow. In this vacuum pan, the liquor is heated in the vessel a by coiled steam pipes b, and also by reason of its passing upwards through small tubes c, through a steam chamber, d, the down flow of the liquor taking place through the central large tube e. In other respects, the operation of this vacuum pan is similar to that shown in Fig. 1.

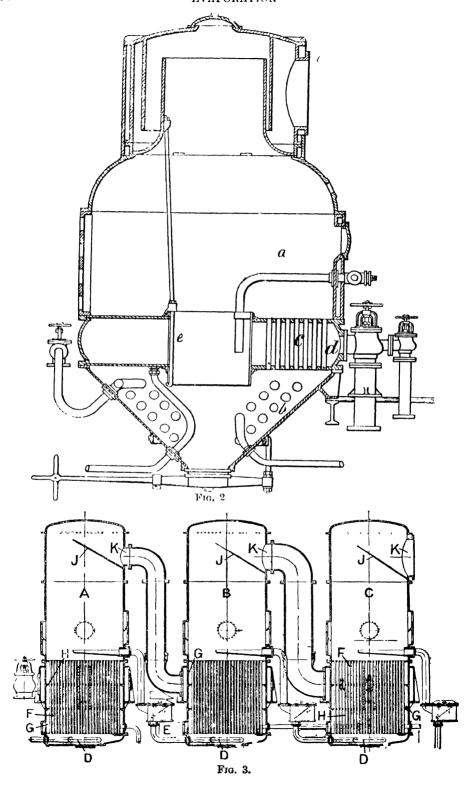

Evaporation under reduced pressure by triple and multiple effect. It is evident that as a liquor becomes more concentrated the boiling-point rises, and in evaporating liquids liable to chemical change by overheating, the pressures under which boiling is effected must be arranged to keep the temperature within safe limits. In the case of sugar liquor this safe limit is 227°F Steam at 5 lbs. per square inch above atmosphere has this temperature, and if it be applied to a pan containing a weak sugar liquor at atmospheric pressure, the liquor will boil.

Neglecting losses by radiation and like bottom of the apparatus, the liquor, after causes, the steam coming from it has the same passing through the 'climbing film' tubes, amount of heat as was imparted to the liquor being conducted thereto by a set of 'falling by the steam under slight pressure, and if it be film' tubes also within the steam jacket B

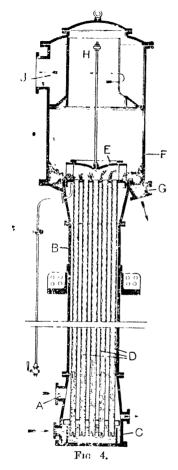

conducted to the coil and jacket of a second pan in which a slight vacuum is maintained, it will generate almost its own weight of steam at lower pressure and temperature, and so evaporate the If the steam so water from the second pan generated be taken to the coil and jacket of a third pan, its heat can again be utilised to evaporate the liquor there, provided the vacuum is sufficient to allow it to boil. This process may be continued until the original heat of the steam supplied to the first pan is dissipated by conduction and radiation. This is the principle of the 'triple effect' apparatus, by which a great economy is effected in the amount of fuel needed to evaporate a given weight of houor. The steam from one pan at higher pressure proceeds to the coil and jacket of the next, and the steam from the second proceeds to the coil and jacket of the third, the pressures within the pans proceeding in descending order as well as the temperatures

Fig 3 is an illustration of a triple-effect evaporator of the 'Hagemann' type, constructed by the Mirilees Watson Co, Ltd, for concentrating sugar. In this evaporator, the liquor is fed through an internal perforated pipe D at the bottom of the vessel A, and the flow of liquid from vessel to vessel is automatically regulated by traps E, the liquor passing through the vessels A, B, and C in turn, the reduction in pressure being so arranged that it is least in A. more considerable in B, and greatest of all in C, so that the boiling-points are lower in each succeeding vessel. The heating surface is obtained by means of a number of vertical tubes F, through which the liquor passes, these tubes being arranged in a steam or vapour space, a. divided by horizontal baffle plates it steam enters the steam space at the top above the upper baffle plate, and passes to the intermediate and lower spaces through apertures in the baffle plates slightly larger than the tubes which pass through them, the rush of steam through the openings removing the water of condensation from the surface of the tubes, and improving their efficiency. The upper part of each vessel acts as a separator, the vapour escaping, past a baffle J to prevent priming, through an outlet K either to the next effect or to the condenser

In the Kestner 'climbing film' evaporator, one complete section of which is illustrated in Fig 4, vertical tubes are also used for the passage of the liquor, but they are fewer and of greater length than in the apparatus last described Steam supplied through an inlet A to a jacket B causes ebullition of the liquor, supplied to a tank c, releasing a volume of vapour in the tubes D which occupies the central portion of each tube and carries up a film of the liquor on the internal surface. A fixed baffle E, by means of suitably shaped vanes, produces a whirling motion of the liquor and vapour mixture as it emerges into the separator F, whereby the liquor is thrown outwards and drawn off through an outlet g, and the vapour escapes, through a 'save-all' H, by an outlet JIn another form the separator is placed at the bottom of the apparatus, the liquor, after bassing through the 'climbing film' tubes, passing through the 'climbing film'

connected to form a multiple effect apparatus, the liquor and vapour from the outlets a and J of one section being respectively led to the tank c and inlet A of the next

The Yaryan evaporator. This ingenious evaporator is the invention of H T Yaryan, of Ohio, USA, and it is now largely used in this country, the Continent, and America utilises evaporation under reduced pressures as with the triple effect and also multiple effect differs from other inventions of the same class in the method of applying heat to the liquid to be evaporated, whereby the liquid is heated in small quantities at a time, and is brought into very effective contact with the heating surfaces Instead of using coils immersed in a liquid which is also heated by jacketed surfaces, the heat is applied by steam to the exterior surfaces of tubes, and the liquid to be evaporated is pumped within these tubes. The tubes are arranged in straight cylindrical drums, and pass from end to end, terminating in chambers with partitions so placed that when the liquid is pumped in at one end of a series it must pass through the whole series before escaping into the separating chamber. Fig. 5 is a section of

Any number of sections as described may be one drum of the evaporator, showing that the liquid is pumped in at one end, travels along in the direction of the arrows, and finally escapes with the steam which is generated into the separator The tubes are divided into sections termed 'coils,' and each section consists of fine tubes coupled at the ends so as to form a con-The liquid and vapour pass tinuous passage from section to section in series, and so come into effective contact with the whole surface As the liquid is pumped in it evaporates, and the steam produced carries it forward through the tubes, so that a mass of liquid and steam is brought in contact with every part of the whole heating surface, moving at a high velocity because of the steam generated, which has only the one direction of escape, that is, through the whole system of tubes in each towards the separator. The liquor under treatment issuing from the last set of tubes into the separator falls to the bottom, as shown in Fig. 5, and the vapour using up flows in the direction of the arrow to the catch all, where any liquor entrained is caught during its passage through the number of small tubes with which this vessel'is fitted,

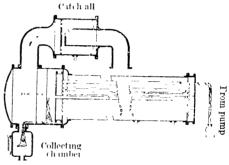

Fig 5

and, striking against the end cover, falls to the bottom and is drained off into a receiver This ensures dry vapour being passed on to the evaporating shell of the next vessel, where it in turn boils the liquor which is inside the tubes, and so on through the various effects until the vapour from the last vessel reaches the condenser. The advantages of this apparatus are its economical working and rapid flow of the liquor under treatment. Only a small quantity of liquid is in the apparatus at one time, and so it is exposed to heat for a much shorter period than in the ordinary vacuum pan, which is an important point. The appaiatus avoids entirely the loss of colour which always occurs to some extent in the older vacuum pans because of the long period of time taken to evaporate the large quantity of liquid they contain, amounting in some cases to thousands of gallons The Yaryan evaporator can be started very rapidly, as it contains but a small mass to be heated At the same time, the details are arranged to permit of ready access to the tubes and ready cleaning. This is greatly assisted by the fact that the tubes are Fig 6 shows a quintuple-effect straight evaporator with its vacuum and auxiliary pumps in general use for soda ash recovery in paper mills, caustic soda, caustic potash, meat extract,

distillery refuse, and other liquids readily amenable to concentration.

According to the patentees of the Yaryan apparatus, their double effect will evaporate

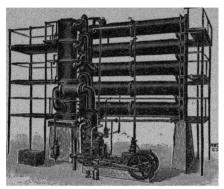

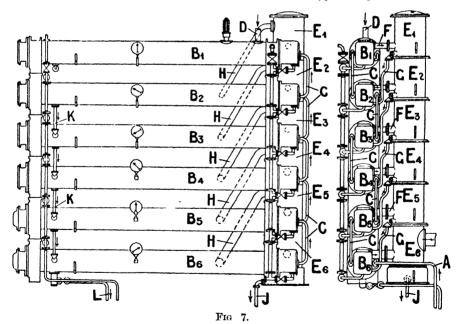

Fig 6.

16 lbs. of water for every pound of coal consumed under the boiler, 23½ lbs in a triple effect, 30½ lbs in a quadruple effect, assuming that the boiler is so constructed as to evaporate 8½ lbs of water per pound of coal

The Yaryan apparatus has, since its first introduction in 1888, been greatly improved in design and efficiency, and large sextuple-effect apparatus working on the Yaryan principle have been constructed by the Mirrlees Watson Co, Ltd, for the distillation of fresh water from salt water, producing from 25 to 350 tons per day of 24 hours, and also for use in the Solviy process of soda manufacture in Europe and America Fig 7 indicates the essential features of such an appuatus for the distillation of salt water Salt water, previously warmed by being passed through heaters, is supplied by a pipe A to heating tubes in the lowest evaporator B<sub>6</sub>, and thence is passed in succession by means of pipes c through heating tubes in the remaining evaporators It has then reached boiling-point, and is circulated through the evaporating tubes of the first evaporator B<sub>1</sub>, to which boiler steam is supplied by a pipe D. The mixture of liquor and vapour is conducted from the evaporators  $B_1-B_6$ , to the respective separators  $E_1-E_6$ , by pipes F, the outlets for the liquor and vapour from each separator to the next evaporator stage being by pipes  $\alpha$  and H respectively. ('oncentrated brine is drawn off from the last separator  $F_6$  by a pipe J, and the cordensed fresh water passes from stage to stage by pipes к, and is finally drawn off through an outlet L

In the Lillie type of evaporator the tubes are

also arranged horizontally, but the steam is passed through them and the liquor is allowed to fall over their external surfaces.

Evaporation in mechanical refrigerators. A separate class of mechanical refrigerators exists in which the cooling or refrigerating effect is produced by evaporation. Liquids used air ether, anhydrous ammonia, and anhydrous sulphur dioxide. In all of these the process of the machine is identical. The volatile liquid is during ice

introduced into a chamber at a pressure at which it is liquid, and the vapour is rapidly withdrawn from the vessel by a pump. The rapid evaporation absorbs heat so quickly that the temperature falls and a brine or other liquid is cooled within a coil of pipes immersed in the liquid. By circulating this brine, the low temperature may be utilised for reducing the temperature of a cold store room or for producing ice.

The vapour drawn off by the pump is com- 1. pressed and cooled by passing through tubes surrounded by water, and so becomes liquid again It is then injected into the evaporating chamber again, so that the process is practically continuous, and but slight renewal of the volatile liquid is necessary to make up for small les kages.

The same principle is applied in Carre's freezing machine for freezing water. In this case the vapour is removed from the surface of the water by a pump and condensed by strong sulphuric acid. Ammonia is also utilised in another apparatus in solution in water for the same purpose. By alternate expulsion from the water and absorption, cold is obtained

The rapid evaporation of liquid carbonic acid, air, and other bodies which are gaseous at normal temperatures and pressures, has also been used to produce low temperatures for liquefying the more permanent gases.

EVERNIC ACID and EVERNINIC ACID. Evernic acid, or lecanoric acid monomethyl ether, was first isolated by Stenhouse from the Everma prunasti (Annalen, 68, 83), and has been found also by Hesse (Ber 1897, 30, 366) to exist in the Ranalina pollinaria (cf. also Zopf, Annalen, 1897, 297, 271).

The lichen is extracted with diluted milk of lime, the extract neutralised with acid, the precipitate collected, dried, and digested with a little boiling alcohol The hot alcoholic liquid. treated with its own volume of water, deposits crystals of evernic acid (Stenhouse)

Evernic acid crystallises in small colourless needles, mp 168°-169°, readily soluble in hot alcohol, and when boiled with solutions of the alkalı hydroxides or baryta water, gives (O2, orcinol, and everninic acid

$$C_{17}H_{16}O_7 + H_2O = C_9H_{10}O_4 + C_7H_8O_2 + CO_2$$
  
Ramalic acid suffers a similar decomposition

Fischer (Ber 1913, 46, 3253, and 1914, 47, 505) showed that when evernic acid was methylated by means of diazomethane, in ethercal solution, a neutral crystalline ester identical with trimethyl-lecanonic acid methyl ester was obtained, and he pointed out that, as the methoxy group in everninic acid is in the paraposition to the carboxyl group, the structure of evernic acid must be.

From this it follows that the isomeric ramalic acid (v. Ramalic acid) may be expressed as

For descriptions of the Na, Ba, Ca, Cu, Pb, and Ag. salts of evernic acid, of Hesse (J. pr. Chem 1915, [ii ] 92, 425)

Diacelyl-evernic acid  $C_{17}H_{16}O_7Ac_2$  is a crystalline powder, m p.  $144^\circ$ 

Everninic acid (orsellinic acid monomethyl ether) resembles benzoic acid in appearance, melts at 157°, and yields the ethyl ester

m p. 72°. By digestion with hydriodic acid, everninic acid gives orcinol, ('O\_, and 1 molecule of methyl rodide According to Hemrich (Ber 1904, 37, 1406), two formula are possible for everninic acid:

$$(1) \begin{array}{c} \mathrm{CH_3} \\ \mathrm{OCH_3} \\ \mathrm{OCH_3} \end{array} \\ \mathrm{OH} \\ (2) \begin{array}{c} \mathrm{COOH} \\ \mathrm{OH} \\ \mathrm{OCH_3} \\ \end{array}$$

Fischer and Hoesch (Annalca, 1912, 391, 347) have, however, shown that orsellinic acid amethyl ether, prepared by them, and which has the structure (2), is identical with everning acid.

This conclusion has been further substantiated by the synthesis of everninic aldehude. m p. 65°C (and from it of evernine acid) (Hoesch, Ber 1913, 46, 886), by the careful methylation of orcyl aldehyde with methyl sulphate, and 2N caustic soda in the presence This when treated with an acctone solution of methylchlorocarbonate, yielded methylcarbonato-everninic aldehyde, needles, mp. 77°C, and the latter, when oxidised with potassium permanganate, was converted into methylcarbonato-everninic acid, needles, decomposing at about 100°C, which on hydrolysis with N caustic soda solution yielded everninic acid.

These changes may be represented thus:

Hesse (J. pr Chem. 1915, [n ] 92, 425) has described the following derivatives of everning acid :-

Acetyl everninic acid C9H9O4Ac, colourless prisms, m.p 111°C.

Nutro-everninic acid, orange-red needles,

тр 195°C CaHaOa(NO2)2HaO Dinitro-everninic acid golden-yellow needles, mp 87°C—the potassium salt is very explosive

253) of the isomerum of evernic acid and ramalic acid, and which was based upon the older formula of orsellinic acid, is as follows:

EVERNIIN v. Gums

EVODIA MELIÆFOLIA. This tree, belonging to the Rutacew, is found in China and Japan. where its bark is largely employed in dyeing and It was formerly described by in medicine Loureiro as Pterocarpus flavus, but this error was eventually corrected by P W Squire (Pharm J 1888, [3] 18, 785), who showed it to be really Evodia glanca, which is synonymous with E melia folia By qualitative tests, Martin, Tokio (Arch Pharm 1898, 13, 337) and Squire (le) suspected the presence of berberne, and this colouring matter was subsequently isolated by Perkin and Hummel (Chem Soc Trans 67, A G P

**EVODIN**  $C_{17}H_{20}O_6$  A crystalline substance found in the fruit of *Evodia rutacarpa*, used in China and Japan in medicine and perfumery First isolated by Keimatzu by treatment of the dued fruits with benzeae, mp 285° Insoluble in water, alcohol, ether, and light petroleum, slightly soluble in hot benzene, ethyl acetate, and chloroform, soluble in acetic acid and alkali solutions (cf. Asahina and Ishio, J. Pharm Chim. 1916, [viii.] 13, 53)

EXALGIN. Trade name for methyl acetandide (v. Synthetic Drugs)

EXODIN & SYNTHETIC DRUGS

EXPLOSION, GASEOUS, Within years there has been an enormous increase in the extent to which the internal combustion engine has been utilised, and there are now many millions of h p at work on this principle Gas engines using coal gas, producer gas, or blast-furnace gas, are now working for all powers up to 2000 h p per cylinder, and a large number of heavy oil engines are also in use In addition, there are many thousands of petiol motors at work

In internal combustion engines working on the constant volume cycle, the motive power is produced by the explosion of mixtures of inflammable gas or vapour and air in certain proportions, and the pressure produced by the explosion is utilised to propel the piston of an engine, as is done by the steam pressure in a steam engine

Seeing that a proper understanding of the phenomena associated with gaseous explosions is necessary, not only for persons in charge of internal combustion engines, but also for those responsible for the safety of workers both in coal mines and in factories where explosive mixtures may be encountered or used, it is desirable first to consider generally the proparties of such mixtures and the mode in which flame is propagated through them. At the

Hesse's expression (J. pr Chem. [ii ] 57, outset, it should be recognised (1) that, under given conditions of temperature and pressure, the "range of inflammability" of mixtures of any particular combustible gas and air (or oxygen) may be strictly defined, so that all mixtures outside of certain 'lower' and 'upper' limits are non-inflammable; (2) that the ignition of any given inflammable mixture at a particular pressure is determined by the attainment of a certain definable thermal (or electrical) condition at some point or region in it; (3) that after ignition the speed and mode of propagation of flame through the mixture are usually capable of measurement or analysis by well-established experimental methods, and (4) that when such a mixture is inflamed in a closed vessel, the maximum pressure attained on explosion may be accurately determined. But notwithstanding the truth of this statement, it is needful to warn the reader against errors involved in the loose employment of such terms as 'unition temperature,' speed of inflammation or flame propagation,' pressure of explosion,' etc., unless the concomitant physical cucumstances are simultaneously defined

#### A -IGNITION PHENOMENA

Chemical change may be determined in a gaseous explosive mixture at a much lower temperature than is required to develop flame Thus, for example, if electrolytic gas be heated in an enclosure to a temperature somewhat higher than 400°, the formation of steam can usually be detected after a lapse of a few On gradually raising the temperature the rate of interaction between the hydrogen and oxygen rapidly increases until at length a point would be reached when the rate at which heat is lost from the system (eg by conduction through the walls of the enclosure) is more than counterbalanced by the rate at which it is developed by the interaction. The reaction would then become self-propellant

The temperature at which such autogenous (or self-propellant) reaction begins in a given gaseous mixture is usually termed its temperature' or 'syntion point,' although it is not ordinarily a well defined physical constant, being dependent, for example, upon the manner in which heat is conveyed to the mixture is clear also that the ignition temperature, as thus defined, does not necessarily correspond with the appearance of flame in the mixture. There is, indeed, usually a definite 'pre-flame period, the duration of which can be controlled, and which varies considerably with the different gas mixtures Only when a mixture is fired by adiabatic compression, and the pre-flame period is negligibly short, can its 'ignition temperature' be regarded as a physical constant and determined with precision. In most cases the ignition temperatures assigned to a series of gas mixtures merely give an approximate index of their relative ignitibilities

The Determination of Ignition Temperatures -Several experimental methods (of which three principal ones will be hereafter described) have been used to determine the so-called 'ignition temperatures' of gases The results naturally differ according to the details of the method adopted, and must therefore be carefully differentiated.

(1) A common method is to pass successive samples of a particular inflammable mixture into a vessel whose temperature is gradually raised until the lowest degree at which flame appears has been found. In this way the 'relative ignitibilities' of a series of gas-air mixtures may be determined, and for such purpose the method is a useful one. Thus, for example, one of us (R V W) has recently determined by 'this method the 'relative ignitibilities' of a series of methane-air mixtures, expressed in each case as the lowest temperatures of the particular enclosure required to inflame each mixture, as follows.

Per cent r cent { 6 0 70 80 90 100 120 130 Temperature 695° 698° 701° 707° 713° 726° 732 It may be noted, in passing, that the most ignitable of these mixtures is not the one (9 45 pe methane) which on combustion gives the greatest heat development per unit volume, but rather those containing a considerable The method does not, howexcess of oxygen ever, disclose the lowest temperature at which a given mixture can be ignited, because the walls of the heated vessel, by inducing chemical combination on their surface, retard the actual appearance of flame

(2) A better method (first employed by H B Dixon and H F Coward, Chem Soc Tians 1909, 98, 514), which to a large extent eliminates the effect of heated surfaces, consists in heating the combustible gas and the air (or oxygen) separately to a known temperature and then allowing them to mingle, increasing the temperature of each gas stream, pari pursu, until their mixture results in flame The ignition temperature ranges of some combustible gases, at atmospheric pressure, as determined by this method, are as follows—

Ignition Range Combustible Gas In o**vyč**en In air Hydrogen 580° 590°C. . 580°-590°C Carbon monoxide . 637° 658° 644°--658° Cyanogen 803°-818° 850°-862° Ethylene 542° 547° 500°-519° 416°-440° 406°-440° Acetylene 346°-379° Hydrogen sulphide 220°-235° . 556°-700° 650°-750° Methane . 520°-630° 520°-630° Ethane.

These figures record for a given gas the lowest temperature at which any mixture of it with air or oxygen would inflame. But they afford no information as to the effect of varying the proportions of the gas and air.

(3) The temperature produced by the adiabatic compression of a gaseous explosive mixture within a closed cylinder may be accurately calculated from the fundamental gas laws, and this method has been successfully employed by H. B. Dixon and his co-workers for determining the 'ignition temperatures' of various mixtures of hydrogen and oxygen, as follows.—

Mixture			Igni dete	tion Temperature rmined by Adiabat Compression
$\substack{2 H_2 + O_2 \\ 2 H_2 + 2 O_2 \\ 2 H_2 + 8 O_2 \\ 2 H_2 + 16 O}$	:	:	•	. 526°C. . 511° 478° 472°

According to Dixon and Croft's determinations by this method of the ignition-points of mixtures containing electrolytic gas, whereas successive additions of hydrogen or nitrogen progressively raise the ignition temperature of the undiluted gas by regular increments, as would be supposed, successive additions of oxygen, on the other hand, lower it, as shown in the following table—

THE IGNITION-POINTS OF MIXTURES CONTAINING ELECTROLYTIC GAS BY ADIABATIC COMPRESSION

(By H. B. Dixon and J. M. Crofts, 1914)

The observed raising effects of successive dilutions with hydrogen and nitrogen call for no comment, save that the relative greater effect of hydrogen, as compared with nitrogen, may be attributed to its greater thermal conductivity, but the lowering effect of oxygen is indeed puzzling, and its meaning can only be conjec-Dixon and Crofts have suggested that it may be due either to the formation of some active polymende of oxygen under the experimental conditions (which seems doubtful), or that the concentration of oxygen in some way or other brings about increased ionisation of the This at once raises the larger combustible gas question of whether or not ignition is a purely thermal problem, as until recently has generally been supposed

Ignition by adiabatic compression is utilised in the Diesel oil engine, and in gas engine practice pre-ignition of the charge may take place during the compression stroke it too high a compression is employed. Knowledge of the degree of compression required to cause the ignition of a particular gaseous mixture is, therefore, of considerable industrial value.

Ignition by a Source of Heat of Short Duration This is a very common way of igniting explosive mixtures in everyday practice, although up to the present experimental data regarding it are very meagre. It will be realised that if the inflammation of a large volume of gas is attempted by rapidly heating a small portion of it, the size and duration of the source of heat employed, as well as its temperature, will be of importance, because the effectiveness of any means of ignition depends upon whether or not the volume of mixture first inflamed communicates by its combustion sufficient heat to the adjacent layer of mixture to inflame it in its turn In general, the shorter the duration of the source of heat employed to ignite a given gas mixture, the higher must be its temperature. Unfortunately, until now this aspect of the question has been but little explored, but the point may be illustrated by some recent determinations of the 'relative ignitibilities' of mixtures of various gases with air expressed in the terms of the lowest temperatures at which a hot body of minute area must be raised in order to cause immediate ignition of the particular mixture to which it was momentarily applied. Such temperatures have obviously only an empirical interest.

> Minimum temperature of hot body required for Gas immediate ignition by (Mixtures with air) momentary contact 747°C. Hydrogen 931° Carbon monoxide 1000° Ethylene 878° Coal gas 995° Petrol (Fraction 0-80°C.)  $1062^{\circ}$ Benzene 1033° Ether .

Ignition by Electric Sparks .- It is still a matter of controversy whether ignition by means of an electric spark is a thermal phenomenon, or whether there is simultaneous ionization of the mixture by the spark, the ionization playing a necessary and important part in promoting the combustion of the gases So far as the secondary discharge is concerned, ionization of the mixture between the electrodes undoubtedly precedes the passage of the discharge, and it is possible that this preliminary ionization may render the molecules more reactive than usual towards each other It is known that the exposure of some gaseous mixtures to a source of intense ionization causes their combination at quite low temperatures. The point of controversy would, therefore, appear to be whether in the ignition of gaseous mixtures by an electric spark ionic rather than thermal phenomena predominate; whether, in fact, an electric spark is more effective as an ionizer than is a flame or a heated solid.

Insufficient experimental work has been done to enable a decision to be reached on this matter. The character of the phenomena of spark ignition seems to differ from that of the phenomena of ignition by the prolonged contact of a heated surface Thus, the type of curve that can be constructed connecting 'igniting-current' or 'spark-energy' with percentage composition of mixtures of any given inflammable gas with air differs from the type of curve connecting ignition temperatures, as determined by the first method described, with percentage composition (see Fig. 1). It may be, however, that this difference is due to a large extent, if not entirely, to the short duration and small size of the electric spark; also that the rapidity with which flame can travel in a mixture away from the source of heat becomes of importance equally with the susceptibility of the mixture to ignition when the source of ignition is very small and lasts but a short time. It may be noted that the spark ignition curve in Fig. 1 is nearly the inverse of the speed-percentage curve for flame in methane-air mixtures described in the ensuing section of this article (see Fig. 2).

Limits of Inflammability.—If the whole volume of a gaseous mixture be raised to its ignition-temperature, as it is, for example, in the cylinder of a Diesel engine, it necessarily follows that the whole of it is inflamed. On the other hand, the introduction into a gaseous mixture of a small source of heat at a tempera-

mixtures of various gases with air expressed in ture considerably higher than the ignitionthe terms of the lowest temperatures at which temperature of the mixture need not cause a hot body of minute area must be raised in complete propagation of flame.

It is well known that when a flame is introduced into a mixture of an inflammable gas and air containing but little inflammable gas, a 'cap' or aureole is formed around the flame; and that this cap is larger the greater the proportion of inflammable gas present. The coalminer regularly uses this formation of a cap as an indication of the presence of firedamp in the workings of the mine It has been observed also that in a current of gas and air, poor in combustible gas, passing a lamp flame or similar source of heat, the cap or aureole may become separated from the burning body by which it is originated and be carried along for a limited distance, giving a 'cloud' of flame But unless this cloud were fed by some mixture richer in combustible gas than that in which it originated it would gradually die away a uniform mixture of gas and air the flame could only be carried on automatically throughout the extent of the mixture if the inflammable gas were present in quantity above what is termed the 'lower limit' of inflammability.

When a source of heat is introduced into a stagnant mixture of combustible gas and air, two things are necessary to ensure propagation of flame throughout that mixture, namely, (a) an adequate means of ignition, and (b) a sufficient

proportion of inflammable gas

Supposing that too small a proportion of combustible gas is present, only a small quantity of heat per unit volume of mixture is generated when the layer surrounding the initial source of heat is inflamed, and the products of combustion have to impart heat to a considerable volume of mert gases. The number of collisions between molecules of combustible gas and of oxygen that are chemically effective is therefore small. Such collisions, resulting in combination, will occur only in the neighbourhood of the mitial source of heat around which an aureole will form of a size dependent on the nature and quantity of the combustible gas present.

As the proportion of combustible gas is increased a proportionately greater quantity of heat is evolved per unit volume of mixture, and a smaller quantity of inert gases is present to absorb it. At length a point is reached when the amount of heat contained in the products of combustion of any given layer is just sufficient to raise the adjacent layer to its ignition temperature. Flame is then propagated progressively throughout the mixture without any necessity for the continued presence of the source of heat which started the inflammation, and the mixture is said to 'inflame' or 'explode,' according to the rapidity of the propagation.

To ensure propagation of flame throughout the mixture, therefore, it is necessary for the initial source of heat to be of a volume, intensity, and duration sufficient to raise the layer of gases surrounding it to the ignition temperature of the mixture, and for the heat contained in the products of combustion of this first layer to be sufficient to raise the next layer to its ignition temperature, and so on. An inflammable mixture can be defined as a mixture in which flame can spread to any distance, independently c., and away from, the original source of ignition

under given physical conditions, certain limits of composition within (but not outside of), which self-propagation of flame will take place after ignition has once been effected. These limits, defined in terms of the percentage of the combustible gas present, are usually referred to as the 'lower' and 'higher' limits of inflammability of the gas under the given conditions. For any particular gas they differ slightly with the position of the source of ignition, since the progress of the flame may be assisted or 'retarded' by convection-currents dependent upon whether it has to pass in an unward or downward direction. For example, with mixtures of methane and air and of acetone vapour and air the limits, expressed as percentages by volume of the mixtures, are as follows for upward, downward, and horizontal propagation of flame :-

Lower limit

Methane . Acetone vapour	5 40	Downward 6 00 2 35	Horizontal 5 40 2.20
7		Higher Limit	

Downward Upward Horizontal Methane 13 40 14 30 8 50 9 50 Acetone vapour . 9 70

The limits of inflammability of a number of gases and vapours, mixed with air at atmospheric temperature and pressure, are given in the table that follows. For all but hydrogen and carbon monoxide the criterion of inflammability adopted for the determinations was propagation of flame throughout a 21-litre sphere, ignition being at the centre. The figures for hydrogen and carbon monoxide refer to upward propagation of flame.

Gas		Lower limit	Upper limit
Hydrogen Carbon mond	oxide .	рс. . 41 . 125	71 5 73 0

The Effect of Temperature.-From what has been said in the preceding paragraph, it is evident that the self-propagation of flame through a mixture is, in principle, dependent on the temperature that the portion of the mixture which is burning can impart to the portion which is about to burn, from which it follows that the higher the initial temperature of the

In the case of mixtures of any particular | mixture the less dependent is the propagation combustible gas with air (or oxygen) there are, | of flame upon the heat generated by combustion Hence the effect of increasing the initial temperature of mixtures of an inflammable gas and air should be to widen the range of inflammability, lowering the lower, and raising the higher

> Thus it has been found experimentally that a progressive increase in the initial temperature of mixtures of methane and air from 20° to 700° caused a corresponding decrease in the amount of methane required to enable self-propagation of flame to take place from 6 00 to 3 25 p c (downward propagation) Similarly, the higher limit was raised gradually from 13 40 p.c at 20° to 16 40 at 600°

The Effect of Pressure —As exemplifying the influence of the initial pressure of gaseous mixtures upon their limits of inflammability, the case of mixtures of methane and an may be cited. A reduction of the initial pressure, at 20°C, from 760 to 380 mm has but little effect on the limits; but below a pressure of 300 mm mercury the effect is marked, the limits narrowing rapidly until, at a pressure of 120 mm no mixture of methane and air is capable of selfpropagation of flame (downwards). On the other hand, an increase of pressure above 760 mm slightly raises both the lower and the higher limit, the figures at 6 atmospheres being 6 40 and 14 05 p c of methane respectively, for downward propagation of flame

The lower limit with mixtures of hydrogen and air, and of carbon monoxide and air, is also raised by increasing the initial pressure above 760 mm, but with these two gases the higher

limit is lowered

Mixtures of Inflammable Gases -In the case of a mixture of inflammable gases such as coal gas, a general formula is available by means of which its limits of inflammability with air may be calculated if its composition, and the corresponding limits of the individual gases are known If a, b, c, . are the relative proportions of its components, and A, B, C, their respective limits of inflammability, then L, the limit for the mixed gases, is given by the equation:-

$$L = \frac{a+b+c+\dots}{a-b-c} \qquad (1)$$

This relationship holds both at the lower and the higher limit. It implies that if a limitmixture with air of one inflammable gas is mixed in any proportion with a limit-mixture with air of another inflammable gas, a limit-mixture results

It has been necessary to emphasize the fact that this formula refers to mixtures of combustible gases with air, for the reason that the presence of any considerable quantity of an uninflammable constituent, such as nitiogen, in the commercial gas would narrow the range of inflammability, just as the range for a pure gas is nairowed if the oxygen-content of the air is reduced.

The effect of Incombustible Gases -The effect of a reduced oxygen-content of the 'air,' or of the presence of inert constituents in the 'combustible gas,' is more marked at the higher than at the lower limit. This is well illustrated

methane with 'atmospheres' containing different proportions of oxygen. These determinations afford an index of the general effect of 'mert' gases on the limits of inflammable gases in general when the actual data are not available. the effect of carbon dioxide is rather more pronounced than that of nitrogen.

Atmosphere		Methane-p c			
Oxygen	Nitrogen	Lower limit	Higher limit

$13\ 25$	86.75	No mixture	e capable of		
		propagating flame			

Speed of Propagation of Flame —During the propagation of flame in any 'limit' mixture, a balance is struck between heat generated by combustion and heat employed in starting combustion, together with heat lost by conduction Theoretically, therefore, proand radiation vided that the amount of energy imparted to the system by the initial source of ignition is small, so that no appreciable impetus to the propagation of flame occurs near the source of ignition, flame should travel in a limit-mixture at a uniform speed. This is found to be so in practice, the speed of the flame is slower in a limit mixture for downward than in one for upward propagation, but under either condition it is quite uniform throughout the extent of the mixture

It is otherwise when the proportion of inflammable gas lies at some intermediate point between the limits, that is to say, when the mixture is such that one layer on burning is capable of imparting to the uninflamed layer adjacent to it a temperature higher than the ignition-temperature of the mixture. The phenomena of propagation of flame in such mixtures are dependent in a marked degree upon the conditions under which ignition is effected, so that it is necessary when speaking of the propagation of flame through them to specify exactly those conditions

When ignition of a mixture of combustible gas and air has been effected at the open end of a long tube which is closed at the other end, the flame can be propagated in two principal ways, namely, (a) by transmission (by radiation, conduction, and convection) of the heat developed by the burning of one layer of gas to the layer adjacent to it, and (b) by the transmission of a sufficiently high pressure

According to the first mode of propagation, the flame travels along the tube at a uniform speed for a certain distance, and then develops vibrations, swinging backward and forward with oscillations of increasing amplitude. The mean speed of the flame during this vibratory movement, which comprises a series of compression and rarefaction waves, is usually greater than the speed of the uniform movement. According to the nature of the mixture, either the vibrations may continue to the end of the productive of mechanical disturbance of the tube, or the flame may become extinguished mixture. The speed of the uniform movement

by determinations of the limits for mixtures of during a particularly violent vibration (eg. during rarefaction) Or again, a sudden permanently greater enhanced speed of flame may be developed as the result of the second mode of propagation coming into play (during a compression).

During this second mode of propagation cach layer of gas is compressed so suddenly that it is raised beyond its ignition temperature by the heat of compression, and in burning it compresses in turn the unburnt layer in front As already stated, the speed of the flame during this mode of propagation is permanently enhanced, it is, in fact, the maximum speed attainable by the flame and is a physical constant for each mixture of gases The phenomenon is termed the 'detonation wave'

When ignition takes place at the closed end of a tube open at the other end, the flame travels at a rapidly increasing speed towards the open end If the tube is long enough, the flame may eventually assume a vibratory character and the detonation-wave may be developed.

What has been said in this short summary refers only to mixtures of a combustible gas with air, mixtures with pure oxygent behave somewhat differently With regard to the latter, it may be stated that, in general, (a) the preliminary period of uniform movement is shorter, (b) a rapid acceleration follows, and (c) this is immediately succeeded by the detonation-wave without any vibratory movement taking place

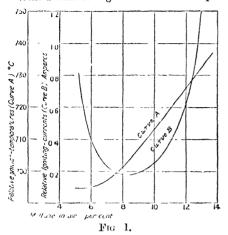

Of the different phases in the propagation of flame in mixtures of gases, the two regarding which most information is available are the 'uniform movement' and the 'detonation uave.'

Some further account of these will now be given.

The Uniform Movement—The initial slow propagation of flame that takes place when an inflammable mixture at rest is ignited at a point, is usually regarded as controlled by the transference, by conduction, of the heat developed by the combustion of the mixture immediately surrounding the point of ignition, whereby successive contiguous portions of the mixture are raised in temperature until chemical action becomes rapid The initial speed of propagation of flame in a given mixture away from the point of ignition should mainly depend, according to this view (a) on the conductivity for heat of the unbuint mixture, and (b) on the velocity with which a moderately heated layer begins to react chemically and so to use gradually in temperature, or, in other words, on the rate of change of reaction velocity with temperature

Under certain conditions, with all inflammable mixtures of gases and air at atmospheric temperature and pressure, the initial slow propagation of flame can be maintained at a uniform speed over a considerable distance of travel from the point of ignition. The conditions most favourable, or perhaps even necessary, to initiate and maintain this 'uniform movement' of flame are (a) that the inflammable mixture should be contained in a long straight tube open at one end and closed at the other; and (b) that ignition should be at the open end by a source of heat not greatly exceeding in temperature the ignition temperature of the mixture, and not then depends on the composition of the mixture (presumed to be at atmospheric temperature) for the umform movement of flame in mixtures and pressure), and on the diameter of the tube of some of the common combustible gases with in which it is contained

With a tube of a given diameter the speed

of the uniform movement of flame in a mixture can be regarded as a definite physical constant for that mixture, and its measurement is of considerable value in enabling a judgment to be formed of the behaviour of the mixture under normal conditions of burning

In Fig. 2 are shown speed-percentage curves air over the whole range of inflammability for each gas All the measurements were made in a tube of 25 cm internal diameter, so that they are strictly comparable one with another Apart from the striking differences in the speeds obtainable in different gases displayed by this diagram, a noticeable feature of the curves is the fact that with each gas the maximum speed is obtained not, as might perhaps be expected, with the theoretical mixture for complete combustion, but over a range of mixtures containing an excess of inflammable gas.

The extent to which the speed of the uniform movement is affected by the size of the tube along which the flame travels has been determined for mixtures of methane and air results are recorded in Fig. 3 For all practical purposes it can be assumed that the speed of the uniform movement of flame in mixtures with air of gases other than methane will be affected to a similar degree, so that the absolute speeds of the flames in pipes 30, 60, and 90 cm in diameter will be respectively about 25, 3, and 35 times as great as the speeds recorded in the 25 cm tube (Fig. 2)

It should be noted that the uniform speeds of the flames in tubes of large diameter (greater than 10 cm for methane-air mixtures) are not, strictly speaking, those of the 'uniform morement' as previously defined, since they are not controlled solely by conduction of heat. A

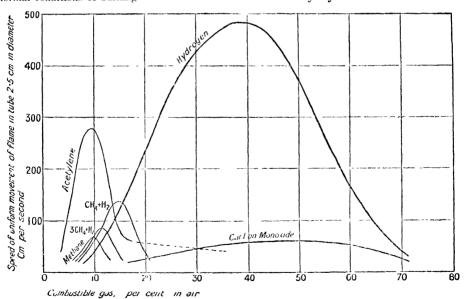

Fig. 2.

second factor, namely, convection, comes into uniform movement of flame for any complex play when the tubes are large, and is responsible gas mixed with an, from a knowledge of its for the enhanced speed of flame.

found that a similar expression to that used for calculating the limits of inflammability of mixed combustible gases can be employed to determine, with fair accuracy, the maximum speed of

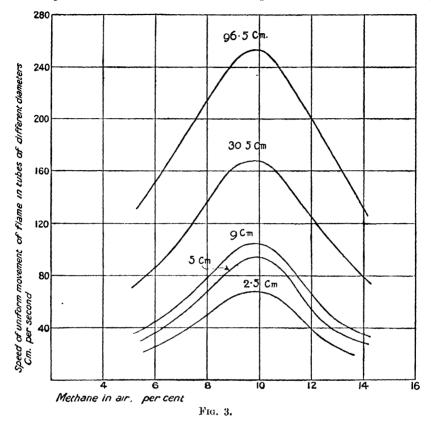

composition and the maximum speeds of each Mixtures of Inflammable Gases -It has been of the components. The expression is -

$$S = \frac{a+b+c+}{a+b+c+} . \quad (11)$$

$$S_a + S_b + S_c + . . .$$

the proportions of the different simple consti-tuents in the complex inflammable gas (coal-gas, for example); and S<sub>2</sub>, S<sub>b</sub>, S<sub>c</sub> . . . the the composition of the mixture of the complex

in which S is the speed required; a, b, c . . . maximum speeds of flame in mixtures of the

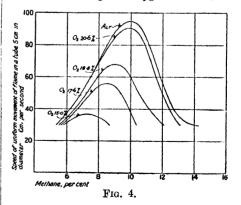

gas and air in which the speed of the uniform | curves for the uniform movement of flame in movement of flame will be greatest, and mixtures of methane with nitrogen-oxygen formula (11) for determining the speed of flame in the limit-mixtures, and (though with rather less accuracy) in the mixture containing the gases in theoretical proportions for complete combustion.

The value of these formulæ will be appreciated if reference be made to Fig 2, wherein are recorded, for comparison with the simple gas-air mixtures, the speeds of the uniform movement of flame in mixtures of the composite gases CH<sub>4</sub>+H<sub>2</sub> and 3CH<sub>4</sub>+H<sub>2</sub> with air as determined by actual measurement in a tube 25 cm. in diameter. It will be seen that the gas with the lower speed of flame and the smaller range of inflammability (methane) has the predominating influence in deciding the magnitude of these constants for the mixed gas

Effect of Incombustible Gases —In addition to restricting the limits of inflammability, the presence of an incombustible gas mixed with the combustible gas has the effect of reducing the speed of flame in any of the mixtures with air. This effect is illustrated in Fig. 4, which shows the speed-percentage

mixtures containing less oxygen than air, the

curve for air-mixtures being given for comparison. This diagram shows also the effect of nitrogen in reducing the range of inflamma-bility and establishes the fact, theoretically deducible, that the speed of travel of flame is the same in all limit-mixtures that comprise the same constituent gases. The experiments from which these curves are constructed were made in a tube 5 cm in diameter, so that the speeds are not directly comparable with those recorded in Fig. 2.

B .- THE DEVELOPMENT OF 'DETONATION' IN GASEOUS EXPLOSIONS THE EXPLOSIVE WAVE AND 'RETONATION'-RATIO OF EX-PLOSTON

It was in the year 1881 that Berthelot and Vieille, and independently also Mallard and Le Chatelier, announced the discovery of the rapid acceleration of the initial velocity of inflamma-

tion in the progress of gaseous explosions and the final attainment of the enormously higher constant velocity of the 'explosion wave.' Since that date, the phenomena associated with the development of 'detonation' and the propagation of the ex-plosion wave has been extensively studied in this country by H. B Dixon and his co-workers

Ma'lard and Le Chatelier devised a photographic method for investigating the initial phases of gaseous explosion, and the development of detonation, which consisted in recording on a sentitised plate, moving at a known velocity on a vertical plane, the movement of the flame as it travelled along a horizontal glass tube A graph compounded of the two velocities was thus obtained

H B Dixon's experimental method consisted in photographing the explosion flame travelling along a horizontal tube on a highly sensitive film rotated vertically with a constant high velocity (varying, however, between twenty-five and fifty metres per second in different experiments), the explosion tube being placed at such a distance from the camera that the size of the image was about onethirtieth that of the flame In this way it was found possible to analyse the progress of an explosion from its point of origin up to the final attain-

ment of its maximum force and velo-city in 'detonation.' The investigation also included the discovery of the wave of 'retonation,' which is thrown back through the still burning gases from the point where detonation starts (a phenomenon also discovered by Le Chatelier independently in 1900), of the effects of collision between two explosion waves, and of the passage of reflected waves through the hot

products of explosion.

The phenomena associated with the development of an explosion in a gaseous mixture, fired in a closed tube by a spark passed between wires a few inches from the closed end, are very clearly shown in the photograph reproduced in Fig 5 which is analysed in Fig. 6 This photograph was taken during an experiment in which carbon disulphide was exploded with a quantity of oxygen represented by the expression  $CS_2+5O_2$ . It is reinforced by another reflected wave) the The flame in starting at the point o, sends or velocity of the retonation wave is always

mysible compression waves in both directions along the tube, which travel in advance of the tlame with the velocity of sound through the unburnt gases, as represented by the dotted lines om, on in the diagram. The flame itself, travelling at first more slowly than the compression waves, traces the curves on and ob. The compression wave on, on reaching the closed end of the tube, is reflected back again as NC, and, on meeting the flame (which is still travelling in the direction OA), retaids it, and passes thence through the hot and probably still burning gases as the visible wave co instant later it overtakes at D the front of the flame, travelling in the direction on, thereby accelerating it and increasing its luminosity in

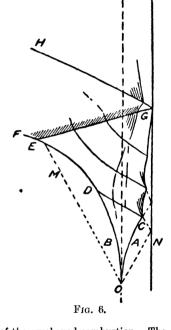

FIG. 5.

consequence of the quickened combustion. flame then continues to move forward with rapidly accelerated velocity until 'detonation' is set up at the point E At this point a strongly luminous wave of compression EG (the 'retonation wave') is sent backwards through the still burning gases, which, on reaching the near end of the tube, is reflected back again as GH The detonation 'wave' EF passes onward through the mixture with its characteristic uniform high velocity and intense luminosity Fig. 7 is a similar photograph showing the development of 'detonation,' and the phenomenon of 'retonation' in the case of mixture of cyanogen and oxygen  $(C_2N_2+O_2)$  fired near the closed end of a tube.

Except in special circumstances (e.g. when it is reinforced by another reflected wave) the

inferior to that of detonation, thus Le Chatelier gives 2990 metres per second for the 'detonation wave' and 2330 metres per second for the 'retonation wave' in an equimolecular mixture of acetylene and oxygen When, however, the 'retonation wave 'is developed just at the closed end of a tube (e.g. when the explosive mixture is fired at such a distance from the closed end that 'detonation' is set up just as the flame arrives at the end) it may be reinforced by a reflected wave, in which case its velocity cannot be distinguished from that of a true 'detonation

The explanation of the intense luminosity of the retonation wave, and its higher velocity than sound through the exploded gases, is to be found in the fact that the combustion during the initial stages of an explosion is very much

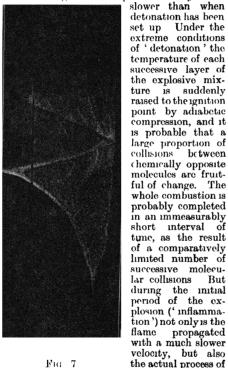

Fig. 7

combustion is much more prolonged than in detonation, and at the moment when detonation is set up combustion is still proceeding in the layers of gas for some distance behind the flame-front The 'retonation' wave, in passing backward through these layers, quickens this residual combustion, and is itself thereby rendered highly luminous This interthereby rendered highly luminous. This inter-pretation is supported by the repeated observations of Dixon, that the collision of two flames, in neither of which 'detonation' has been determined, will frequently give rise to reflected waves more rapid and more luminous than the There can be little doubt as incident waves to the important part played by reflected waves in determining the violent shattering effects associated with gaseous explosions on a large scale.

The Explosion Wave -Berthelot and Vieille, in announcing their discovery of the develop-

ment of detonation '(l'onde explosive') in gaseous explosions, described it as "une certaine surface régulaire, où se développe la transformation, et qui réalise un même état de combinaison, de température, de pressure, etc Cette surface, une fois produite, se propage ensuite, de couche en couche, dans la masse tout entière, par suite de la transmission des chocs successifs des molécules gazeuses amenées à un état vibratoire plus intense en raison de la chaleur dégagée dans leur combinaison, et transformées sur place, ou, plus exactement, avec un faible déplacement relati. ' Such conditions are comparable with those of a sound wave passing through the gaseous mixture, with, however, the important difference that, whereas a sound wave is propagated from layer to layer with a small compression and a velocity determined solely by the physical condition of the vibrating medium, it is an abrupt change in chemical condition which is propagated in the explosion wave, and which generates an enormous force as it passes through each successive layer of the medium.

In their experimental work Berthelot and Vieille proved that the velocity of the explosion wave is independent of the length of the column of gas traversed, and of the material or diameter of the tube employed (at least above a certain small limiting diameter) It is also immaterial whether the tube is laid out straight, coiled round a drum, or even zigzagged. They also concluded that the velocity is independent of the initial pressure; but this is not strictly correct, as H B Dixon has since shown. The rate increases slightly with the initial pressure, attaining a nearly constant value at a pressure of about two atmospheres

It must be understood that when detonation is once determined in a particular explosive mixture, the wave is propagated with constant velocity (i.e. for a given initial temperature and pressure), which velocity is indeed an important physical constant for the particular mixture. I'he following 'rates of explosion,' as determined by Dixon, may be considered as typical of the extremely high velocities attained .

RATES OF EXPLOSION FOR MIXTURES FIRED AT 10° AND 760 MM.

Mixture			M	Ictres	per second
$2H_{2}+O_{2}$					2820
$H_2 + Cl_2$		•			1729
$2CO + O_2$	(moist,	sat'd	at 28)		1703
$NH_3+3O$	٠ ، (		• ′		2390
$CH_4+2O$		•			2322

In detonation, each successive layer of the explosive mixture is fired by compression, and the chemical change in the wave occurs under strictly adiabatic conditions This means that the chemical action is more intense and of much shorter duration than during the initial phases of an explosion ('inflammation'); moreover, the pressures developed in the wave and the consequent shattering effects are much greater than in ordinary explosions. Thus, for example, in a mixture  $2H_2+O_2$ , fired at the ordinary atmospheric temperature and pressure, the initial velocity of the flame (i.e during the short period of 'inflammation') is only 20 metres per second, and chemical action endures in each uccessive layer of the mixture for as long as

3700°

13 750

7 641

3400°

13 102

7 608

as detonation is set up, the flame travels forward pression, and the abrupt variation in the with a constant velocity of 2820 metres per density and pressure of the medium is due to second, and the duration of chemical action in the chemical change. Chapman's formula for  $\frac{1}{5000}$  and possibly not much less than  $\frac{1}{10000}$  of a second. Needless to say 'detonation,' is not set up in a gas-engine cylinder; the terrific force developed in detonation would play havoc with the mechanism

Dixon's photographic researches, already alluded to, have demonstrated beyond doubt the important rôle of 'compression waves' in determining detonation in explosive mixtures, and it is probable that the disastious effect of colliery explosions are primarily due to the intensifying effects of reflected compression waves upon the burning mixture of gas and (oi) coal dust and air

In 1899 D L Chapman published a mathematical analysis of the explosion wave carding Berthelot's sound-wave theory, which indeed had led to values for rates of explosion which were difficult to reconcile with facts, he regards the explosion wave as a wave of compression not in a homogeneous medium, but in a medi m which is discontinuous in the vicinity of the wave-front It is assumed (1) that the · front ' of the wave (i e from the unexploded gas to the point of maximum pressure) does not alter in character, or, in other words, that every portion of the wave travels with the same velocity, (2) that the velocity is the minimum consistent with (1), and (3) that at the point of maximum pressure the chemical change concerned in the propagation of the wave is complete

Temperature .	$4300^{\circ}$	4000°
Cv steam .	14 750	$14\ 297$
Diatomic gases	7 707	7.674

With the aid of this series of numbers he proceeded to apply his formula to the calculations of the rates of explosions of some forty other mixtures investigated by Dixon, finding in all cases close agreement between the found and calculated values, of which the following may suffice as examples -

Mixture exploded	Products in the wave	Temp	Rate of sion I per — Calcu- lated	Metren
$2H_2 + 2N_2O$	$2H_{2}O + 2N_{2}$	3813°	2408	2305
$4H_{2} + 2N_{2}O$	$2H_{2}O+2N_{2}+2H_{2}$	3077	2604	2545
6H2+2N2O	$2H_{2}O + 2N_{2} + 4H_{2}$	2612	2720	2705
$2H_2 + 2N_2O + 2N_2$	$2H_{2}O + 4N_{2}$	3077	2097	1991
$C_2 II_4 + 2O_2$	2CO+2H2O	4365	2619	2581
$C_2H_4 + 3O_2$	$2CO + 2H_2O + O_2$	3882	<b>234</b> 8	2368

$CH_4 + O_2$	$CO + H_2O + H_2$	2772	2502	2528
$2CH_4 + 3O_2$	$2CO + 4H_2O$	3764	2485	2470
$2CH_4 + 3O_2 + N_2$	$2CO + 4H_2O + N_2$	3513	2353	2349
1	ì	j		1

A characteristic feature of detonation is the extremely short duration of chemical action and subsequent rapid cooling of the products, as compared with ordinary combustion Summ

one-twentieth of a second. As soon, however, I front of the wave are, of course, fired by comeach successive layer certainly does not exceed, the velocity of the explosion wave in centimetres per second is-

when R=the gas constant (1985), J=the dynamical equivalent of heat (42+10° crgs), μ=the gram equivalents of the mixture exploded, n and m = the number of gaseous molecules before and after the chemical change in the wave, Cp and Cv=the mean specific heats of the products at constant pressure and volume respectively, h=the total heat generated in the wave, and  $t_0$  = the initial temperature (abs.) of the mixture exploded

From the fact that the dilution of electrolytic gas (2H<sub>2</sub>+O<sub>2</sub>) with oxygen lowers its rate of explosion a little more than a corresponding dilution with nitrogen, Chapman considers it improbable that there is any appreciable dissociation of steam in the wave He assumes that the molecular heat of steam rises more rapidly with temperature than that of a diatomic gas, and that the molecular heats of oxygen, hydrogen, nitrogen, and carbon monoxide may for all practical purposes be considered as equal at any given temperature Selecting some seventeen of Dixon's found rates of explosion, he has calculated by means of his formula the corresponding molecular heats and temperatures, arriving at the following results for Cv at inter-The unbuint gases immediately in mediate temperatures by interpolation .-

years ago, W. A Bone and B Lean found by a photographic method that the duration of luminosity in each successive layer of gas in the detonation of electrolytic gas is certainly less than boloo second, a much shorter interval of time than was required to shatter a tube of thin glass attached to the end of the explosion coll used This tube, although invariably smashed by the force of the explosion, always appeared perfectly intact in the photograph. Dixon's subsequent photographic researches have demonstrated the abrupt suddenness with which the gases attain the maximum temperature in detonation, the intensity and short duration of luminosity, and the subsequent rapid cooling, as compared with ordinary combustion over, high as is the temperature attained, there is no evidence of any considerable dissociation of steam in the wave, for, despite the instantaneous cooling of the products, there is less than 1 per cent of the gases left uncombined

gas  $(2H_2 + O_2)$ Influence of an Excess of an Inert Gas upon the Rate of Explosion of a particular Mixture -It has been found experimentally that whereas an excess of nitrogen or oxygen retards the rate of explosion of a particular mixture, an excess of hydrogen actually increases it. Thus in the

after the wave has passed through electrolytic

case of electrolytic gas, we have-

Mixture exploded			
			2817
			3268
			3527
			3532
			2328
			1927
			2426
			2055
	:	: : :	: .

The accelerating influence of an excess of hydrogen was for long an enigma, but it was perfectly explained when Chapman published his formula. It must, however, be understood that an excess of oxygen always has a somewhat greater influence than a corresponding excess of nitrogen by virtue of its relatively higher density

The Burning of Guseous Carbon—Of the many important facts brought to light during the course of Dixon's investigations none are of greater interest than those relating to the burning of gaseous carbon in the explosion wave, as illustrated by the case of cyanogen. In view of the fact that the molecular heat of combustion of cyanogen, when burnt completely to carbon dioxide, is 259 6 K C Us, whereas, if buint to the monoxide, it would only be 123 K C Us, it might be expected that the rate of explosion for a mixture  $C_2N_2+2O_2$  would be much higher than for  $C_2N_2+O_2$ , if gaseous carbon is primarily burnt to carbon dioxide in the wave. The exact opposite is the case, however, as the following results show.—

$$\begin{array}{ccc} \text{Mixture} & \text{Products} & \text{Rate} \\ C_2N_2+O_2 & 2CO+N_2 & 2728 \\ C_2N_2+2O_2 & 2CO_2+N_2 & 2321 \\ \end{array} \\ \text{metres per sec.}$$

Still more cogent is the evidence in favour of the initial formation of carbon monoxide in the wave, when the following figures are considered—

$$\begin{array}{cccc} & C_2N_2 + O_2 & & C_2N_2 + O_2 + N_2 & & C_2N_2 + O_2 + O_2 \\ \textbf{Rate} & 2728 & & 2398 & & 2321 \end{array}$$

The conclusion to be drawn from the preceding figures is that cyanogen is initially burnt to carbon monoxide and nitrogen in the wave itself, any excess of oxygen afterwards burning up the carbon monoxide as the gases cool down in the rear of the wave

This conclusion was driven home by Dixon, in conjunction with Strange and Graham, by photographing on a sensitive film rotated at a speed of about 1500 metres per minute, the explosion flame in the case of the three mixtures (a)  $C_2N_2+O_2$ , (b)  $C_2N_2+O_2+N_2$ , and (c)  $C_2N_2+2O_2$ . In each case the flame was photographed, after detonation had been set up, as it dashed past a glass window inserted into the lead explosion coil <sup>2</sup>. The image obtained in the case of (a) showed an intensely brilliant flame (the explosion wave), slightly drawn out in tapering form; in the case of (b), with nitrogen as diluent, the flame was less brilliant and somewhat more drawn out than in (a) but with (c) the flame, whilst no more luminous than in (b), was drawn out to great length, owing to the continued combustion of carbon monoxide in the rear of the wave. The following diagram, Fig. 8 (approximately to scale), will convey an idea of the relative durations of the flames in the three cases.

Fig. 8.

The Burning of Hydrocarbons in the Wave—
It was during the course of measurements of
the rates of explosion of hydrocarbons with
varying proportions of oxygen in 1891-92 that
Dixon and his collaborators rediscovered facts
(originally set forth by Dalton in his 'New
System of Chemical Philosophy') which finally
disposed of the dogma that in a deficient supply
of oxygen a 'selective' burning of hydrogen
occurs Bone, in conjunction with Lean and
Cain, found that when either ethylene or acetylene
is detonated with its own volume of oxygen the
ultimate products consist almost entirely of
carbon monoxide and hydrogen <sup>1</sup> The rates of
explosion of hydrocarbon-oxygen mixtures,
whilst they do not reveal the real mechanism
of the combustion, show very clearly that,

1 Vide Lean and Bone, Trans. Chem. Soc 1892, 61, 873, and Bone and Cain, ibid 1897, 71, 26.

as in the case of cyanogen, the carbon of a hydrocarbon is burnt to the monoxide in the wave itself, the formation of the dioxide being an after-effect and taking place in the rear of the wave. In the cases of methane and acctylene the fastest rates are observed with equimolecular mixtures, whereas with ethylene the rate increases with the proportion of oxygen up to the limit  $C_2H_4+2O_2$ .

## C.—THE PRESSURES PRODUCED IN GASEOUS EXPLOSIONS.

Many investigators, from the time of Bunsen's well-known experiments in 1867 onwards, have measured the pressures produced in gaseous explosions, with doubtless considerable success so far as what may be termed the mean effective

- Trans. Chem. Soc. 1803, 69, 759

pressures are concerned The explosion vessel employed by Bunsen was a stout glass tube 8 15 cm long, 1.7 cm internal diameter, and of i8 cc capacity It was closed by a suitable valve, the load on which could be adjusted until it was just lifted when the explosive mixture was fired by means of a powerful spark passed along the axis of the tube Bunsen considered that the combustion would occur under adiabatic and 'constant volume' conditions, and he identified the rate of ignition of a particular mixture with that of the completion of chemical change. In calculating from his results the corresponding flame temperatures, he assumed the constancy of the specific heats of steam and carbon dioxide Finding that the pressures recorded in the cases of electrolytic gas and of a mixture of carbon monoxide and oxygen in their combining proportions (namely, 95 and 10.1 atmospheres respectively) were somewhat less than one-half of those theoretically re-

quired on the above assumption, he concluded that in each case combustion had proceeded per saltum, owing to the supposed theoretical flame temperatures exceeding the limits at which steam and carbon dioxide respectively are completely dissociated. The problem was again attacked independently by Mallard and Le Chatcher in 1883, and by Berthelot and Vieille in 1885 2 The last-named fired various gaseous mixtures at atmospheric pressure in a spherical non bomb, measuring the effective pressures by the movement of a light piston working against a spring in a tube attached to the bomb. In order to gain some information respecting the possible cooling influence of the walls upon the effective pressures recorded, three bombs of different capacities, namely, A of 300 ee, B of 1500 cc, and C of 4000 cc, were employed The results, expressed in each case as atmospheres in excess of the atmospheric pressure, were as follows .-

Bomb	Λ	В	C
Capa ity in cm 3 .	300	1500	4000
Surface in cm <sup>2</sup>	216	648	1200
Surface per unit volume	0 72	0 43	0 33
Diameter in cm	6.0	14 2	217

$C_2N_2+2O_2 \qquad . \qquad .$			20 96)
Time required for flame to travel from the firing piece to piston of indicator.			
$ \begin{array}{cccccccccccccccccccccccccccccccccccc$	0 00104 sec		$0.00214~\mathrm{sec}$
$100000 \cdot 200 + 0$	0 01286 sec		$0.01551~\mathrm{sec}$

results is the smallness of the difference between the pressures observed with bombs A and C in any particular case. These differences might at first sight be attributed to the (supposed) much smaller cooling influence of the walls of the bomb C as compared with bomb A, but if this were the true explanation the difference should be greater with the slow-burning 200+0, mixture than with the fast-burning  $2H_2 + O_2$ , whereas the opposite was the case Morcover the fact that dilution of the mixture 2H2+O2 with twice its own volume of nitrogen almost obliterated the difference between the pressures observed in the cases of bombs A and C (the ratio  $\frac{pC}{c}$ ). for the diluted being 0.95, as against 0.76 for the undiluted mixture) is all against the cooling theory The more probable explanation is to be found in the fact that, owing to the much longer travel of the flame before it reached the piston of the indicator in bomb C as compared with A, the explosion would be in a more advanced phase of its development, and this would be most marked in the case of the fastest bu.ning mixtures. Berthelot and Vieille assumed

Perhaps the most notable feature about these alts is the smallness of the difference between pressures observed with bombs A and C m particular case. These differences might at the sight be attributed to the (supposed) much slight be attributed to the (supposed) much blief cooling influence of the walls of the bomb is compared with bomb A, but if this were true explanation the difference should be attributed the marked disparity between the observed pressures (bomb (') and those calculated from the heats of combustion (on the assumption of adiabatic conditions) to a rapid increase in the specific heats of steam and carbon dioxide at high temperatures with the fast-burning  $2\Omega + O_2$ , whereas opposite was the case. Moreover the fact

Mallard and Le Chatcher (l c) who used a Bourdon gauge for measuring pressures and applied a 'cooling correction' to their results, agrived at practically the same conclusion as Berthelot and Vieille (Ann Chim. Phys [vi] 4, 13) respecting both the increase of the specific heats of steam and carbon dioxide with temperature and the small if not negligible influence of dissociation. They calculated that the temperature of the flame when moist electrolytic gas is exploded in a closed vessel at atmospheric pressure is about 3350°, and that the mean molecular heat of steam at constant volume

Annales des Mines, sec viii vol 4 Ann. Chim Phys. (vi ) 4, 13

between  $0^{\circ}$  and  $3350^{\circ}$  is 16.6. In the case of REVOLVING DRUM the mixture 2CO+O, they concluded that the molecular heat (C2) of carbon dioxide rises to 136 at 2000°, above which temperature dissociation comes into play Dugald Clerk also made experiments with hydrogen-air mixtures in a large cast-iron vessel comparable in dimensions to the cylinder of a six-horse-power gas engine It was a cast-iron cylinder truly bound out and the end covers turned, internal dimensions 7 inches r manif diameter and 81 Minimin's 2 2 2 2 2 2 1 1 inches long, capacity INDICATOR 317 cubic inches Upon the cover was placed a Richards indicator, in which the reciprocating drum had been replaced by a re-FAN GOVERNOR volving one; the rate of revolution was adjusted by a small fan, a 11/1 weight and gear giving the power evlinder was filled with the explosive mixture to be tested, the drum set in motion, the pencil of the indicator pressed gently against it, and the EXPLOSION VESSEL electric spark passed within the cylin-

a line upon the drum which showed
the use and fall of pressure. The using line | Fig. 9 shows the arrangement of the apparatus traced the progress of the explosion, the falling | Experiments with hydrogen and air mixtures line the progress of loss of pressure by cooling gave the following results

The pressure of the explosion, acting upon the indicator piston, traced

Frg. 9.

## MIXTURES OF HYDROGEN AND AIR (CLERK).

		Tem	p. before explosion 16°.	Pressure 14 7 lbs (atm	ospheric)
Experi- ment	Mıv H	Air	Max pressure above atmosphere in lbs per sq_inch	Time of explosion	Max temp of explosion
	1 vol. 1 vol. 2 vols	6 vols. 4 vols. 5 vols	41 68 80	0 15 sec. 0 026 sec 0 01 sec	826° to 909° 1358° to 1539° 1615° to 1929°

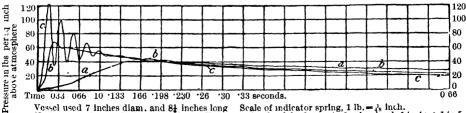

The maximum temperatures were calculated | on the two extreme assumptions of complete contraction and no contraction

The curves of explosion from which these figures are deduced are given at Fig. 10

The rate of cooling was comparatively slow; for instance, in all these experiments, at the end | ing for loss of heat to the walls during time of

of 0 66 second from the beginning of explosion there still remains above 20 lbs per sq inch above atmospheric pressure. The explosion was followed by a very slow fall of pressure

Calculating from these curves the total heat accounted for by maximum pressure, and allow-

Vessel used 7 inches diam, and 84 inches long—Scale of indicator spring, 1 lb. =  $\frac{1}{2}s$  inch. Mixtures used, pure hydrogen and air—Experiment a, 1 vol hydrogen to 6 vols. air; b, 1 to 4; c, 1 to 5 Temperature of gases before ignition, 16°, pressure (atmospheric), 14 7 lbs.

explosion, as estimated from the falling curves, a great deficiency becomes evident.

Experiment Heat of combustion of hydrogen present 100 100 Heat accounted for by maximum temperature and loss previous to its attainment 55 70

Even with hydrogen and air mixtures the deficiency ranges from 30 to 46 p.c. It is remarkable that the deficiency at the temperature of about 900° is identical with that at about 1800° within the limits of error It should be noted, however, that this method of allowing

for heat loss will probably give a low value, as no account is taken of the difference in the action of the walls on the using and falling lines, nor of the possible difference in radiation

In 1915 W A Bone and his collaborators published the results of experiments in which mixtures corresponding to (1)  $2H_1+O_2+4N_2$ , (2)  $2CO+O_2+4N_2$ , and (3)  $CH_4+O_2+4N_2$ , were exploded at an initial pressure of 50 atmospheres m a spherical bomb (capacity=275 cc) to which was attached a Petavel recording manometer with its optical accessories. The results of two typical experiments with each of the three mixtures are recorded in the following table .-

W. A. BONE'S PRESSURE EXPERIMENTS.

The pressure records which are reproduced | in the following diagrams (Figs 11, 12, and 13), in which pressures in atmospheres are plotted against time in seconds, prove conclusively the absence of any direct relation between the

explosive mixture is transferred on explosion as sensible heat to its products and the magnitude of the chemical affinity between its combining constituents This is hardly to be wondered at, seeing the extreme rapidity of chemical interactual rate at which the potential energy of an action at high temperature as compared with

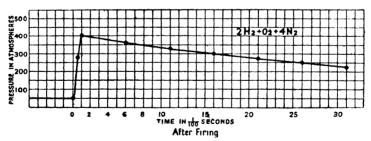

Fig. 11.

the rate at which the liberated heat can be communicated to and uniformly distributed amongst the products by ordinary physical processes. Attention may be drawn to the extreme slowness of the cooling in each case after the attainment of maximum pressure; this has also been observed by previous workers in other similar cases of gaseous explosions This was particularly marked in the case of the methane-air mixture, in which there was hardly

0.22 seconds after the attainment of maximum pressure (in 0.08 sec), a circumstance which may be due in part to the combustion taking place in well-defined chemical stages, and in part also to the operation of the exothermic secondary interaction between carbon monoxide and steam during the cooling period. On the other hand, the curve for the hydrogen-air mixture, where the combustion to steam is a direct and comparatively simple transaction any appreciable cooling during an interval of suggests that the attainment of maximum

pressure is succeeded by a period of gradual cooling uninfluenced by chemical combination.

It may be taken as the common experience of all investigators since Bunsen's day that the maximum effective pressures recorded when gaseous mixtures are fired in closed vessels are always considerably less than those calculated on the old assumption (now discarded) that the

whole heat of combustion is communicated without loss to the products, and that the specific heats of the products do not vary with temperature Another feature of the phenomenon is the very short time required for the attainment of maximum pressure relative to the subsequent cooling period

The great disparity between the found and

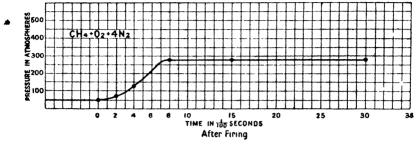

Fig. 12.

'calculated' maximum pressures has been attributed by the various investigators ('concerned to one or other of the following causes,

namely
1 To the marked increase in the specific heats of steam and carbon dioxide with temperature.

2 To the fact that in ordinary gaseous explosions, where detonation has not been determined,

combustion is by no means instantaneous, and may not be completed within the period required for the attainment of maximum pressure. Sn Dugald Clerk put forward this suggestion as long ago as 1886 1 in criticising the conclusions of Mallard and Le Chatcher respecting the great increase in the specific heats of steam and of carbon dioxide with temperature. He considered it highly

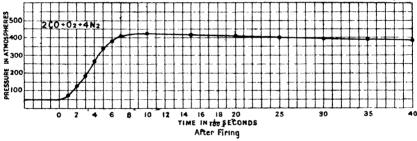

Fig 13

probable that combustion extends far into the actual 'cooling period' in gaseous explosions (and hence the long drawn-out 'cooling curve'), so that the system loses a certain part of the heat of combustion before the chemical action is completed This idea of a continued combustion finds support in H. B. Dixon's photographic researches, and chemists generally will concede its reality in any gaseous combination in which But to what detonation is not determined extent it may be held to affect the pressures actually recorded by explosions is still a matter o. conjecture.

3. To loss of energy by direct radiation -Thus in the explosion of a mixture of hydrogen and oxygen it is conceivable that the initial action results in the formation of an intensely vibrating molecular complex from which steam issues as the first recognisable product. Some experiments made in 1890 by Robert von Helmholtz (Beiblatter, 14, 589), showed that non-luminous hydrocarbon flames radiate about

5 pc of the heat of combustion of the gas, and more recent experiments by Callendar and Nelson show that the heat radiated from an ordinary non-luminous Bunsen flame may amount to between 15 and 20 p c. of the total heat of combustion.

4 To dissociation of products (steam and carbon dioxide) In the case of two combining gases producing a dissociable product, it is clear that if the average temperature in the system reaches that at which dissociation begins the combustion must be delayed whilst heat escapes from the system by radiation and con-Qualitatively the partial dissociation of steam and carbon dioxide has been proved at temperatures which are certainly exceeded by those of explosion flames; but it may be urged that, masmuch as all experiments upon dissociation have up to the present involved contact with hot solid surfaces, there is no positive evidence that the phenomenon would <sup>1</sup> Proc. Inst. Civil Engineers, 85.

play any conspicuous part in an unconfineu On the other hand, there is gaseous system direct experimental evidence of the attainment of enormously high temperatures in the explosion wave, temperatures which would generally be considered as far beyond that of the initial, or serhaps even of the complete, dissociation of steam or of carbon dioxide. Moreover, the fact that the rate of explosion of electrolytic gas is retarded rather more by an excess of oxygen than by a corresponding excess of nitrogen is

inconsistent with the supposition of any appreciable dissociation of steam in the explosion wave, and photographic records give no evidence of continued combination in the rear of the wave except where there are two or more chemical stages in the combustion.

Explosion of mixtures of coal gas and air -Experiments were made many years ago by Clerk with mixtures of coal gas and air in the explosion apparatus already described, with the following results:-

## GLASGOW COAL GAS AND AIR MIXTURES (CLERK).

Experiment	Proportion of gas by volume	Maximum pressure in lbs per sq inch above atmosphere	Maximum tempera- ture centigrade	Time of explosion
$egin{array}{c} a \\ b \\ c \\ d \\ e \end{array}$	14 12 10 10 10 10	52 63 69 89 96	1047° 1265° 1384° 1780° 1918°	0 28 second 0 18 ", 0·13 ", 0 07 ", 0 05 ",

that the greatest possible pressure exerted by a mixture of Glasgow coal gas and air at atmospheric pressure and temperature was 96 lbs. per square inch above atmosphere, the maximum pressure falling as dilution with air increased, while the time of explosion also increased. The shortest time of explosion was  $\frac{1}{20}$  second, and the the following results .-

From these experiments, it will be observed longest over 4 second, at the end of 060 to the greatest possible pressure exerted by a second from 30 to 35 lbs per square inch pressure above atmosphere still remained in the vessel. It is very noticeable that, volume for volume, coal gas produced higher pressure than hydrogen.

Experiments with Oldham gas and air gave

OLDHAM COAL GAS AND AIR MIXTURES (CLERK).

Experiment	Proportion of gas	Maximum pressure in lbs per sq inch above atmosphere	Maximum temperature centigrade	Time of explosion
a b c d e f y h	15-14-15-15-15-15-15-15-15-15-15-15-15-15-15-	40 0 51 5 60 0 61 0 78 0 87 0 90 0 91 0 80 0	806° 1033° 1202° 1220° 1557° 1733° 1792° 1812° 1595°	0 45 second 0 31 " 0 24 " 0 17 " 0 08 " 0 06 " 0 04 " 0 055 " 0 16 "

The greatest pressure produced by a mixture | the same vessel with mixtures previously comof this gas and air was 91 lbs. per square inch above atmosphere Comparing these numbers with the Glasgow gas experiments, it appears that with 14 vol. of Oldham gas present, the pressure attained was 0 5 lb. per square inch less, and the time of explosion is 0 31 second against 0.28 second with the same proportion of Glasgow With 1 of the two gases, Oldham was 5 lbs. less maximum pressure and 0 055 second against 0.05 second Glasgow.

In all these experiments the suppression of heat at the maximum temperature is very considerable, ranging from 50 to 60 p.c.

Experiments were also made by Clera 'n

pressed, and it is found that the pressures produced with any given mixture are proportional to the pressure before ignition—that is, with a mixture of constant composition double the pressure before explosion, keeping the temperature constant, doubles the pressure of explosion.

In 1900 Clerk made further experiments with London coal gas and air, with very complete precautions to ensure mixing, and with more accurate timing devices. The curves obtained with this apparatus are shown at Fig. 14, and the maximum temperatures and pressures, and time of explosion for the different mixtures, are as follows :-

J. E. Petavel has also made experiments on the explosion of coal gas and air compressed before ignition to pressures of over 1000 lbs per square inch Fig 15 shows the diagrams obtained, with the particulars marked thereunder.

In all these experiments, it is clear that if the temperature be calculated from the maximum pressure of explosion, there is apparently a suppression of heat of a very considerable amount at maximum temperature, the amount

being about 60 p c

Important experiments were also made by Prof. B Hopkinson, of Cambridge University, who investigated the actual temperatures reached during explosions of coal gas and air in an explosion vessel of the form shown at Fig 16 and found very large temperature variations at different parts of the vessel, and that the temperature differences existed after complete inflammation; quite independently of the local cooling effect of the walls of the vessel.

Explosion in a closed vessel, London gas, 1900 (Clerk).

He found that after the explosion of coal gas and air in the vessel, the distribution of temperature at the moment of maximum pressure was roughly as follows :-

Mean temperature (inferred from pressure) 1600° Temperature at centre of vessel, thermometer B 1900° Temperature 10 cm (4 inch) within wall, 1700° thermometer C Temperature 1 cm (04 mch) from wall, 1100° to 1300° at end, thermometer D Temperature 1 cm. (04 inch) within wall at side 850°

Half a second after maximum pressure, the distribution was as follows :---

Mean temperature (inferred from pressure) 1100° Mean temperature, exclusive of layer l cm thick at walls, determined by long platinum wire from B to D 1166° Temperature vessel, at centre of thermometer B . 1100° to 1200°

Here the temperature differences are much smaller than at the moment of maximum pressure Hopkinson found that the explosion vessel is entirely filled with flame when the pressure reaches 70 lbs, although the maximum pressure attained later is 82 lbs per square inch above atmosphere; that is, maximum pressure is not attained until one-thirtieth of a second after the vessel is completely filled by flame. Hopkinson's experiments also distinctly prove that the highest temperature reached in the vessel is at the point of origin of the ignition, and is due to the compression of the gases which are first heated by explosion to about 1200°, and then compressed by the compression from the walls inwards, as the mixture near the walls inflames.

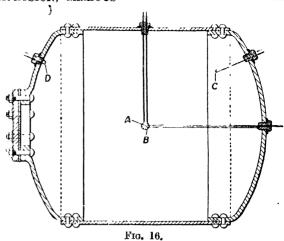

Explosion in gas-engine cylinders—In all internal-combustion engines in general use at the present time, the mixture of fuel and air is compressed before ignition, the maximum temperature ranging from 1200° to 2500°; while the temperature of the hot gases at the moment of opening the exhaust valve may be

about 1000° Fig. 17 is a reproduction of an indicator diagram of an internal-combustion engine working on the Otto cycle The effect of weakening the mixture is shown by the different lines on the diagram the line a shows a diagram obtained from a strong mixture; b, a diagram from a slightly weaker mixture, and c, a diagram obtained from a very weak mixture. The effect of apparent suppression of heat appears on the gas-engine diagram as well as in the diagrams obtained by explosion in closed vessels at constant volume, referred to above, and it is extremely important, for the purpose of a correct theory of the internalcombustion engine, to ascertain exactly what takes place on explosion, and immediately after explosion of the mixture used, and a complete knowledge of the thermal properties of the working fluid and

its chemical composition at any instant during

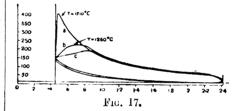

the cycle is necessary

In the normal gas-engine diagram, the expansion line is at first usually considerably above the adiabatic, showing that the whole of the heat of combustion is not added before maximum pressure, and that heat must be added to the gases during a portion of the expansion, to make up for the flow of heat through the cylinder walls If, however, the cooling on expansion is too great, the expansion line may fall below the adiabatic, although there is still heat being added. The adiabatic expansion line tor any given mixture of gases depends on the specific heat of the mixture, and therefore, in order to determine what are the conditions as

Hopkinson's Explosion Vessel.

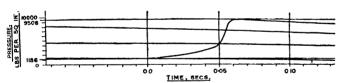

regards addition of heat, it is necessary to know the specific heat or internal energy of the mixture at any given temperature

Clerk has investigated the properties of the

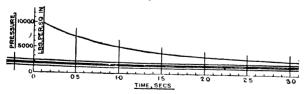

working fluid in the gas engine itself, by a method which allowed direct observation to be made upon an actual charge taken into the engine in the ordinary operations of its cycle. The method consisted in subjecting the whole of the heated products of combustion to alternate compression and expansion, within engine cylinder, while the cooling proceeded, and observing by the indicator the successive pressure falls from revolution to revolution, together with the temperature and pressure use and fall due to the alternate compression and expansion. The engine was set to run at a given speed, and after the charge of gas and air had been drawn in, compressed and ignited, the exhaust valve and inlet valve prevented from opening, so that when

the piston reached the

Pise and kall of Pressure during and after Explosion (Petavel).

end of its power stroke, the exhaust gases were retained within the cylinder, and compressed by the piston to the maximum volume, and again allowed to expand and again compressed, and so on. These operations gave a diagram as shown at Fig. 18. From this diagram, by determining the temperature fall due to work done on expansion, Clerk determined the apparent specific heat of the products of combustion, and found that for the gas-engine mixture there was a considerable rise of apparent specific heat with temperature, and it seemed probable that this was largely due to a real increase of the actual specific heat or internal energy of the gases at high temperatures. The experiments, however, could not differentiate between the possible effects produced by dissociation and real specific heat change. Further, the values obtained were subject to some uncertainty, due to the difficulty of apportioning heat loss between successive compression and expansion lines, and it is probable that the values are somewhat raised by some film phenomena, or by smouldering combustion, tending to keep the expansion line from falling as rapidly as it would otherwise do.

Work of the British Association Committee on Gaseous Explosions .- Owing to the great importance to the theory of the internal-combus-

Jon engine of a complete understanding of the phenomena of gaseous explosions, the British Association appointed a committee for the purpose of investigating the whole matter, and although the work of this committee is not yet completed, very important results have already been obtained. These are set out in the Reports of 1908, Dublin; 1909, Winnipeg; and 1910, Sheffield The committee regard it as proved that on the explosion of gaseous mixtures with air, the quantity of carbonic acid or steam dissociated at the temperature of the explosion is so small, that the suppression of heat cannot be due to this cause.

They also concluded that chemical equilibrium is complete within an extremely short period after inflammation at any point outside the influence of the walls, and that there is no time rate of combustion, such as will account for the

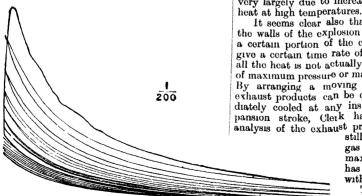

apparent suppression of heat

The committee have also made a very careful comparison of the specific heat found by Holborn and Henning by methods not depending on explosion, with the values found by explosion experiments, such as those of Clerk, Mallard, and Le Chatelier, and Langen. The results given in calories per gram-molecule for the internal energy calculated from 100° at temperatures of 800°, 1200°, 1600°, and 2000°, are as follows .--

_							8	00,	1	200°	1600°	2000°

\*  $C_1 = 4.0$ .

In this table, in order to reduce to foot-lbs, the figures should be multiplied by the factor 3 96.

Clerk diagram from engine at a brake load of 50 H.P. at '60 revolutions per minute.

The agreement between the figures by the two methods shows that the suppression of heat is very largely due to merease in the real specific

It seems clear also that the cooling due to the walls of the explosion vessel will damp out a certain portion of the combustion, and thus give a certain time rate of combustion, so that all the heat is not actually evolved at the point of maximum pressure or maximum temperature. By arranging a moving piston so that the exhaust products can be collected, and immediately cooled at any instant during the expansion stroke, Clerk has shown from an analysis of the exhaust products that there is

still some uncombined gas after the point of maximum temperature has been reached, even with strong mixtures

The committee also consider that the apparent suppression of heat in explosion experiments, when temperature is calculated from pressure, is partly due to under-estimation of the heat loss due to radiation. Callendar predicted that this would be the case from his experiments on the radiation from a Bunsen flame; and Hopkinson has shown that the
